FOREWORD

A Word from the Editor-in-Chief

Dear colleagues,

In your hands is the Book of Proceedings of the X International Scientific Agricultural Symposium “AGROSYM 2019”, which I hope you will find useful in your work. As many as 900 contributions, from 82 countries, have been accepted for oral or poster presentations. Symposium themes cover all branches of agriculture and are divided into 7 sessions: 1) Plant production, 2) Plant protection and food safety, 3) Organic agriculture, 4) Environmental protection and natural resources management, 5) Animal husbandry, 6) Rural development and agro-economy, 7) Forestry and agroforestry. Papers dealing with agricultural engineering and technology were included into one of the seven sessions depending on their focus.

In the plenary lectures were addressed interesting topics; one keynote was on biotechnology and two others dealt with organic farming in Australia and Europe. This confirms the role of AGROSYM as a forum for open discussions and exchanges on agriculture, food, the environment and rural development in the Balkans and beyond. Many of the papers identify a number of approaches and market-based incentives to encourage producers to achieve higher levels of performance (from both economic and environmental points of view) and as a result to meet the expectations of governments and consumers.

The successful management of agricultural resources to satisfy changing human needs, while maintaining or enhancing the quality of the environment and conserving natural resources, indicate a long-term agricultural development imperative. Advances in productivity, profitability and stability of modern cropping, animal and forestry systems will have to be achieved globally on an ecologically sustainable basis. Today, it is obvious that conventional methods of agricultural production, while providing sufficient food and various products to humanity, have led to a number of negative impacts, including the transgression of many planetary boundaries. These negative impacts raise serious questions about the long-term sustainability of high-input agriculture and call for a genuine transition towards sustainable agro-food systems, which achieve food and nutrition security for present and future generations within the safe operating space for humanity.

Full texts of the submitted communications will be available on the website of AGROSYM (http://agrosym.ues.rs.ba). Each paper included in the present Book of Proceedings was positively reviewed.

Much appreciation is due to the authors of all papers submitted and presented at the symposium as well as to all symposium participants whose ideas and contributions allowed rich and lively discussions during the various sessions. Many thanks to all reviewers, session moderators and colleagues for their help in editing the Book of Proceedings. Special thanks go to all co-organizers, partners and sponsors for their unselfish collaboration and comprehensive support.

Abstract

Maize cultivation with application of proper organic and bio-fertilizers could increase nutritional value of crop grain and maintain soil fertility. The aim of the study was to examine variations in concentrations of phytate, soluble phenols, total glutathione (GSH), yellow pigment (YP), DPPH radical scavenging capacity (DPPH), Ca, Mg, Fe, Zn and Mn in maize hybrids with white, yellow and red colour grain, under the influence of bio-, organic fertilizer and urea in regard to control (without fertilization). Results indicated that phytate, DPPH, Ca, Mg and, Mn varied slightly (< 10%). Red grain maize was characterized with the highest concentrations of phenols, Ca, Mg, Fe, Zn, and DPPH. White grain maize, particularly in urea and bio-fertilizer treatment, accumulated higher GSH values, while red and especially yellow grain hybrid accumulated higher YP amount in urea treatment. Irrespective to lower variations in Mn concentration, higher values were determined in yellow hybrid. Organic fertilizer mainly induced increase in Mg bio-fertilizer which positively affected Fe accumulation, while urea caused higher Zn and Mn accumulation in maize grain. It could be concluded that yellow and particularly red grain hybrid enabled increased accumulation of mineral elements, together with higher DPPH values, mainly in treatments with organic fertilizer and urea giving it advantage in production of highly nutritious food.

Keywords: *Colored maize grain, Sustainable production, Mineral nutrients, Antioxidants.*

Introduction

All nutrients that humanity consumes came mainly from the agricultural production. When ability of agricultural systems to produce enough of diverse foods fail, people will suffer, mortality and morbidity rates will increase, working productivity will be reduced, societies will deteriorate (Welch 2002). That is one of the main reasons why nutritional deficiencies affect over three billion people globally, irrespective that they live in developed or developing countries, causing chronic diseases, such cancer, cardio-vascular diseases, stroke, diabetes, osteoporosis etc. (Graham et al., 2007). At the same time, soils are deteriorated worldwide Maintenance and even increase of soil is of particular importance for agricultural production. This means that proper mineral nutrition is significant measure when crops are grown on infertile soils. When pea and wheat were grown on soil with adequate Zn and Se supply, they accumulated about three-fold more Zn and five-fold more Se in their grains, when compared to plants grown on Zn- and Se-deficient medium (Miller and Welch, 2013).

Different fertilizer types, such as organic and bio-fertilizers contribute to the maintenance and/or increase of soil organic matter and status of mineral nutrients, thus contributing to the soil fertility, together with the improved availability of nutrients to plants and increased yielding potential. Mineral nutrition is complex practice, since some nutrients are able to promote or reduce absorption of the other ones, like application of higher N rates, which decreases Mg and Zn absorption and promotes Mn absorption and accumulation, thus altering nutritional quality of maize grain (Feil et al., 2005). There are many records about contribution of bio-fertilizers to improved crop production. Vessey (2003) find that bio-fertilizers improve availability of nutrients from the rhizosphere, promoting crop growth and their nutritional quality. El-Sirafy et al. (2006) underlined that bio-fertilizer significantly affected Fe, Mn and Zn concentration in wheat tissues. Nevertheless, there are some negative aspects of bio-fertilizer application, such as decreased Fe and β-carotene concentrations in maize grain with elevated phytate concentration (Dragicevic at al., 2015).

Irrespective to the status of mineral nutrients in grains, their further bio-availability from digestive organs depends on chemical composition of grain (Nuss and Tanumihardjo, 2010; Welch and Graham, 2000), so it is important to evaluate relation between essential elements and factors that contribute or restrain their bio-availability, like phytic acid, phenols, carotenoids, glutathione, fiber, etc.

The relation between phytate and mineral elements is important trait for evaluation of their potential bio-availability (Dragičević et al., 2014; Dragicevic et al., 2016; Šimić et al., 2012; Wiesler, 2012), indicating that genotypes and cropping practices that reduce phytate content and increase concentrations of essential mineral elements are desirable, from the nutritional standpoint.

The aim of the study was to examine variations in concentrations of phytate, soluble phenols, total glutathione (GSH), yellow pigment (YP), DPPH radical scavenging capacity (DPPH), Ca, Mg, Fe, Zn and Mn in maize hybrids with white, yellow and red colour grain, under the influence of bio-, organic fertilizer and urea in regard to control (without fertilization).

Material and Methods

The research was conducted in Zemun Polje (44°52'N 20°20'E), in the vicinity of Belgrade, on a slightly calcareous chernozem soil in 2017, within an on-going experiment in dry-land conditions. The field experiment was arranged in a split-plot design with 4 replications. Three maize hybrids were used in experiment: ZP 737, ZP 5048*c* and ZP 522*b* with yellow, red and white grain, respectively. Also, three fertilizers were tested: bio-fertilizer (BF) Team Mycoriza Plus (containing *Glomus spp*. 300 spore^{-1} g and rizoshere bacteria 10 UFC^{-1} g, in amount of 0.5 kg 100^{-1} l water; organic fertilizer (OF) – Fertor (containing 65% of organic matter, 65% N, 4.1% organic N, 2.7% K, 2.3% K, 1.1% MgO, 9.3% CaO in amount of 2.5 t ha^{-1}; urea (U), as a standard mineral fertilizer, in amount of 200 kg ha^{-1}; and control (C) – without fertilization. Fertilizers were incorporated into soil at the end of April, prior to sowing.

After harvesting (second half of October) maize grain was milled and chemical composition was determined. Phytate (Pphy) was determined by the method of Dragičević et al. (2011), total glutathione (GSH) by the method of Sari Gorla et al. (1993), yellow pigment (YP) by the method described by Vancetovic et al. (2014), soluble phenols by method of Simić et al. (2004), DPPH radical scavenging capacity (DPPH) by the method suggested by Abe et al. (1998). Mineral elements were determined by Inductively Coupled Plasma - Optical Emission Spectrometry.

Results were analysed with ANOVA and the significance of the treatments effect were determined by the Fisher's least significant difference (LSD) test at p = 0.05 and by correlation (Pearson's coefficients).

Results and Discussion

The main source of variability in content of examined parameters was hybrid (for phytic P, phenols, glutathione, yellow pigment DDPH radical scavenging capacity, Mg and Zn), as well as interaction between hybrid and fertilizer (for all examined factors) (Table 1). Feil et al. (1990) and Mladenović Drnić et al. (2009) also acquired high genotypic variability in seed phosphorus, i.e. phytate content. Fertilizer expressed significant influence on the variation of Mg, Fe, Zn and Mn content in maize grain. Besides, red grain maize was characterised with the highest content of phenols, yellow pigment DPPH scavenging capacity, and all examined minerals, as well as the lowest content of phytic P, signifying it mainly as the favourable source of antioxidants, and so factors that contribute to the potentially increased bio-availability of mineral nutrients. Nevertheless, white grain maize had the highest GSH content. When impact of applied fertilizers was taken into consideration, it could be assumed that bio-fertilizer expressed the highest impact on phytate decrease, as well as increase in content of phenols, GSH, Ca and Fe, while urea was mainly important for increased accumulation of yellow pigment, Cu and Zn and organic fertilizer was reflected positive on increase of Mg and Mn. These results were mainly supported by results of Dragicevic at al. (2015) who pointed rather negative effect of bio-fertilizer, which led to decreased Fe and β-carotene concentrations in maize grown as intercrop with soybean, as well as in maize monocrop. Nevertheless, El-Sirafy et al. (2006) proved that bio-fertilizer increased absorption and accumulation of Fe, Mn and Zn in wheat tissues. Also, Singh and Reddy (2011) and Kaur and Reddy (2015) showed that particular bio-fertilizers could be used to improve availability of some target mineral elements, like P is, for maize and wheat crops, even from insoluble forms.

Due to the fact that accumulation of essential elements in maize grain depend on agro-ecological conditions and applied cropping measures (Bender et al., 2013), and that further bio-availability from digestive organs depends on chemical composition of grain (Nuss and Tanumihardjo, 2010; Welch and Graham, 2000), it is important to evaluate relation between essential elements and factors that contribute or restrain their bio-availability. The correlation between these factors and examined minerals from maize grain shown significant and negative dependence between phytate and majority of minerals (Ca, Fe, Cu and Zn) (Table 2), indicating that any factor which reduce phytate content, such as particular usage of bio-fertilizer in yellow and white grain maize, positively impacts accumulation of mineral elements, with exception of Mn, which correlates positive with phytate in maize grain. Feil et al. (2005) also pointed that mineral nutrition, such as application of higher N and P rates affects absorption and accumulation of other mineral elements, thus changing nutritional quality of maize grain. Increased accumulation of mineral elements, particularly micro-nutrients with parallel phytate decrease is positive trend, since many data support finding that parallel increase in concentration of mineral elements and reduction of phytate concentration is desirable for their improved bio-availability (Dragičević et al., 2014; Dragicevic et al., 2016; Šimić et al., 2012; Wiesler, 2012). Potentially increased Mg bio-availability is also supported by increased content of yellow pigment, emphasizing yellow grain maize as potentially better source of Mg in nutrition. Nevertheless, increased phenols content, as it was found in red grain maize, correlates significantly and positive with Cu and Zn, reducing their potential bio-availability to some extent. This is essential, since results demonstrate that red grain maize accumulates higher concentration of mineral elements, when compared to yellow and particularly white grain maize. What is more, increased DPPH radical scavenging capacity, as it was find in red and white grain maize, also positively correlates with Cu and Zn, indicating the importance of antioxidants for potential bio-availability of mineral elements, mainly Cu and Zn.

Table 2. Correlation between phytic P (Pphy), phenols (Phen.), total glutathione (GSH), yellow pigment (YP), DPPH radical scavenging capacity and Mg, Ca, Fe, Cu and Zn

Conclusions

Based on obtained preliminary results, it could be concluded that accumulation, and potential bio-availability of mineral elements from maize grain is complex trait, depending mainly on genotype characteristics and its interaction with production conditions. It is shown that red grain maize is better accumulator of mineral elements, having lower phytate and higher content of phenols, yellow pigment and DPPH radical scavenging capacity, making it as desirable source of antioxidants and mineral in nutrition. But, when increased level of phenols is taken into consideration, potential bio-availability from digestive system could be compromised to some extent. Owing to the higher yellow pigment content and little bit lower values of mineral elements, yellow grain maize could be also a great source of carotenoids and minerals. Irrespective that white grain maize is lower among all three genotypes in mineral elements it is also a good source of antioxidants, such as GSH. Among tested fertilizers, bio-fertilizer expressed full potential in increase of antioxidants content and phytate reduction, together with increase of Ca and Fe content in maize grain, while urea is much more important for accumulation of yellow pigment, Cu, Zn and Mn.

Acknowledgments

The study was a part of the Project No. TR 31037 - Integrated system of field crop cultivation: conservation of biodiversity and soil fertility, supported by the Ministry of Education, Science and Technological Development of the Republic of Serbia.

Abstract

Application of bioinoculants using plant growth promoting rhizobacteria (PGPR) as root-colonizing non-pathogenic bacteria and their metabolites can increase plant resistance to biotic and abiotic stress factors. Co-inoculation using bacteria belonging to *Bacillus* and *Bradyrhizobium* genera, as PGPR members, can lead to synergistic activity and improvement of growth, nodulation and yield of leguminous plants, as well as to better tolerance against drought as abiotic stress. Assessment of soybean (*Glycine max* L.) growth and yield enhancement by co-inoculation with *Bacillus* sp. and *Bradyrhizobium japonicum* was the aim of this study. The field trial was conducted in Vajska locality (Vojvodina, Serbia) during 2017 on 0.5 ha plot per treatment under low rainfall. Commercial fertilizer containing *B. japonicum* strain (Kf) was used as positive control, while negative control (K) was without any inoculation. *Bacillus* sp. strain Q10b (B), mutant for the production of growth stimulating IAA (indole acetic acid), and its extracellular metabolites (Em) in addition to *B. japonicum* strain 526 were used in field trial. *Bacillus* sp. strain Q10b, as induced mutant, produced eightfold higher amount of IAA than wild type strain Q10. The B, Em and Kf treatments significantly improved morphological parameters of plant growth at flowering and maturity stage comparing to K. The values of plant height, trifoliate leaf number, pod number per plant and SDW were higher for treatments B and Em than in Kf at the flowering stage, as well as grain mass per plant at the maturity stage. The seed yields of 1600 (K), 1800 (Kf), 2220 (B) and 2480 kg ha^{-1} (Em) were obtained, suggesting soybean exerted high response to IAA-producing mutant *Bacillus* sp. Q10b and its metabolites in the addition to *B. japonicum* strain.

Keywords: *Bacillus sp., B. japonicum, IAA, soybean, coinoculation.*

Introduction

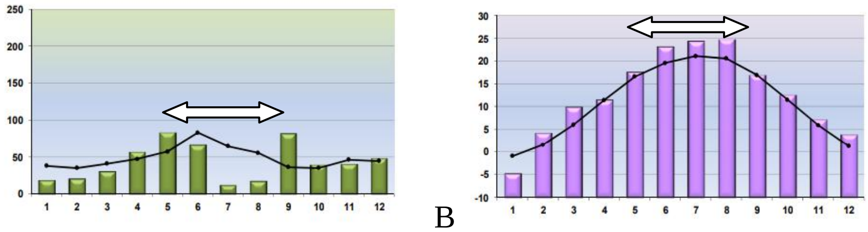
Soybean [*Glycine max* (L.) Merr.], a member of the Leguminosae family, is one of the most important oil seed crops worldwide; it is the best source of proteins, oil, minerals (calcium, zinc and iron) and vitamins (folic acid, riboflavin, thiamin and niacin) (Ali, 2010). Soybean is a source of food for livestock and human, and the food industry source for many products (flour, oil, milk, vegetable cheese, lecithin). Improvement in production of this legume depends on many factors, including edaphic factors and biological processes related to the host plant and microorganisms.

Among the large number of microbes living in the endosphere, rhizosphere and the root surrounding soil are some beneficial bacteria. PGPR are distributed around the plant root system and have impact on plant growth and productivity due to effect of its metabolic activities and plant interactions (Berg, 2009; Lugtenberg and Kamilova, 2009). The important mechanisms of growth promotion include biofertilization through production of growth stimulating phytohormones, solubilization and mobilization of phosphate, siderophore production, N_2 Fixation, as well as biological control of pathogens through antibiosis, secretion of lytic enzymes, production of antibiotics and induction of plant systemic resistance to pathogens. Plant growth promotion by beneficial bacteria is usually a result of combined action of two or more of these mechanisms. PGPR may synthesize phytohormones such as

auxins, cytokinins and gibberellins able to enhance or regulate various stages of plant growth. Indole-3-acetic acid (IAA), as auxin, is able to stimulate root growth, to enhance lateral root and root hair development and to increase surface area (Idris et al. 2007; Richardson et al. 2009; Verma et al. 2010). Phytohormones also help the plants to escape abiotic stress or survive stressful conditions (Skirycz and Inze, 2010; Fahad et al. 2015).
Rhizobacteria belonging to the genus *Bacillus* (*Bc*.) and *Bradyrhizobium* (*B*.) may improve plants growth by producing extracellular metabolites, including IAA. *Bacillus,* rod-shaped Gram-positive bacteria, are the most commonly commercialized member of PGPR because of their ability to produce endospores tolerant to heat and desiccation (Akinrinlola et al. 2018). *B. japonicum* is one of the symbionts of soybean that possess the ability to reduce molecular nitrogen into ammonia during biological nitrogen fixation (BNF) (Bottomley et al. 2007; Franche et al. 2009). Although *Bradyrhizobium* inoculation is very effective at enhancing BFN and crop yields in soybean, co-inoculation of *Bradyrhizobium* and other PGPR significantly improved soybean growth and yield as compared with the sole application of *Bradyrhizobium* (Wasule et al. 2007). Co-inoculation is effective practice considering demands of agricultural, economic and environmental sustainability (Chaparro et al. 2012).
The aim of this study was the estimation of the production of growth stimulating phytohormone IAA by mutant strain *Bacillus* sp. Q10b and its evaluation as co-inoculant with *B. japonicum* on growth promotion and yield improvement in soybean under drought conditions.

Material and methods

Bacteria were grown aerobically in nutrient broth (NB) (*Bacillus* sp.) or yeast mannitol broth (YMB) (*B. japonicum*) for 24 h or 48 h at 28ºC on a rotating shaker (150 rpm). The density of culture was measured spectrophotometrically (Shimadzu Spectrophotometer UV-160) at 600 nm, diluted in sterile medium to a final concentration of 5 x 10^8 CFU $ml^{-1,}$ and used for further analyses. Cell free supernatant containing extracellular metabolites (Em) of *Bacillus* sp. mutant strain Q10b was obtained by centrifugation at 12000 rpm for 15 min and filtration through 0.22 μm filters (Merck Millipore Ltd.).
Quantitative analysis of IAA production was tested according to standard procedure (Glickman and Dessaux, 1995). Bacterial suspension (10 μl standardized to OD_{600} of 0.625) was inoculated in NB or YMB medium supplemented with of 2.5 and 5 mM L-tryptophan. After 24h and 48h of incubation at standard temperature, the density of the culture was measured spectrophotometrically at 600 nm for optimization to value 1 and the bacterial cells were removed from the culture medium by centrifugation. The supernatant was mixed (1:2 v/v) with Salkowski reagent (2% 0.5M ferric chloride in 35% perchloric acid) and pink color intensity was measured at 530 nm for IAA production or IAA standard curve (1-100 μg ml^{-1}).
The field experiment was conducted during 2017 from May 12th to September 8th in Vajska locality (Bačka District, Vojvodina, Serbia) using soybean cultivar Tambor. Field trial was performed on 0.5 ha plot per treatment under low rainfall and high temperature (fig. 1). Four treatments were used: K - negative control without any inoculation; Kf - commercial fertilizer containing *B. japonicum* strain used as positive control; B - *Bacillus* sp. mutant strain Q10b and *B. japonicum* strain 526; Em - extracellular metabolites of *Bacillus* sp. mutant strain Q10b in addition to *B. japonicum* strain 526.
At flowering and maturity period, 40 plants per treatment were sampled and main growth parameters such as plant height, trifoliate leaf number, root weight, root length, nodule and pod number per plant, grain mass per plant and mass 1000 grain were measured. The yield was compared to both control treatments.



A B

Figure 1. Average values of monthly precipitation (mm) (A) and air temperatures (^{o}C) (B) during the 2017 and (•) average values in period 1961 – 1990 (RHMZ RS).

Statistical analysis. Data were analyzed using Statistica 8 software. One-way general linear model ANOVA was used to determine the effect of each treatment. The Duncan test was used for post hoc analysis to determine differences between means. Differences were considered significant at $p < 0.05$.

Results and discussion

The results of IAA measurements reflected the ability of *Bacillus* sp. wild type (wt) Q10 and mutant strain Q10b to produce indole compounds. The tested strains exhibited a pink to red color with a variation in intensity. Mutant strain *Bacillus* sp. Q10d produced significantly higher amount of IAA in NB medium than wt Q10, without or in addition of tryptophan. IAA produced naturally by Q10 ranged from 1.63 to 1.87 μg ml^{-1} after 24 h and 48 h of cultivation, while mutant strain Q10b produced about eightfold higher amount. The highest value of auxin production (60 μg ml^{-1}) was obtained by mutant strain Q10b after 48h of cultivation in NB supplemented with 5 mM L-tryptophan. Influence of two tryptophan concentrations on wt and mutant strain is shown in table 1.

Table 1. *Bacillus* sp.: IAA production (μg ml^{-1}) by wild type Q10 and mutant strain Q10b

Strain	L-tryptophan (mM)					
	0		2.5		5	
	24 h	48 h	24 h	48 h	24 h	48 h
Q10	1.63 ±0.11	1.87±0.10	4.91±0.28	6.02±0.12	6.28±0.89	7.81±0.15
Q10b	13.27±0.42	15.63±0.42	27.99±0.13	37.70±3.03	48.92±0.29	60.06±2.28

Tryptophan has been identified as a main precursor molecule for biosynthesis of IAA in bacteria. Tryptophan-dependent production of IAA affects level of plant growth promotion by some *Bacillus* strain (Idris et al. 2007). In our earlier investigation, IAA production from 3.76 μg ml^{-1} in medium without the addition of tryptophan, to 10.62 μg ml^{-1} in medium supplemented with 5 mM L-tryptophan, was observed for *Bacillus* sp. Q3 strain (Starovic et al. 2013). Similar values were observed in this investigation for wild type Q10 strain supplemented with 5 mM L-tryptophan, as well as for several PGP *Bacillus* and *Paenibacillus* strains that showed IAA production of 5-7 μg ml^{-1} in non-supplemented medium (Erturk et al. 2010). The same authors quantified higher values of IAA in the presence of 25 μg ml^{-1} of tryptophan for *Bacillus* RC23 strain that produced 20.4 μg ml^{-1} and *Bc. simplex* RC19 that produced 33.6 μg ml^{-1}. The two fold higher values were quantified for *Bacillus* mutant strain Q10b, although tenfold lowest tryptophan concentration was added.

The effect of co-inoculation treatments on soybean growth and yield components is shown in tables 2 and 3. Data illustrated that *B. japonicum* 526 inoculation amended with extracellular metabolites of *Bacillus* sp. mutant strain Q10b, containing high amount of IAA, or its co-inoculation with the *Bacillus* sp. Q10b strain, caused significant increases in all growth components, as compared with the commercial fertilizer applied or uninoculated treatments. The yield and yield increment compared to two controls are shown in table 4.

*K - negative control without any inoculation; Kf - commercial fertilizer containing *B. japonicum* strain used as positive control; B - *Bacillus* sp. mutant strain Q10b co-inoculated with *B. japonicum* strain 526; Em - extracellular metabolites of *Bacillus* sp. mutant strain Q10b in addition to *B. japonicum* strain 526. **According Duncan test, different letters above data indicate significant differences among treatments ($p < 0.05$).

The appearance of 0-13 (6.79 in average) nodules per plant in uninoculated control on the plot of soil without earlier soybean cultivation could be explained due to the presence of indigenous population of *B. japonicum* different from introduced strains (data not shown). The effectiveness of indigenous *B. japonicum* was lower than applied strain and commercial fertilizer comparing to growth parameter and yield of soybean.

According to Masciarelli et al (2014), *Bc. amyloliquefaciens* strain LL2012 produces high levels of gibberellins and salicylic acid in addition of IAA (18.8 μg ml^{-1}). In co-inoculation of soybean plants with *B. japonicum*, strain LL2012 improves nodulation and other plant growth parameters. IAA production of *Bacillus* sp. strain Q10b was higher than LL2012 and showed PGP effect. Several *Bacillus* strains impact root colonization and growth promotion not only soybean, but also other plants, as *Bc. cereus* YL6 of wheat and Chinese cabbage (Ku et al. 2018).

Table 4. Yield of soybean cv. Tambor and its increase as affected by *Bacillus* sp. mutant strain Q10b co-inoculated with *B. japonicum* strain 526

Treatment	Yield (kg ha^{-1})	Yield increase (%) compared to	
		negative control	positive control
K*	1600	-	-11.11
Em	2480	55	37.78
B	2220	38.75	23.33
Kf	1800	12.5	-

*K - negative control without any inoculation; Kf - commercial fertilizer containing *B. japonicum* strain used as positive control; B - *Bacillus* sp. mutant strain Q10b co-inoculated with *B. japonicum* strain 526; Em - extracellular metabolites of *Bacillus* sp. mutant strain Q10b in addition to *B. japonicum* strain 526.

Drought affects plant–water potential and change physiological and morphological traits in plants (Rahdari and Hoseini, 2012). It influences the availability and transport of soil nutrients, affects at various sub cellular compartment, cell organs and whole plant level (Rahdari et al. 2012). Improvement in soybean growth and yield in the field trial under drought stress using *Bacillus* sp. wt strain Q10 in co-inoculation with *B. japonicum* 526 and *Pseudomonas chlororaphis* Q16 are reported (Iličić et al. 2017). Growth and yield reduction under drought stress were also observed during vegetation of soybean in our field trial. Comparing to results obtained earlier on the neighbor locality, yield increment of 7.15% impacted by wt Q10 strain in co-inoculation with *B. japonicum* 526 on soybean cv. Angela is lower than yield increment of soybean cv. Tambor under *Bacillus* sp. mutant strain Q10b co-inoculated with the same *B. japonicum* strain (23.33%). Soybean inoculated with mutant strain Q10b showed good response to drought stress. *Bc. thuringiensis* AZP2 application on wheat seedlings under drought stress increased plant biomass and survival under drought by reducing emissions of volatile compounds and increasing photosynthesis, suggesting that bacterial inoculation improved plant stress tolerance (Timmusk et al. 2014).

Conclusion

Co-inoculation of *Bacillus* sp. mutant strain Q10b, as producer of IAA and other PGP substances, and *B. japonicum* 526, or application of *B. japonicum* with addition of extracellular metabolites of Q10b, may be an efficient strategy for enhancing the productivity of soybean in drought conditions.

Abstract

Rape seed (*Brassica napus* L.) is one of the major industrial high-yielding oilseed and fodder crops. Water deficit in the limits plants genetic potential in all agro-climatic zones of growing. One of the main ways to increase rape seed productivity is to create new hybrids with the optimal response to environmental changes. The efficiency of breeding is largely determined by the genetic diversity of plant breeding genotypes, which is accepted to be evaluated by morphological features in the process of state variety testing and by using DNA markers. The purpose of this study was to evaluate the genetic polymorphism of spring and winter rape seed varieties using morphological and DNA markers, followed by their use for obtaining drought-resistant lines with the aid of *in vitro* cell selection. The study involved varieties of winter and spring rape seed. Resulted from cluster analysis were two clusters formed by morphological features. According to the varietal distribution by SSR markers (Ra3-H09, Na12-A02, FITO-063, Na10-B07), three clusters were obtained. No correlation between the matrices of genetic distances by morphological features and the DNA markers under study was found; however, the distribution obtained by genetic distances allowed to detect the difference between the studied rape seed varieties. As a result of the mutagenic action (γ-irradiation in a dose of 40 Gy) on micro calluses of rape seed varieties, which significantly differed by morphological and DNA markers, and subsequent gradual cell selection *in vitro*, about 4% of the drought-resistant rape seed clones were selected. Thus, the obtained distribution of varieties by morphological traits and SSR markers ensures a reliable basis for identification of varietal differences in selection for drought-resistant rape seed.

Keywords: *SSR markers; morphological traits; cluster analysis; cell selection*.

Introduction

Rapeseed (*Brassica napus* L.) is one of the leading oilseed and forage crops in Ukraine and in the world. The breeding programs dedicated to winter and spring rapeseed are aimed at the obtaining of high-yielding varieties and hybrids of various types based on the content and composition of the oil, with high plasticity to meteorological and agro-ecological factors (Sytnik and Kliachenko, 2010; Klyachenko, 2016; Clapp *et al*., 2018). The efficiency of breeding is largely determined by the heterogeneity of the plant parent material, which requires new approaches to increase the genetic heterogeneity of the breeding genotypes (Ana *et al*., 2009; Jamali *et al*., 2017). The description of marker morphological traits is known to be one of the effective methods for determining the differences between varieties in the process of their registration which used in Ukraine and in European countries (Ana *et al*., 2009). However, today one of the fastest and most effective methods for assessing the polymorphism of crops is the use of SSR markers. In our previous studies, an assessment of the genetic diversity of rapeseed varieties of different origin was made and the efficiency of the marker system for determining the variance of varieties was demonstrated (Klyachenko *et al*., 2018). Scientists have described the use of cell selections *in vitro* to obtain crop genotypes resistant to biotic and abiotic stress factors (Liu *et al*., 2003). Drought stress significantly limits plant growth and yield. However, in some crops possessing high adaptive capacity, such as rapeseed, morphological and metabolic changes occur in response to drought, contributing to adaptation to such environmental constraints (Rad and Abbasian, 2011). The action of ionizing (X-rays and γ-rays) and ultraviolet radiation induces mutagenesis with the widest spectrum of mutations and significantly increases the efficiency of cell selections (MacDonald *et al.*, 1991). The purpose of our study was to evaluate the genetic polymorphism of spring and winter rapeseed varieties using morphological and DNA markers, which will be used to obtain drought-resistant lines with the aid of cell selection *in vitro*.

Material and Methods

In the study, we used rapeseed varieties of Ukrainian and foreign origin: five winter varieties (Senator Liuks, Aliot, NK Technik, NK Petrol and Nelson) and two spring ones (Kliff and Geros). The varieties differed in terms of ripeness: mid-early and early-ripening, as well as different levels of drought resistance (Klyachenko *et al.*, 2018). The research was carried out during the 2016−2018 period on the basis of the Biotechnology Laboratory of the National University of Life and Environmental Sciences of Ukraine and the Laboratory of Molecular Genetic Analysis of the Ukrainian Institute for Plant Variety Examination.

Determination of the genetic diversity of rapeseed varieties

The description of the morphological traits of rapeseed varieties was made using 22 markers in the process of qualification examination of plant varieties for distinctness, uniformity, and stability (DUS). According to the DUS Test Guidelines, the degree of detection of the traits is indicated by numeric values from 1 to 9.

The molecular genetic polymorphism of rapeseed varieties was determined using four SSR markers: Ra3-H09, Na12-A02, FITO-063 and Na10-B07. In accordance with the obtained alleles, the number of polymorphic alleles and the level of polymorphism was determined (Klyachenko *et al.*, 2018).

The evaluation of genetic distances between rapeseed varieties was made by the cluster analysis using unweighted pair-group average method for SSR markers and single-link relationships based on morphological traits with a calculation of Euclidian distances (Fortin *et al.*, 2002; Everitt *et al.*, 2011). The correlation between the investigated SSR markers and the degree of manifestation of morphological traits was determined by genetic distances by the Mantel test using the computer program XLSTAT 2018 (Trial version) (Tommasini *et al.*, 2003; Legendre *et al.*, 2010; Diniz- Filho *et al.*, 2013; Klyachenko and Prysiazhniuk, 2018).

Obtaining of drought-resistant rapeseed lines in vitro

Rape seeds (100 seeds of each variety) were sterilized using 0.9% NaCl at the 15-min exposure and then three times rinsed with sterile distilled water. The callus tissue was obtained from the stems of aseptic seedlings through cultivating them in a thermostat at a regulated temperature from 25 to 26°C, relative humidity from 70 to 80%, without illumination, followed by transfer of the formed primary callus to the medium of the same composition every 21 days. To achieve the mutagenic effect of ionizing irradiation, callus tissues were treated with γ-rays at a dose of 40 Gy (Sydorov, 1990). A suspension culture for determining the sublethal concentration of selective agents was obtained according to Sidorov (1990).

The incremental *in vitro* cell selection of rapeseed for drought resistance was carried out according to the following scheme: seed germination in solutions with a selective agent → 3 passages in a selective environment → 3 passages without a selective factor → 3 passages in a selective environment → plant regeneration (Klyachenko, 2016).

As stress factors 15−20% mannitol and 5−25% high molecular weight PEG 6000 on the callusogenic medium MS (MS+0.5 mg/L BAP, 0.5 mg/L NOC, 0.05 mg/L of GA_3) were used (Sydorov, 1990). To study the influence of the concentration of selective agents in the selection process, the growth rate of the callus tissue was determined (Kucherenko *et al.*, 1991; Butenko, 1999). To obtain the regenerated plants, the callus was planted on an MS medium supplemented with 6-BAP at a concentration of 0.05 mg/L and cultivated in a light culture chamber at 25°C, illumination of 3000−4000 lux and a 16-hour photoperiod. Statistical data processing was carried out using the computer program STATISTICA 12.0 (Trial version).

Results and Discussion

Estimation of the genetic diversity of rapeseed varieties

To study the polymorphism of the studied rapeseed varieties, a cluster analysis was carried out with the purpose to evaluate the genetic distances between the objects. Showed in the Fig. 1 is a phylogenetic tree of the hierarchical rapeseed clustering by morphological markers.

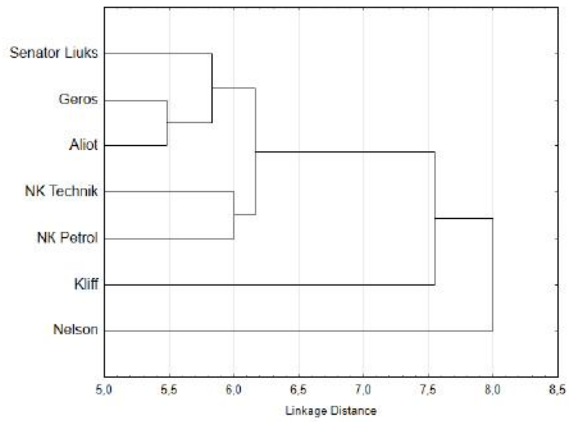

Fig. 1. Distribution of rapeseed varieties by the degree of proximity on the basis of morphological traits

It can be seen that two clusters are formed by Geros and Aliot, NK Technik and NK Petrol varieties, while other varieties are placed in adjacent clusters. The least values of genetic distances were found between varieties Geros and Aliot, NK Technik and NK Petrol (5.48 and 6.00, respectively). Noticeably, that the most distant varieties by morphological traits appeared Kliff and Nelson with the value of the genetic distance of 12.1. Thus, the obtained results reflect the degree of proximity in the manifestation of the specified characteristics and are not related to the type of development of a variety, unless indicated by the characteristics on which these varieties differ, namely the tendency of formation of inflorescences in the year of spring and late summer sowing (Official bulletin, 2010).

Analysis of rapeseed varieties by SSR markers yielded 36 detected alleles, with an average of 9 alleles per marker. The highest level of polymorphism was determined by the marker Na12-A02 (83%) while FITO-063 was the least polymorphous (40%). The markers Ra3-H09 and Na10-B07 have a polymorphism of 60 and 44%, respectively. These results are in the line with our previous studies of a large number of rapeseed varieties and are consistent with the results obtained by other researchers for these markers (Tommasini *et al.*, 2003; Hasan *et al.*, 2006; Li *et al.*, 2011; Klyachenko *et al.*, 2018).

The results of the cluster analysis of rapeseed varieties by the four SSR markers proved the presence of three genetically remote groups of genotypes (Fig. 2).

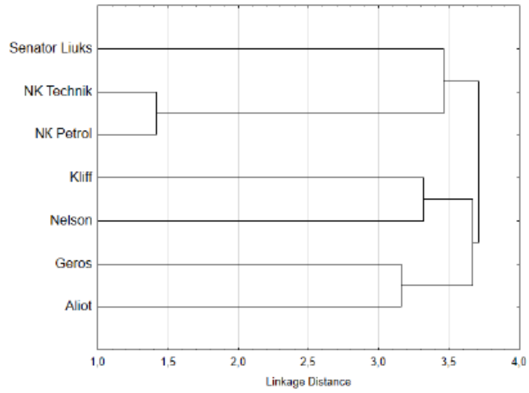

Fig. 2. Distribution of rapeseed varieties by the degree of affinity based on SSR markers

Varieties NK Technik and NK Petrol, Kliff and Nelson, Geros and Aliot have formed separate clusters. The most related by markers Ra3-H09, Na12-A02, FITO-063 and Na10-B07 appeared varieties NK Technik and NK Petrol (genetic distance of 1.41), and the most distant ones were Kliff and Nelson (4.00) included in one cluster. Senator Liuks variety did not fit into any cluster by both marker systems. Thus, for an objective assessment of the genetic diversity of rapeseed varieties as breeding genotypes for the production of drought-resistant lines, it is advisable to determine the correlation between marker systems.
The evaluation of the correlation between genetic distances obtained by SSR markers and morphological features was performed using the Mantel test (linear correlation by Pearson). As a result of the analysis, the calculated significance level p-value and the coefficient of correlation r (AB) for the theoretical significance level α=0.05 were obtained. According to the interpretation of the results of the comparison test, these indicators allow accepting one of the hypotheses about the presence (Ha) or absence of correlation (H0) (Fig. 3).

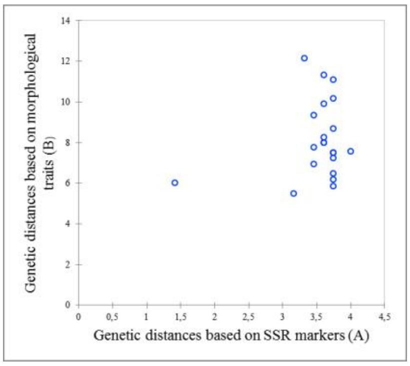

Fig. 3. Relationship between genetic distances of rapeseed varieties by morphological characteristics and SSR markers

The calculated p-value 0.345 was higher than the significance level α=0.05. Consequently, we have to accept the hypothesis H0 of the absence of a correlation which condition is $p > \alpha$ (Diniz-Filho *et al.*, 2013). Some scientists reported the absence and presence of correlation between genetic distances (Karuri *et al.*, 2010; Darvishzadeh, 2012). Tommasini *et al.* (2003) and investigated the relationship between genetic distances by morphological traits and using 46 SSR markers in ten winter and spring rapeseed varieties. According to the Mantel test, there was a lack of correlation between the studied markers and the morphological traits. It should be noted that, due to a sufficiently large number of SSR markers, the authors described only five morphological features. Ana *et al.* (2009) examined the polymorphism of rapeseed varieties with 9 RAPD markers and 10 quantitative morphological features. The authors obtained the results which indicated a lack of correlation between the studied DNA markers and morphological characteristics. The accuracy of determining the genetic proximity or distance based on the DNA markers may be affected by many factors, such as the number of markers used, their distribution by the genome, and the degree of accuracy of the analysis. In addition, it should be noted that molecular markers cannot be used in making conclusions about intergalactic interactions that result in the expression of individual genes (Ana *et al.*, 2009). Consequently, the distribution by genetic distances obtained by us made it possible to detect the difference between the studied rapeseed varieties using SSR markers and morphological traits. We found that the distribution of the studied varieties by clusters along with the absence of correlation between two marker systems does not have significant differences and proves the genetic proximity of the varieties included in one cluster by both morphological and SSR markers.

Rape selection in vitro for drought tolerance

To obtain drought-resistant lines on the basis of the studied varieties we used winter rapeseed varieties Aliot and Nelson. It is known that winter crops, under other equal conditions, are more productive due to the full use of autumn-winter moisture reserves. As a result of the gradual change in climate and the increase in the average annual temperature in the regions of rapeseed growing, insufficient rainfall is increasingly observed in winter which in turn affects the stock of moisture in the soil (Dyirenko, 2012; Clapp *at al.*, 2018). The lack of water in the soil inhibits growth processes in plants, changes the intensity and direction of the processes of photosynthesis, respiration, the course of carbohydrate, nitrogen and nucleic exchanges, the activity of enzymes, etc. (Bray, 2002; Rabbani *et al*., 2003).

According to the description provided by the breeders, the varieties under study possess medium to high capacity to withstand drought conditions and belong to different groups of ripening: Aliot is early ripening and Nelson is middle ripening (Official bulletin, 2010). It is known that the selection of varieties and lines attributed to different geographical groups and their involvement in crossbreeding will allow the use of all genetic breeding potential of rapeseed (Ashadullin and Ashadullin, 2007). It should be noted that varieties Aliot and Nelson are quite different both on the basis of morphological traits and for DNA markers. The values of genetic distances between them were 8.00 and 3.61, respectively.

According to the available literature, agar nutrient media supplemented by osmotically active substances that reduce the external water potential of cells are usually used to induce drought stress *in vitro* (Sydorov, 1990; Rai *et al.*, 2011; Masoabi *et al.*, 2018). To determine the concentrations of PEG 6000 and mannitol, which can be used as selective agents in the process of *in vitro* incremental selection, the growth of callus at different concentrations of osmotically active substances was determined (Table 1).

Table 1. Callus increment in winter rapeseed at different concentrations of PEG 6000 and mannitol

Variety	Control	Callus increment (%)					
		PEG 6000 (%)			Mannitol (%)		
		5	12	20	15	17	20
Aliot	92.2	90.3	55.3	5.7	61.8	48.6	4.0
Nelson	91.8	79.0	43.9	4.0	62.3	39.8	3.8
$LSD_{0.5}$	4.5	3.4	1.4	0.2	2.6	1.8	0.6

When studying the effects of different doses, it was found that action of 12% PEG 6000 and 17% mannitol caused significant differences between the studied varieties of winter rapeseed and about 50% decrease in the growth of callus tissue. The studies conducted by Masoabi *et al.* (2018) showed that 20% PEG 6000 was effective in *in vitro* selection of sugar cane. However, in the same studies, the ability of the callus tissue to grow at the 10% concentration of PEG 6000 was noted. In the works by Rahayu and Sudarsono (2015), 15% PEG 6000 concentration appeared sublethal during *in vitro* selection of peanut varieties. Similar studies were carried out by Galovic *et al.* (2005) for winter wheat establishing the efficiency of PEG 6000 at a concentration of 5% for drought-resistant lines. Research on the selection of drought-resistant rapeseed varieties was carried out by Ashraf and Mehmood (1990). However, genotypes were selected based on field studies and evaluation of the osmotic potential of leaves.

Analysis of the obtained data shows, that PEG 6000 (12%) and mannitol (17%) can be used as selective agents in the work with the studied winter rapeseed genotypes.

In our studies, in the subsequent cell selection scheme, PEG 6000 was used, since it impedes water stress without penetration into a cell and acts as an osmotic agent (Chandler and Thorpe, 1987; Priyanka *et al.*, 2011; Jan *et al.*, 2018). The microcalluses treated with γ-irradiation were planted in a medium with a sublethal concentration of PEG 6000. The sublethal concentrations of PEG 6000 were determined by seeding a suspension culture in nutrient media of various concentrations (10%, 20%, 30%, and 40%). As a result, the sublethal concentration of PEG 6000 (20%) was determined by a significant decrease in the growth of the mass of the callus tissue. This concentration was subsequently used for *in vitro* incremental cell selection. To do this, at the end of the first passage only light portions of the callus tissues were isolated and transferred to a freshly prepared medium with a selective agent. A count of the colonies that grew under selective and non-selective conditions was carried out. It was found that up to the seventh passage the number of the first selected colonies substantially decreased (Table 2).

Table 2. Dynamics of elimination of adaptive variants in winter rapeseed genotypes

Variety	The number of treated with γ-rays microcolonies	The number of live colonies in passages (% of the colonies treated with γ-rays)						
		1	2	3	4	5	6	7
Nelson	275	45.7±2.2	34.8±1.6	28.3±1.4	28.3±1.4	28.3±1.4	12.8±0.5	4.7±0.2
Aliot	310	54.8±2.6	32.1±1.5	20.4±1.0	20.4±1.0	20.4±1.0	15.4±0.7	4.8±0.2

Note: $p < 0.05$

The data presented in Table 2, show that the number of viable colonies in the first passage decreased to 35−50% as a result of treatment with γ-irradiation, with the elimination of colonies by passage being almost the same in quantitative terms for the studied rapeseed varieties. After three selective passages, the number of live colonies ranged between 15 and 25%. Beversdorf and Kott (1987) used γ-rays for an embryonic rapeseed culture. The authors determined that the survival rate of callus in the first passage after irradiation was 50%. To obtain forms tolerant to oxalic acid, Liu *et al.* (2003) also applied the mutagenesis of rapeseed with γ-rays. MacDonald *et al.* (1991) obtained rapeseed clones resistant to herbicides by applying ultraviolet rays to microcolonies. In this case, the proportion of surviving embryos was 4%.

In our studies, after carrying out two passages in a medium without a selective agent and checking the growth of the microcolonies under selective conditions, it was possible to isolate about 4% of the resistant rapeseed clones that stably manifested the sign of drought-resistance.

The calluses of all clones were similar in morphotype, forming a dense, globular structure of greenish coloration, and grew slowly. The resulting drought-tolerant rapeseed lines were used for plant regeneration by adding exogenous hormones to various nutrients in different concentrations.

Thus, in order to induce somatic embryogenesis in the callus tissue of winter rapeseed, the concentration of growth regulators in the medium was changed in accordance with the procedure and record of sprout formation was performed after 3−5 weeks of cultivation (Table 3).

Table 3. Morphogenesis and regeneration of shoots in the callus culture of winter rapeseed

Variety	Callus count	Morphogenetic calluses (%)	Regeneration (%)
Nelson	30	57	38
Aliot	30	59	40
$LSD_{0.5}$	-	2.8	1.8

According to the presented data, the percentage of regeneration of the studied rapeseed varieties was 38 and 40%. The obtained regenerated plants of drought-resistant lines of winter rapeseed after rooting and adaptation were transferred for use in breeding programs.

Conclusions

In summary, in this study, the polymorphism of winter and spring rapeseed varieties on the basis of morphological traits and using SSR markers was determined, and the rapeseed line tolerant to drought were obtained. Geros and Aliot varieties were found the most related on the basis of morphological traits with the genetic distance value of 5.48. The studied rapeseed varieties have differences by at least seven traits. The distribution of varieties by SSR markers is similar to the obtained distribution by morphological marker traits. Cluster analysis shows that varieties NK Technik and NK Petrol are the most related varieties with the genetic distance value of 1.41. The results of the Mantel test showed a lack of correlation between the marker systems under study on the ground of the genetic distances between the varieties. However, it should be noted that the application of an integrated assessment of the genetic variation of varieties is promising for use in the selection and examination of new varieties.

It was found that in the process of cell selection *in vitro* aimed at the production of drought-resistant rapeseed lines, it is expedient to use PEG 6000 at a concentration of 12%. The study proved the effectiveness of incremental selection *in vitro* with the use of γ-irradiation as a mutagenic agent. According to the proposed scheme, we obtained about 4% of drought-tolerant winter rapeseed clones that stably retained the trait.

Abstract
An industrial crop which can produce high yield of a quality fiber is *Cannabis sativa* subsp. *sativa*. For the purposes of the study, a field experiment was established at the Experimental Farm of the Technological Educational Institute of Thessaly in Greece (TEI; Larissa plain) in 2017, in order to determine height, dry biomass and fiber yield of *Cannabis sativa* subsp. *sativa* (cv. Fibranova). The effect of two different plant populations (P_1 = 160 plants/m^2 and P_2 = 80 plant/m^2), two irrigation levels (I_1 = 100 % ETo, I_2 = 60 % ETo) and two N-fertilization levels (F_1: 244, F_2: 184 kg ha^{-1}) were investigated. It was found that at harvest period the average plant height was 3.67 m, while the final plant height was significantly affected by irrigation input. Moreover, the average biomass dry yield and fiber yield may overcome 13t ha^{-1}and 4 t ha^{-1}, respectively. Dry biomass partitioning showed that 17% of total biomass was the dry yield of the leaves and the 83% the dry yield of the stems, while the 36-37% of the dry stem yield was the fiber dry yield. Therefore, it could be concluded that *Cannabis sativa* subsp. *sativa* (cv. Fibranova) is a very promising annual crop for fiber production in Greece and other areas of the Mediterranean region with similar environmental conditions, but further investigation is needed.

Keywords: *yield, plant density, fertigation, fiber.*

Introduction
Hemp (*Cannabis sativa* subsp. *sativa*) is an annual herbaceous crop considered to be one of the oldest crops known to man (Yang, 1991) and it is grown in many regions for its fiber production (Amaducci et al., 2015). Moreover, hemp is a remarkable plant containing many valuable natural components. It has been cultivated throughout the world for use as a food, fuel source, nutritional supplement, body care product, source of paper, building material, medicine, and in textiles (Small and Marcus, 2002; Bertoli et al., 2010; Mihoc et al., 2012).
Although industrial hemp can be used in a wide range of industrial applications, the growing popularity of synthetic fibers and the increase in labor costs are probably responsible for the continual drop in hemp cultivation worldwide since the 19th century (Allavena, 1962).
Furthermore, hemp production has been forbidden due to its Δ^9-tetrahydrocannabinol (THC) content, which is a phyto-chemical drug component.
Unlike medical cannabis abundant in the psychoactive ingredient Δ^9-THC, modern hemp has been selectively bred to produce low levels of Δ^9-THC and high levels of fiber, seed, and, more recently, cannabidiol (CBD). Most of the European Union and Canada have recognized the value of hemp and have defined a legal limit of 0.3% Δ^9-THC in the dry plant material (Small and Marcus, 2003), with the exception of Italy (0.2% Δ^9-THC) (Cappelletto et al., 2001). To date, 51 hemp cultivars have been approved for commercial use by the European Union (Directive, 2013).
Industrial hemp is a high-yielding crop (Struik et al., 2000) characterized of little technical inputs (Amaducci et al., 2015) and of a positive environmental impact (Bouloc and Werf, 2013). Its stem contains high-quality cellulose (De Meijer, 1994), the seed contains high-

quality oil (Callaway, 2004) and the inflorescence contains valuable resins (Bertoli et al., 2010).
Moreover, industrial hemp is an excellent break crop that can improve soil structure due to its extensive root system (Amaducci et al., 2008), reduce weed pressure and increase the yield of the sub-sequent crop (Bósca and Karus, 1997). Due to its numerous crop characteristics, hemp has great potential as an alternative rotation crop and could improve the agronomic and economic sustainability of farmers (Finnan and Styles, 2013).
Nowadays, environmental concerns and multi-purpose production have brought renewed interest in industrial hemp; however there is great lack of agronomical data to support hemp cultivation (Tang et al., 2016). It is really important to evaluate hemp phenology and crop adaptability in order to provide farmers with decision support information concerning cultivation practices.
The aim of this study is the assessment of the impact of plant density, irrigation and N fertilization on the yield of leaves, stems, and fiber, under the Mediterranean agro-climatic conditions of Thessaly plain, central Greece. Such data will be useful for the evaluation of hemp production and its future include in the cropping systems of Greece and the Mediterranean region in general.

Material and Methods

Experimental site

For the purpose of the study, a field experiment was established in a typical soil-climatic environment of Thessaly plain, in central Greece. The experimental site is located at the Experimental Farm of the Technological Educational Institute of Thessaly (TEI; Larissa plain, coordinates: latitude 39°62′69″ N, longitude 22°38′14″ E).

Field management and experimental design

A modern cereal seeding machine was used (on April 2017), applying 22.5 and 45 kg ha^{-1} of seed cv. Fibranova, in a row-distance of 25 and 12.5 cm, respectively.
A split-split-plot design 2 × 2 × 4 with four replications was used and the plot size was 14 m^2 (2 m width × 7 m length). Plant density was the main factor at two different populations [P_1 = 160 plants/m^2 and P_2 = 80 plant/m^2], irrigation the sub-factor at two treatments [I_1 = 100 % ETo, I_2 = 60 % ETo, because the precipitation during summer months in central Greece ranges from 90 to 200 mm, and the evapotranspiration is 500 mm, depending on the year and the microclimate of different sites], and N-fertilization the sub -sub-factor at 2 levels (F_1: 244, F_2: 184 kg ha^{-1}). Irrigation took place in 8 applications during the dry summer period (May–July) using a drip irrigation system. N-fertilization occurred at 4 applications through the irrigation system and the used type was 34,5-0-0. Weed management took place only during the establishment year (mechanically) while during the different plant growing stages, cultivation could compete the weeds. Complete weather data were recorded hourly in an automatic meteorological station which was installed next to the experimental field.

Laboratory measurements and data analyses

Soil analysis

Soil samples were analyzed using the following methods which are referred by Page et al. (1982).
Organic matter was analyzed by chemical oxidation with 1 mol L^{-1} $K_2Cr_2O_7$ and titration of the remaining reagent with 0.5 mol L^{-1} $FeSO_4$.
Inorganic forms of nitrogen were extracted with 0.5 mol L^{-1} $CaCl_2$ and estimated by distillation in the presence of MgO and Devarda's alloy, respectively. Available P forms (Olsen P) were extracted with 0.5 mol L^{-1} $NaHCO_3$ and measured by spectroscopy.

Exchangeable forms of potassium were extracted with 1 mol L^{-1} CH_3COONH_4 and measured by flame Photometer (Essex, UK). Available forms of Mn, Zn, and Cu were extracted with DTPA (diethylenetriaminepentaacetic acid 0.005 mol L^{-1} + $CaCl_2$ 0.01 mol L^{-1} + triethanolamine 0.1 mol L^{-1}) and measured by atomic absorption. In the case of the determination of total metals Mn, Cu and Zn, 1 g of wet material, was digested at 350 ^oC + 10 ml HNO_3 + 5 ml $HClO_4$. According to the method described by (Allen et al., 1974 and Varian, 1989), the samples were analyzed by Atomic Absorption (Spectroscopy Varian Spectra AA 10 plus, Victoria, Australia), with the use of flame and air-acetylene mixture.

Plant analysis

Fresh and dry biomass partitioning was monitored by means of samplings. To avoid any border effect sampling took place in the inner plot, where 1 m^2 was harvested in each sampling on 10 cm above ground. Plant height was determined by the average of all harvested plants per plot. The samples were weighed fresh and then a subplot of 10 plants was taken for further laboratory measurements. The plants of each subplot divided into the various plant components: leaves and stems in the laboratory. Then stems were placed into specific water basins for a week as to be able to separate the fibers from the stem. Leaves, stems and fiber were dried until constant weight and weighed again to determine the final dry weights.
The dry leaves were chopped and grounded. Nitrogen content in leaves was measured using the standard Kjeldhal method (Nelson and Sommers, 1973), while the total phosphorus and potassium contents were determined with the of dry combustion method, using a spectrophotometer (P) and flame photometry (K) (Jones and Case, 1990).
Then, the dry weight of the leaves was multiplied by the respective N-P-K concentration to calculate the final nutrient removal (uptake) of the sampled biomass through the canopy.

Statistical Analysis

The statistical package GenStat (7th Edition) was used for the analysis of variance (ANOVA) within sample timings for all measured and derived data in order to evaluate the main effects and interactions of all factors. The $LSD_{0.05}$ was used as the test criterion for assessing differences between means (Steel and Torrie, 1982).
Moreover, Tukey's procedures were used to detect and separate the mean treatment differences of soil samples at P = 0.05, where were four replications. Statistical analyses for the soil measure were performed by the statistical program MINITAB (Ryan et al., 2005).

Results and Discussion

Weather Conditions

The study area is characterized by a typical Mediterranean climate with cold humid winters and hot-dry summers. In particular, the average air temperature ranged to 22.9 ^oC while the noticed precipitation was 290 mm during the growing period of hemp in 2017 (Figure 1). The 33 % of the precipitation was noticed in May (113.4 mm) during the first growing stages and the 33% during July. In the same period the average temperature was 21 and 28 ^oC, respectively.

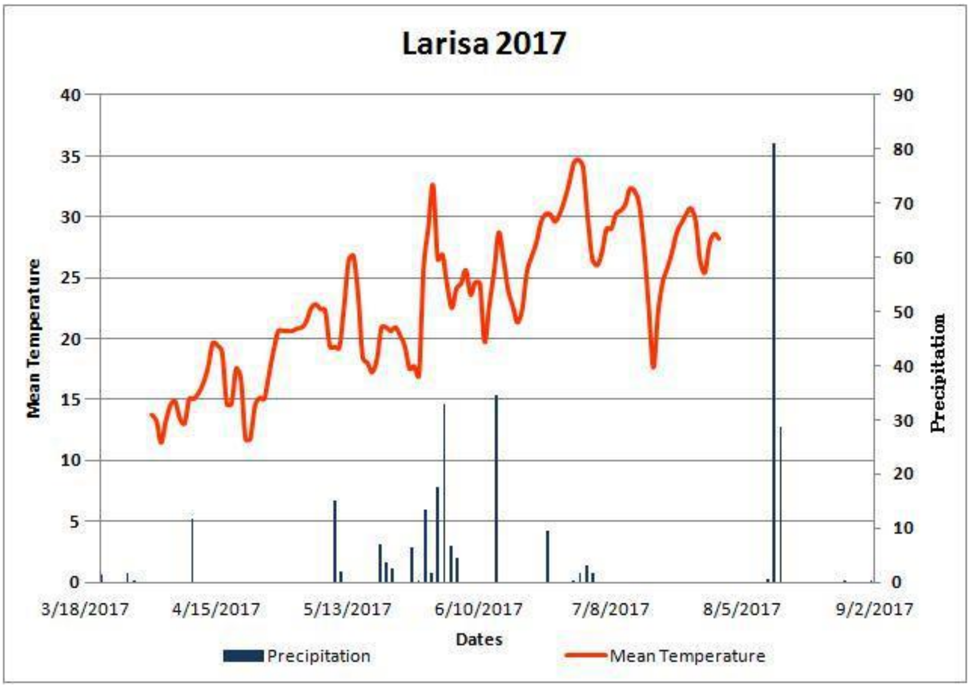

Figure 1. Mean air temperature and precipitation noticed to the study site in 2017.

Soil characteristics

The soil of the experimental site is characterized as a, calcareous (pH = 7.26), sandy clay loam (sand 46.5-48,5%, loam 17-19%, clay 34.5%), with soil organic matter content of 1.44% at a depth of 30 cm. An underground pumping irrigation network is used in this territory (east Thessaly plain), which indicates a deep groundwater table.
Moreover, the soil properties and the contained elements of the experimental field are shown in Table 1, 2.

Table 1.Soil properties/elements.

Properties / Elements	Soildepth
	0-30 cm
Texture	Sandy Clay Loam
pH, extract (1:5)	7.26 ± 0.05
EC, extract (1:5), dS m^{-1}	0.20 ± 0.01
*CEC (cmol kg^{-1})	19.3 ± 0.80
$CaCO_3$ (%)	2.42 ± 0.14
Organic matter(%)	1.44 ± 0.07
Cu- DTPA (mg kg^{-1})	0.93 ± 0.11
Zn- DTPA (mg kg^{-1})	0.70 ± 0.04
Fe- DTPA (mg kg^{-1})	0.37 ± 0.17
Mn- DTPA (mg kg^{-1})	4.92 ± 0.80
Cd- total (mg kg^{-1})	< 0.01
Pb- total (mg kg^{-1})	< 0.1

Data represent average means and SE deviation. n= (4).

Table 2. Soil elements at soil depth 0-30 cm.

Treatments	Cu	Zn	Mn	Na	P	K	Mg	Fe
	(mg/kg soil)					(g/kg soil)		
	25.6	514.3	1391	447	347.4	9.09	14.71	44.17

Plant height

At the harvest period the average plant height was 3.67 m. The final plant height was significantly affected by irrigation input (Table 2). This height was higher than the reported 2.4 m (Cosentino et al., 2013; Campiglia et al., 2017) and the reported height measured in Italy (Tang et al., 2016) and in agreement with the measured height in Czech Republic (Tang et al., 2016).

Yield and Fiber yield

Hemp management depends primarily on soil and climatic conditions of the region, which determine the genotype and variety choice (Tang et al., 2016).
Average dry biomass was higher for the irrigated treatment without significant differences (Table 3). The average harvested yield was 13.3 t ha^{-1}. The above dry yield is separated to 2.23 t ha^{-1} dry leaves and 11.07 t ha^{-1} dry stems. Table 3 shows a significant difference for the interactions of the three factors (plant density, irrigation and fertilization) for dry yield of leaves and stems. Furthermore, the produced stem yield is higher with reported stem yield in Italy and France (Tang et al., 2016) and in agreement with the results in Czech Republic and Latvia (Tang et al., 2016). According to the Table 3 the average dry fiber yield was 4.15 t ha^{-1}. A significant difference was noticed for the interactions of plant density, irrigation and fertilization.
Finally, as it has already been mentioned, the total average dry yield was 13.3 t ha^{-1} where the 17% is the dry yield of the leaves and the 83% the dry yield of the stems. Moreover, the 36-37% of the dry stem yield was the fiber dry yield.

Nutrient concentration in leaves

The data on N-P-K uptake from the leaves per hectare for all treatments are summarized in Table 3.
The average N-concentration in leaves is 3.26%, which is the triple than the N-content in switchgrass leaves [1.2-1.4%; (Giannoulis et al., 2017)] or six times the N-content in rice leaves [0.5%; (Abbeddou et al., 2011)]. Therefore, protein content of hemp leaves is 20.3%, while the average nitrogen removal from the leaves is 66.05 kg ha^{-1} and there was found a significant difference for the interactions of the three factors (plant density, irrigation and fertilization; Table 3).
The average P and K concentration in leaves is 0.35% and 1.89%, respectively. The above values lead to an average phosphorus and potassium removal up to 6.83 and 38.1 kg ha^{-1}, respectively. In case of P and K there was found a significant difference for the interactions of the three factors (plant density, irrigation and fertilization; Table 3).

Table 3. Hemp yield and leaves N-P-K content (%) as affected by 2 plant densities (P1, P2), 2 irrigation (I1, I2) and 2 N-fertilization levels (N1, N2).

Conclusions

Hemp dry yield may reach the 13.3 t ha^{-1} under Mediterranean environmental conditions where the 17% is the dry yield of the leaves and the 83% the dry yield of the stems. Moreover, the 36-37% of the dry stem yield was the fiber dry yield. The fiber yield can overcome the 4 t ha^{-1}, which is an acceptable yield.

The N-P-K content in leaves is variable among interactions of the three factors (plant density, irrigation and fertilization). The average N-concentration in leaves is 3.26%, while P-content is lower 0.35% and the K-content 1.89%.

Hemp removes from soil (from its leaves) 66.05, 6.83 and 38.1 kg ha^{-1} nitrogen, phosphorus and potassium, respectively.

As an overall conclusion, *Cannabis sativa* subsp. *sativa* (cv. Fibranova) is a very promising annual crop for fiber production in Greece and similar Mediterranean environments, characterized by high yields, and its introduction in land use systems should be seriously taken into consideration.

Abstract

The most crucial stage in the life cycle of cultivation is the seed germination as it significantly determines the evolution of the crop. Temperature is one of the most important factors affecting the vegetation. Therefore, a laboratory experiment was conducted to determine the vegetation rate of different varieties of three winter legumes (*Lupinus albus* L. vs Multitalia and Ultra, *Pisum arvense* vs. Arvica and Olympus, *Vicia faba* vs. Tanagra, Favino, Solon and Scuro di Torre Lama), 3 varieties of spring cereals (*Sorghum bicolor* vs EJ 7282, Skyscraper, Grain sorghum – Pacific Graze), and 2 varieties of a perennial cereal (Switchgrass – *Panicumvirgatum* vs. EC 1101 and EC 1102) at 9 different temperatures (24, 20, 16, 12, 10, 8, 6, 4, and 2^{o}C) in a constant parameter chamber (temperature). For each variety, 100 seeds were placed in 2,4 or 5 separate petri dishes depending on the size of the seed. Observations were taken each day for high temperatures and every second day for low temperatures. The hierarchy of the vegetation rate of the studied species was as follows: *Sorghum bicolor* EJ 7282 >*Sorghum skyscraper* >*Grain Sorghum*, *Panicum virgatum*: EC 1101 > EC 1102, *Lupinus albus*: Ultra > Multitalia, *Pisum arvense*: Arvica > Olympus and *Vicia faba*: Scuro di Torre Lama > Solon > Favino > Tanagra. The higher temperatures for the studied seed caused the germination in a shorter period, and as the temperature dropped, it took more days to reach the total vegetation rate. Finally, the speed of day-to-day germination between varieties and species was different.

Keywords: *germination rate, winter legumes, spring cereals, temperature.*

Introduction

Cereals are of enormous economic importance, while *Sorghum* and switchgrass occupy the 5thand 6th position, respectively, in the global production (FAOSTAT Database). *Sorghum* in Europe is mainly grown for its grain and as animal feed in Italy and France (FAOSTAT 2006). In some regions of Africa, it has been found that switchgrass can cover 90% of energy in nutrition. Switchgrass, as a feed, has similar properties to oats and barley (Giannoulis *et a*l., 2013).

On the other hand, legumes are in the second place, in terms of their importance. They are crops of low input requirements and are suitable to sustainable agriculture schemes. Legumes are grown for human and animal nutrition, and as green fertilization. Lupine contains the 2nd highest protein content (33-46%) in the seeds compared to the rest of the legumes, while beans (22-35%) and pea (16-32%) are following.

Successful crop establishment depends on seed quality, environmental factors and genotypes. Literature confirmed that there are differences in the response of the seeds and seedlings to different temperatures in association with their geographic origin.

The interest of Europe and the need to produce animal feed of high protein content and lower cost has increased and farmers are growing such crops over larger areas. Seedling establishment is a crucial stage in crop production and influences yield variations. Literature states that there is a major change in the past 20 years, where legume production has been to

adapt to earlier sowing dates in case to shift successful crop establishment and have plants of higher frost tolerance during winter (Bourion et al., 2003; Vocanson and Jeuffroy, 2008).
Ecological factors and seed characteristics are effective in crop growing in order to obtain a desirable yield and quality. Temperature is one of the most crucial factors that affect plant growth rate, development and the most critical stage in crop life cycle which is seed germination (Walck et al., 2011). Furthermore, germination rate is really important in crop life cycle and can differ according to species, soil structures, sowing methods, soil moisture ratios etc.
Different temperature ranges are needed for the different types of seeds to germinate. Maximum germination can be achieved in minimum time when the ideal temperature prevails. The effect of temperature can be modelled by thermal time and predict seed germination progress and to provide "a measure of physiological time" and yield coefficients (Bradford 2002). The purpose of this study was to quantify the germination temperatures of 8 varieties of winter legumes and 5 varieties of spring cereals.

Material &Methods

This research was carried out in the laboratory of Agronomy and Applied Crop physiology in the University of Thessaly, Greece. The study was performed in a growth chamber adjusted to 9 different temperatures (24, 20, 16, 12, 10, 8, 6, 4, 2) for 8 varieties of winter legumes (*Lupinus albus* L.–vs Multitalia and Ultra, *Pisum arvense*–vs. Arvica and Olympus, *Vicia faba*–vs Tanagra, Favino, Solon and Scuro di Torre Lama), 3 varieties of spring cereals (*Sorghum bicolor* vs EJ 7282, *Skyscraper*, *Grain sorghum – Pacific Graze*), and 2 varieties of a perennial cereal (Switchgrass – *Panicumvirgatum* vs. EC 1101 and EC 1102). Each treatment was repeated four timesfor each temperature value. For each temperature treatment, 100 seeds were placed indifferent separate petri dishes with sheets of Watman No. 1 filter paper. The trial was commenced as soon as the seed was exposed to the moist filter paper. The measurements were taken every day for the high temperatures and every second day for the low temperatures. When a 1mm of radical was visible (Gimeno-Gilles et al., 2009), the seed was thought to have germinated. The number of germinants was measured at frequent and regular intervals by the rate of germination. The maximum germination percentage for each temperature treatment was calculated as the average of the replicates.

Results and Discussion

As it is illustrated in Figure 1, comparing the two varieties of *Lupinus albus*, Ultra had higher growth rates than Multitalia. Regarding Ultra variety, in almost every tested temperature, germination was completed on the third or fourth day. As it was expected, germination rates were higher at the increased temperatures (24, 20, and 16^{o}C), while by decreasing the temperature, also the germination rate was reduced. On the other hand, Multitalia needed seven to eight days to reach the rates of Ultra variety (except the 24 ^{o}C. At low temperatures, germination could not exceed even the 50%.

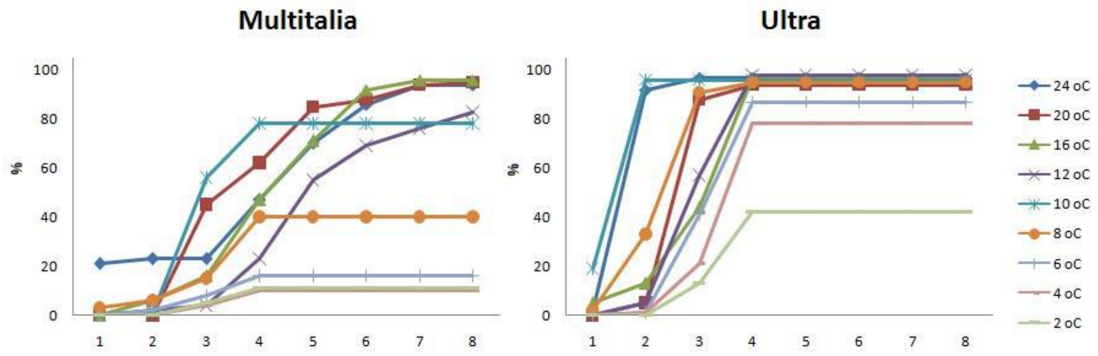

Figure 1. Seed germination percentage of *Lupinus albus* (Multitalia and Ultra) for the different tested temperature.

In case of the two tested varieties of pea (Arvica and Olympus; Figure 2), the germination rates were similar and the same number of days to reach the final germination were needed. At 24 ^{o}C, the germination rate reached 50% for both varieties from the first day.At lower temperatures, this rate was succeeded on the second or third day, while at the very low temperatures the number of days increased. Only in case of 2 ^{o}C only the 50% of the seeds germinated, classifyingthe crop more resistant to low temperatures compared to lupine.

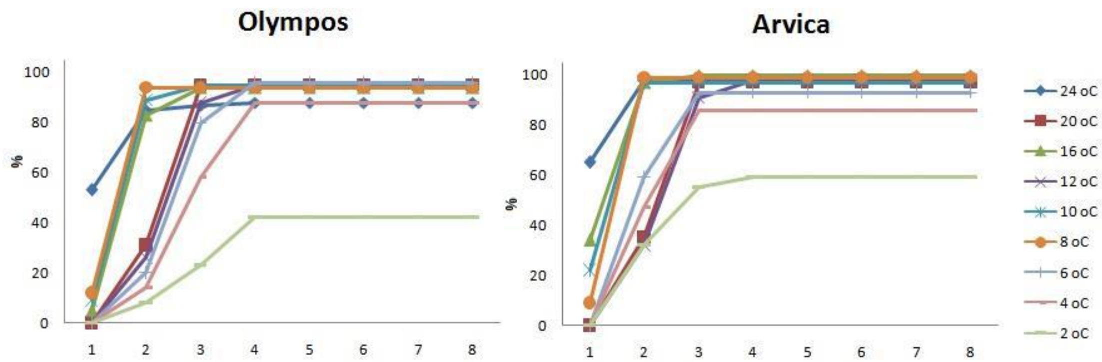

Figure 2. Seed germination percentage of *Pisum arvense* (Olympos and Arvica) for the different tested temperatures.

Figure 3 shows the germination of the four *Vicia faba* varieties. Scuro di Torre Lamahas has the greatest germination capacity, second comes Solon, third Favino and Tanagra is the last one. Scuro di Torre Lama was the only one that managed to reach almost the 100% at almost all temperatures. At the higher temperatures (24 and 20 ^{o}C) seeds germinated from the first day while as the temperature decreased during the first few days there were not germinated seeds.

Solon germination rates for the higher temperatures reached the 85%, while at lower temperatures it was less than 55%. In case of Favino, the percentage of germination was less than that recorded in the previous variety, with the only exception of 16 ° C where all seeds germinated. Finally, Tanagravariety was the variety with the worst germination rates.

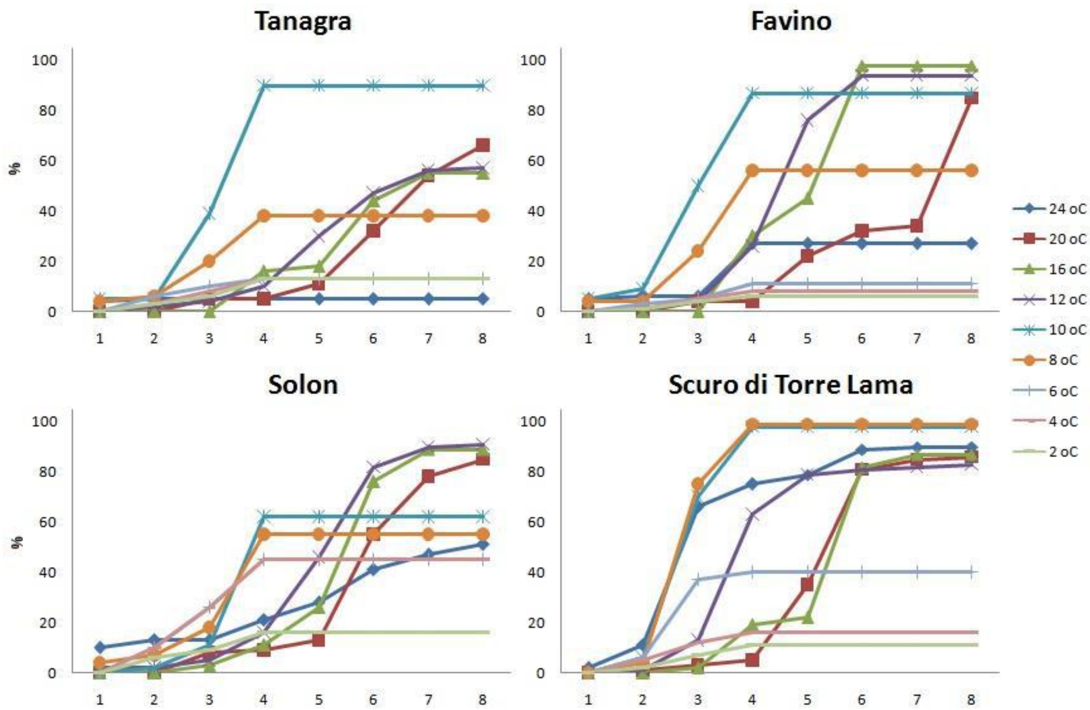

Figure 3. Seed germination percentage of *Vicia faba* (Tanagra, Favino, Solon and Scuro di Torre Lama) for the different tested temperature.

In case of the five studied varieties of spring cereals, three were *Sorghum* varieties (*Sorghum bicolor* EJ 7282, *Sorghum* skyscraper, Grain sorghum) and the other two were *Panicum virgatum* varieties (EC 1101 and EC 1102), which is a perennial crop.
In the case of *Sorghum*, Grain sorghum showed the lowest germination rate compared to the other two varieties which had similar rates. This varietyhad lower germinated seeds but the most important was the delay in reaching the final germination rate regardless of temperature. Sorghum bicolor EJ 7282 variety had the highest rate of vegetation than the other two varieties. At 24 °C and 20 °C, for both varieties (Sorghum bicolor EJ 7282, Sorghum skyscraper) took seven to eight days to reach the final rate.

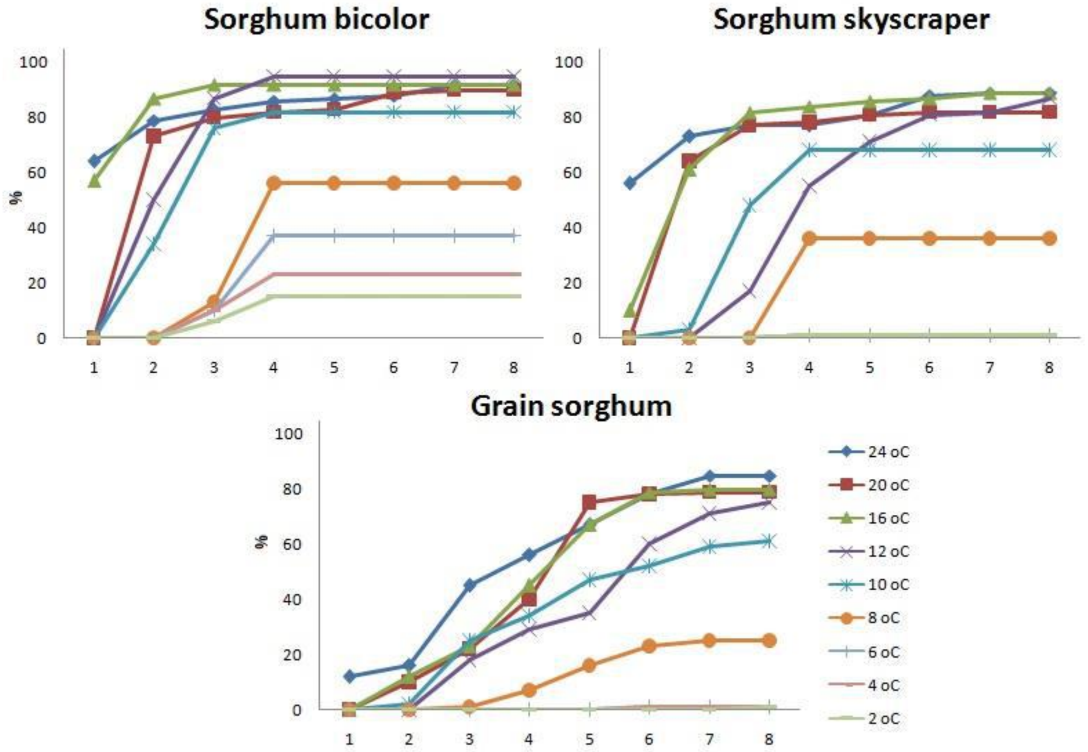

Figure 4.Seed germination percentage of *Sorghum bicolor* (*Sorghum bicolor* EJ 7282, *Sorghum skyscraper*, *Grain sorghum*) for the different tested temperature.

Switchgrass (*Panicum virgatum* L.) for both varieties shown that temperature below 10 ^{o}C is a limiting germination factor. At 12 ^{o}C the germination rate reached the 20% for both tested varieties. Temperatures higher than 16 ^{o}C seem to be the best for in case to reach up to 80-90% germination rates. Of course, between these two varieties a higher rate of vegetation from day to day had Switchgrass EC 1101 (Figure 5).

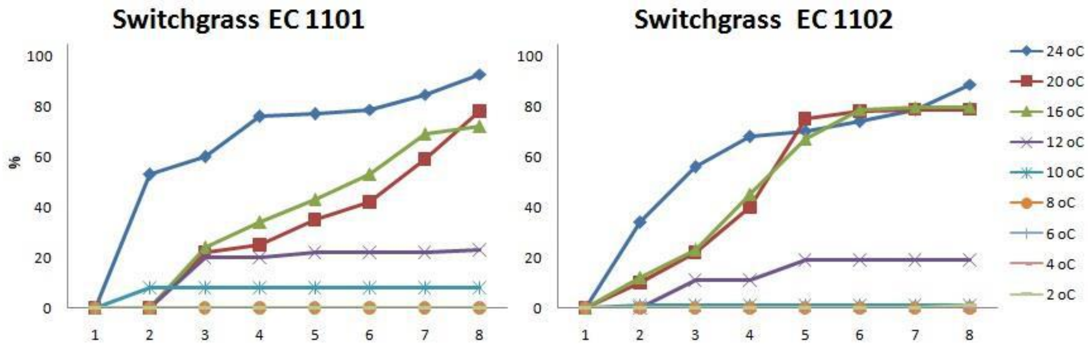

Figure 5. Seed germination percentage of switchgrass (EC 1101 and EC 1102) for the different tested temperature.

Conclusions

Almost in all varieties of the different species that were studied, it was observed that at high temperatures the vegetation rate was higher and as the temperature decreased the seeds needed more days to germinate. In each species there were variations in the rate of germination, some varieties displayed a faster rate than others.

Firstly, from the spring cereals, the germination capacity of sorghum varieties was Sorghum bicolor EJ 7282 > Sorghum skyscraper> Grain Sorghum while *Panicum virgatum* varieties were EC 1101> EC 1102.

In terms of winter legumes, the germination rate of lupine, pea and field beans varieties was as follows: Ultra > Multitalia, Arvica > Olympus and Scuro di Torre Lama > Solon > Favino > Tanagra. In the above mentioned varieties, the speed of day-to-day germination between varieties and species was different.
In few species the low temperature was restricted for their germination and should be taken in consideration.
As a general conclusion is that *Vicia faba* may satisfactorily germinate in rather cool micro-environments, and their sowing in the fall may be postponed for some weeks without substantial germination risk comparing to the rest legume species, while switchgrass is forbidden to be sowed if temperature is lower than 12 ^{o}C.

Abstract

Stand density plays an important role in sunflower productivity. It is one of the basic yield components, which depends on the characteristics of hybrids and agroecological conditions of the growing region. This study investigated the influence of stand density on seed yield of six sunflower (*Helianthus annuus* L.) hybrids, created in the Institute of field and vegetable crops, Novi Sad, Serbia. In each of two years, six sunflower hybrids (NS Kruna, NS Horizont, NS Ronin, NS Romeo, NS Dukat, Sumo 1 PR) were sown in six stand densities (from 30000 to 80000 plants/ha with the increasing step of 10000). The trial was arranged as a randomized complete block design (RCBD) with three replications. Analysis of variance (ANOVA) showed that the main effects year (Y), hybrid (H), stand density (SD) and year × hybrid interaction were highly significant for seed yield. Seed yield was predominantly influenced by the hybrid (48.52%). Year contributed to this trait with 22.77% and stand density with 5.03%. Only interaction Y × H for seed yield was significant, indicating that six hybrids responded differently to varying production years. Seed yield was significantly higher in 2018 (3.86 t/ha) in relation to 2017 (3.46 t/ha).The significantly highest seed yield was stated in NS Ronin (4.01 t/ha) and NS Kruna (3.91) on the basis of average for all densities. Regarding stand density, seed yield ranged from 3.50 (SD1) to 3.76 t/ha (SD4). In average for two years the highest seed yield was achieved at 60000 plants/ha (SD4). This study showed that stand density had a significant effect on seed yield in sunflower hybrids.The results may be helpful in recommending optimal sunflower stand density in this region.

Keywords: *Main effects, Interaction, Seed yield, Stand density, Sunflower.*

Introduction

One of the most widely cultivated oil crops in the world is a sunflower, with a harvested area of about 26.5 million hectares in which 48 million tons of seeds are produced on average (FAOSTAT, 2017). In Serbia, sunflower is the most important crop for the production of edible oil. In our country, the surface under sunflower varies depending on the year and range between 150000 and 230000 hectares.

Stand density is one of the significant production factor contributing to the final yield of crops including also sunflower. It is very important to determine the optimum stand density in order to get a high seed yield. Stand density and genotype have significant effects on seed yield and oil yield, as stated by Alam et al. (2003), Ali et al. (2012), Eco et al. (2017). The extreme weather conditions could increase the risk of sunflower production. As Szabó (2011) concluded in order to reduce the unfavourable weather effects as much as possible, the agrotechnical factors need to be optimized. Selection of hybrids, the proper sowing technology (sowing date, stand density), optimized and rational crop protection are of special importance (Szabó, 2012).

The purpose of this study was to examine the response of sunflower hybrids to different levels of stand density on the seed yield during two vegetation seasons.

Material and methods

Field experiments were conducted in the 2017 and 2018 seasons to determine the response of sunflower (*Helianthus annuus* L.) hybrids to different stand densities on seed yield at the experimental field of the Institute of field and vegetable crops, Novi Sad, Serbia. In each of the 2 seasons six sunflower hybrids (NS Kruna, NS Horizont, NS Ronin, NS Romeo, NS Dukat, Sumo 1PR) were sown in six stand densities: 30000 plants/ha (SD1), 40000 plants/ha (SD2),50000 (SD3), 60000 (SD4), 70000 (SD5), 80000 (SD6). The experiments were arranged in a randomized complete block design (RCBD) with three replications. Seed yield (t/ha) was measured after the harvest. Data were analyzed using three-way analysis of variance (ANOVA), in the STATISTICA 12.0 package computer program (*StatSoft*).Least significance difference (LSD) test at $P \leq 0.05$ was used to compare the differences among treatments means.

Results and discussion

Seed yield is a quantitative trait, which expression is the result of the genotype, environment and the interaction between the genotype and the environment. On the basis of ANOVA, it can be seen that all main effects (year, hybrid, stand density) for seed yield in sunflower hybrids were highly significant. Seed yield was predominantly influenced by the hybrid (48.52%). This is in agreement with the results communicated by Mrđa et al. (2012), that on average the seed yield of the studied hybrids was affected most by the genotype. Year contributed to this trait with 22.77% and stand density with 5.03% in our investigation. Popa et al. (2017) also reported high significance for the main effects for seed yield. The year showed the highest influence on seed yield, then the hybrid.

Table 1. ANOVA for seed yield in sunflower hybrids (2017 and 2018)

Source of variation	df	SS (%)	MS	*P*
Year (Y)	1	22.77	8.37	0.000**
(H)	5	48.52	3.57	0.000**
Stand density (SD)	5	5.03	0.37	0.013**
Y × H	5	8.45	0.62	0.000**
Y × SD	5	0.61	0.05	0.866
H × SD	25	7.31	0.11	0.644
Y × H × SD	25	7.31	0.11	0.644
Error	142		0.12	

$^{*}P < 0.05$; $^{**}P < 0.01$

Concerning interactions only Y × H for seed yield was significant, indicating that six hybrids responded differently to varying production years. The non-significant H × SD for seed yield showed that hybrids reacted similarly to stand density (Table 1). On the contrary Ali et al. (2012), Balalic et al. (2016) reported significant interaction between hybrid × stand density.

0.01	0.29	0.29	0.71	0.31	0.31	0.77

Seed yield was significantly higher in 2018 (3.86 t/ha) in relation to 2017 (3.46 t/ha). Comparing the mean values for six investigated hybrids in the two years experiment it can be seen that between them highly significant differences were stated. Seed yield varied from 3.22 t/ha (NS Dukat) to 4.01 t/ha (NS Ronin). Significantly highest seed yield was stated in NS Ronin and NS Kruna. In the second year of the experiment hybrid NS Ronin had also the highest mean value for seed yield (4.30 t/ha). Hybrid NS Horizont gave the lowest seed yield on average for two years (Table 2).

Regarding stand density, seed yield ranged from 3.50 (SD1) to 3.76 t/ha (SD4). In average for two years the highest seed yield was achieved at 60000 plants/ha (SD4). The results were similar when analyzing the results for each year separately (Table 2). At the optimum rate of plant density crop plants can acquire the optimum rate of light for the process of photosynthesis, at a high plant density the plant species will be more competitive to receive

light and their efficiency for growth and yield production may decrease (Soleymani, 2017). Optimal stand density according to seed yield was nearly 60.000 plants per hectare reported also Crnobarac et al. (2007). Crnobarac et al. (2006) reported that in the average for all investigated hybrids in 2005, seed yield increased to its highest density 60000 and 70000 plants/ha, which was significantly higher than in the case of lower density, while in 2004 only the lowest and highest density gave significantly lowest seed yield. Seed yield (3.6 t/ha) was highest at 75000 plants/ha in the experiment carried out by Ibrahim (2012) with five sunflower hybrids (Malabar, Romson 32, Horizon, Recordand, Galla) and four stand densities (45000, 60000, 75000 and 90000 plants/ha, respectively). Rasool et al. (2015) commented that plant density had a significant influence on seed yield. The maximum value of seed yield (2889 kg/ha) was observed in plots where plant density was 8.33 plants/m^2 and the minimum value of seed yield (2526 kg/ha) of 5.56 plants/m^2. Salehi and Bahrani (2000) reported that increasing plant population of sunflower increased oil and seed yield and reached the maximum at a plant population of 6.67 plants/m^2 with 25 cm plant spacing. Seed yield was increased up to a plant population of 85000 plants/ha while higher stand density led to decrease in production, stated some authors (Mojiri and Arzani, 2003, Ravichandran and Srinivasan, 2017). Lower values of optimum stand density (40000 plants/ha) were reported by Szabó and Pepó (2005). The differences in the results of optimum stand density depended on the material used in the experiments, so as on environment and the interaction between them.
The variability of seed yield was 10.41%. Similar variability (V=9.60%) was stated by Balalić et al. (2018), analyzing 10 hybrids, grown in 15 locations in Serbia. Balalić et al. (2019) have gotten higher variability for seed yield (V=20.21%) in the experiment carried out with 3 hybrids and 8 sowing dates, during two vegetation seasons.

Conclusions

The present investigation revealed that all main effects (year, hybrid, stand density) had significant effects on seed yield in sunflower. Seed yield was predominantly influenced by the hybrid (48.52%). Year contributed to this trait with 22.77% and stand density with 5.03%. Only interaction Y × H for seed yield was significant, indicating that six hybrids responded differently to varying production years. The analysis of variance revealed the significant differences among the hybrids for seed yield indicating the presence of sufficient variability among the genotypes for this trait. In average for two years the highest seed yield was achieved at the stand density of 60000 plants/ha (SD4). The results were similar when analyzing the results for each year separately. The results of this investigation showed the significance of stand density on seed yield in sunflower hybrids.

Abstract

Green onion has high nutritional values reflected in the high content of vitamin C and other bioactive substances, primarily essential oil with high antioxidant properties. This essential oil has a high phytochemical effect and is considered as one of powerful plant antibiotics. Due to its specific chemical composition, spring onion takes a special place in the diet of people, most specifically in the early spring when offer of fresh vegetables is limited. The aim of this research was to determine how production method, ie. adequately applied general and special agrotechnical measures influence the yield and the quality of green onion. The influence of various soil mulching materials (control variant, agro-textile, straw, combination of straw and agro-textile) and fertilizers (control plot without fertilization, NPK (N_{120},P_{100},K_{120}),NPK(N_{120},P_{100},K_{120}) + 30g phytofert 20:20:20/100m²/day, NPK (N_{120}, P_{100}, K_{120}) + 40g phytofert 4:10:40/100m²/day) were tested.

The results indicated that the joint effects of mulch and fertilization were exerted through a positive effect on the yield of green onion. The use of agro-textile showed a statistically higher yield in plants fertilized with NPK + 40g phytofert (1,45 kg/m^2) compared to the control variant (1,06 kg/m^2). In addition, the use of straw contributed to statistically much higher yield in fertilized plants with NPK + 30g phytofert (1,53 kg/m^2) compared to the control variant (1,17 kg/m^2). Applied variants of mulch material had a positive influence on the content of vitamin C. The highest content of vitamin C was found in variants with straw mulching (13,41mg/100 g).The increased quantities of fertilizers did not positively affect the qualitative characteristics of green onion.

Keywords: green onion, production method, yield, quality.

Introduction

Onion is produced on around 3,7 million hectares in the world with an average yield of about 17 t / ha. The three largest producers of this vegetable are China (22,3 million tons), India (19,3 million tons) and the United States (3,2 million tons) with a total production of about 45 million tons, or about half of the world's total production. In the European Union, about 190692 ha (40 t / ha) are cultivated, the highest in the Netherlands is 32723 ha (44,29 t / ha), Spain 23174 (54,14 t / ha) and Germany 11294 (46,27 t / ha). http://www.faostat.fao.org

In Bosnia and Herzegovina production is usually carried out on smaller areas, where very low yields of 9.13 t / ha are realized. In the structure of production, onions represent about 13% and onion is ranked as the fourth product by the volume and significance of vegetable production in B&H. The realized production of the onions in 2016 amounted to 45 thousand tons and it is 19% higher than in the previous year (Statistics Agency of B&H, 2016). A large number of products based on the onion basis has found its application in ready to eat food products. In addition to being used in nutrition, it is part of many medicines and cosmetics (Kumar et al., 2010).

For the domestic market, continuous production of onion with sowing or planting from September to the first days of April. From the adequate application of general (plowing,

fertilization, inter-row cultivation, irrigation ...) and special agro-technical measures (mulching, covering of plants with agro-textile) depends largely yield of green onions.
The aim of this research was to determine how production method, ie. from adequately applied general and special agrotechnical measures influence the yield and quality of green onion.

Matherial and methods

The experiment was carried out in the first decade of March 2014. Two-factorial trial (mulching, fertilization) was arranged on a random block system in a greenhouse without heating. The influence of various soil mulching materials (control variant, agro-textile, straw, combination of straw and agro-textile) and fertilizers (control plot without fertilization, NPK (N120; P100; K120); NPK (N120; P100; K120) + 30g phytofert 20:20:20/100m²/day, NPK (N120; P100; K120) + 40g phytofert 4:10:40/100m²/day) was tested. A variety StuttgarterRiesen was used for trial.The size of the experiment plot was $1,5m^2$.
The basic properties of the soil on which the experiment was placed were 7.13 pH (in KCl); 2.81% CaCO3; 3.66% humus; 3.27 mg 100g-1 Al-P2O5 and 15.17 mg 100g-1 Al-K2O.
The content of vitamin C was determined by the titration method.
The obtained results were analyzed by the method of analyzing the variance (ANOVA) using SPSS 4.5 software. The significance of differences in individual environments was tested with LSD test.

Results and Discussion

Young green onions are harvest in the phase of 6-8 leaves and 40 cm high of the stem.According to Lazić et al., (2001), the yield of green onions depends on the harvest time and ranges from 0.5 to 15 kg/m^2, depending on whether the green onion or bulb is harvested. The average yield of green onions in our research was 1,93 kg / experiment plot, or 1,28 kg / m^2 (Table 1).

Table 1. The yield of the green onion on the experiment plot($kg/1,5m^2$)

Mulching	Fertilization				Average C
	F_1	F_2	F_3	F_4	
C_0	2,11	1,65	1,87	1,93	1,89
C_1	1,60	1,72	1,92	2,17	1,90
C_2	1,76	1,91	2,29	2,09	2,01
C_3	1,87	2,32	1,96	1,87	2,01
Average F	1,83	1,90	2,01	2,01	1,93
LSD	A	B	AxB		
0,05	0,171	0,171	0,342		
0,01	0,231	0,231	0,462		

F-fertilization (F_1- control, F_2- $N_{120}P_{100}K_{120}$, F_3- $N_{120}P_{100}K_{120}$+30gphytofert 20:20:20/ 100m² /day, F_4- $N_{120}P_{100}K_{120}$+40g phytofert 4:10:40/ 100m² /day); C-covering land (C_0-control, C_1- agrotextile,C_2-straw,C_3 straw+ agrotextile)

The results of the variance analysis showed that the investigated factors (mulching, fertilization) did not have a statistically significant effect on the average yield of the onion. However, if we look at the joint effects of the two factors (mulching, fertilization), it is noted that on the second variant of mulching the difference in the average yield of the fourth variant of fertilization b_4 ($2.17kg/1,5m^2$) was statistically significant compared to the first b_1 ($1.6/1,5m^2$).
Also, the interaction effect of the variant of straw mulching showed a statistically significant difference in the third variant of fertilization ($2.29kg/1,5m^2$) compared to the first ($1.76kg/1,5m^2$).

Similar results show Lazić at all., (1968). They conclude that the onion is well responding to the increase in the total quantity of fertilizers, in particular the higher the presence of potassium and nitrogen, if produced from the onion set.

Content of vitamin C

The daily requirement of vitamin C per person is 30 to 75 mg which means that the daily needs of the organism for this vitamin can be easily satisfied with the daily use of fresh vegetables in the diet (Nikolić,1980). Vitamin C (L-ascorbic acid) has a strong antioxidant and antibacterial effect, affects the functioning of the immune system and enhances resistance to infectious diseases.

It works on stress and has an anticancer role in the body (Ilin, 1999).

The nutritional values of the leaves of the onion are even greater than those contained in the bulb. About 8,5 g of vitamin C is contained in a kilogram of onion, and in green leaves about 38 g.

Within the mulching factor (Table2), the highest content of vitamin C was obtained on a variant with straw (13,41 mg/100g), and the smallest in the variant of combination straw+ agrotextile (11,45mg/100g).

If we observe the fertilization factor, we will see that the highest content of vitamin C was recorded on the control variant (14,92mg/100g), and the smallest in the variant with NPK + 40g phytofert(10,44 mg/100g). The results of Šifrina (1955) also show that fertilization of onion affects the decrease in the content of vitamin C, unlike Lazić (1968), which in its studies indicates the increased content of vitamin C in bulbs, using the combination of fertilizers $N_{120}P_{50}K_{160}$ and $N_{120}P_{25}K_{60}$.According to the same author (Lazić,1968) combination of $N_{120}P_{50}K_{160}$ fertilization increase the yield by 47% and the combination of $N_{120}P_{25}K_{60}$ fertilization increase yield by 21% compared to the control.

Table 2.Content of vitamin C in green onion (mg/100g)

Mulching	Fertilization				Average C
	F_1	F_2	F_3	F_4	
C_0	13,69	15,31	12,56	8,13	12,42
C_1	16,22	15,76	16,28	7,75	14,00
C_2	16,17	10,86	10,98	15,63	13,41
C_3	13,61	13,64	8,32	10,25	11,45
Average F	14,92	13,89	12,04	10,44	12,82

F-fertilization (F_1- control, F_2- $N_{120}P_{100}K_{120}$, F_3- $N_{120}P_{100}K_{120}$+30g phytofert 20:20:20/ 100m² /day, F_4- $N_{120}P_{100}K_{120}$+40g phytofert 4:10:40/ 100m² /day); C-covering land (C_0-control, C_1- agrotextile,C_2-straw,C_3 straw+ agrotextile)

Vitamin C is directly dependent on fertilization and mulching of the soil.On average, the highest content showed agrotextile variance (14,00 mg/100g), while the variantstraw+agrotextile had significantly lower content of vitamin C (11,45 mg/ 100g). The results of the research are in parallel with Govedarica-Lučić (2012) which shown that the content of vitamin C in the salads depend of mulching.

According to the same author, the greatest content of vitamin C was shown by the combination of mulching + agrotextile (26,77 mg/100 g), while the control variant had significantly lower content of vitamin C(21,10mg/100g).

Conclusion

Based on the results of the study about the impact of agrotechnical measures on yield and vitamin C content in the green onion, the following can be concluded:

•The achieved average yield during the survey was at a satisfactory level. The lowest yield was determined on the agro-textile in the control variant of fertilization (1,06 kg/m^2), and the highest yield was recorded in the variant straw+agrotextile of fertilization with NPK (1,54 kg/m^2).
• The joint impact of mulch and fertilizers is manifested through a positive impact on the yield of the onion. The use of agro-textile showed a statistically higher yield in variant with fertilizer NPK + 40 g phitofert (1,45 kg/m^2) compared to the control variant (1,06 kg/m^2).
•By using straw and fertilization statistically higher yield was obtained in variant NPK + 30 g phytofert (1,53 kg/m^2) compared to the control variant (1,17 kg/m^2).
•The content of vitamin C depended on the covering material. The highest content of vitamin C was obtained on agrotextilevariant (14,00 mg/100g), and the smallest on variant with straw + agrotextile (11,45 mg/100g).
• The increased quantities of fertilizers did not positively affect the vitamin C content.

Abstract

The aim of this study was to determine the most tolerant winter wheat varieties against osmotic stress at germination stage and early seedlings growth. The osmotic stress was simulated in controlled environmental conditions by adding different concentrations of mannitol solution to the growing media of five winter wheat variety. In all studied varieties the benchmark water potential in which they had germinated and had a good seedlings growth was of -0.3 MPa. Under the stronger stress, -0.6 MPa, all varieties showed reduction in all examined parameters. The variety Bosanka had the highest final germination and germination energy under mannitol. The parameters defining the development or percentage of strong seeds, coleoptile and root length, fresh and dry weight of root and coleoptile of a seed were more affected by water deficit stress than germination and germination energy. Biplot analysis showed that wheat cultivars grown under -0.6 MPa osmotic had higher values of root/coleoptile ratio in relation to control and -0.3 MPa treatment which was the most reliable for screening properties of the genotypes for drought resistance in seedling stage.

Key words: *Winter wheat (Triticum aestivum L.), tolerance, mannitol, biplot analysis.*

Introduction

Drought stress is also a globally widespread and ever growing environmental phenomenon encountered by wheat crop which cause severe reduction in overall crop production (Nezhadahmadi *et al.*, 2013). Under drought stress condition decreasing pattern was experienced in morphologically yield contributing characters like plant height, grains per spike, spikes per plant, thousand grain weight, and reduction in number of fertile tillers per plant, which ultimately caused noticeably low grain productivity in wheat (Kilic and Yagbasanlar, 2010; Joudi, 2017). Generally drought and other stress factors cause the formation of reactive oxygen compound essentially in plants (Reactive Oxygen Species, ROS), which results in biomembranes and macromolecules damage (Sharma *et al.*, 2012). The availability of water and its movement in the seed are important for the process of germination, early growth and elongation of coleoptile and root. Wheat (*Triticum aestivum* L.) is regarded as one of the most important cereal crop, grown in different regions that can be characterized with increased salt level in the soil (Rana *et al.*, 2013). The selection of tolerant wheat genotypes against drought stress at seedling stage is important, especially if the tolerance at the germination stage correlated with tolerance to drought in grain filling period.
The aim of this study was to examine the seed viability of selected winter wheat cultivars in osmotic stress conditions and determine the most tolerant cultivars to osmotic stress at germination stage and early seedlings growth.

Materials and Methods

The experiment

The tests included examination parameters of germination in five different varieties of winter wheat (Jelena, Kristina, Orion, Bosanka and Nova Bosanka) under controlled conditions in the laboratory of the Faculty of Agriculture in East Sarajevo, Bosnia and Herzegovina. Three replicates of 50 uniform, healthy seeds were sterilized in 96 % alcohol for 30 seconds, washed with distilled water several times, and transferred into sterile Petri dishes. A double layered filter paper saturated with solution of a determined concentration mannitol (Table 1) was placed on a dish. Mannitol was dissolved with water potential close to zero (control), -0.3 and -0.6MPa. In each petri dish 15 ml of solution was dispensed. Control petri dishes were filled with distilled water. Alcohol mannitol was used to induce water stress. Petri dishes were incubated for 7 days at 25°C. During this experiment, the following parameters were determined: germination energy, final germination, Vigour Test or percentage of strong seeds, coleoptile and root length, fresh and dry weight of root and coleoptile, and root/coleoptile dry weight ratio. To determine the dry weight of the root and coleoptile seedlings were dried for 24 hours at 80 °C.

Table 1. Amounts of Mannitol in different levels of water deficit

Ψ_O the level of MPa	NaCl (g/l distilled water)
0	0
-0.3	4.20
-0.6	8.40

Data analysis

Data was processed using two-way analysis of variance, with software Infostat 10. Means were compared using Duncan's multiple range test. Principal component analysis (PCA) was used to determine interdependence between the traits.

Results and Discussion

Results from our study showed that increase in osmotic potential had an adverse effect on wheat final germination and germination energy (Table 2). Generally, germination energy was lowest in the presence of the lowest osmotic potential (-0.6MPa). Further, a significant difference among diverse wheat varieties under different treatments was observed. The variety Orion was the most sensitive variety under the lowest osmotic potential (-0.6MPa) and its germination potential compared to control was reduced from 97% to 8%. Results from our study showed a significant effect of mannitol concentration on wheat final germination. By increasing mannitol concentration (decreasing osmotic potential), germination percent decreased almost linearly in the studied wheat cultivars. For example, in the variety Orion with a higher water deficit (-0.6MPa) the percentage of germination decreased by 95% in mannitol stress compared to the control. The cultivar with highest germination percentage at zero potential, -0.3MPa and -0.6 MPa was Bosanka. Therefore, this cultivar could be grown under decreased osmotic conditions. According to Al – Taisan (2010) results like this could be attributed to absence of energy to start a germination process, as energy was obtained by increments in the respiratory pathway after the imbibition and in low levels of water potential tax water absorption was processed slowly.

Table 2. Germination (%), Germination energy (%) of five winter wheat varieties exposed to w ater deficits induced by different concentration of mannitol during germination

Treatment	Germination				Germination energy			
	Mannitol							
	0 MPa	-0.3 MPa	-0.6 MPa	average	0 MPa	-0.3 MPa	-0.6 MPa	average
Bosanka	92.33ab	92.33ab	86.67b	90.44A	90.00a	89.00a	86.33a	88.44A
Jelena	90.00ab	66.33e	70.67de	75.67B	90.00a	64.00def	69.33bcde	74.44B
Kristina	76.67cd	74.67cd	73.00cde	74.78B	75.67b	73.33bc	72.00bcd	73.67B
Nova Bosanka	78.67c	77.00cd	69.67de	75.11B	60.00f	65.67cdef	62.67ef	62.78C
Orion	94.67a	72.67cde	8.00f	58.44C	92.00a	72.67bcd	5.00g	56.56D
Average	86.67A	76.6B	61.6C	74.89	81.53A	72.93B	59.07C	71.17

Different letters indicate significant difference at P < 0.05 level.

Table 3. Vigor (%) of five winter wheat varieties exposed to water deficits induced by different concentration of mannitol during germination

Treatment	Vigor			
	Mannitol			
	0 MPa	-0.3 MPa	-0.6 MPa	average
Bosanka	60.33b	25.00f	0h	28.44C
Jelena	80.33a	28.00ef	0h	36.11A
Kristina	49.67c	43.67d	2.33h	31.89B
Nova Bosanka	25.67f	9.33g	0h	11.67E
Orion	47.67c	30.33e	0h	26.00D
average	52.73A	27.27B	0.47C	26.82

Different letters indicate significant difference at P < 0.05 level.

There was a significant difference in the parameter vigor classification (Table 3) and by decreasing osmotic potential vigor percent declined gradually from 0MPa to -0.3MPa. Generally, most wheat varieties were sensitive to the influence of osmotic potential of -0.6 MPa where their values drastically falls close to zero.

Table 4. Coleoptile length (mm) and root length (mm) of five winter wheat varieties exposed to water deficits induced by different concentration of Mannitol during germination

Treatment	Coleoptile length				Root lenght			
	Mannitol

Different letters indicate significant difference at P < 0.05 level.

Coleoptile and root length (Table 4) in our experiment interfered differently. At zero potential, both coleoptiles and root lengths reached their highest values. The Nova Bosanka variety showed highest coleoptile length at zero potential. On the other hand Nova Bosanka variety was the most sensitive variety under decreased osmotic potential since its coleoptiles length significantly decreased at -0.6 MPa. Similar results were reported by Qayym *et al.* (2911) who investigated the effect of water deficiency on germination in different wheat genotypes, and concluded that the length of the coleoptiles was significantly decreased at a water potential of 0.8 bar.

Table 5. Coleoptile fresh weight (g) and root fresh weight (g) of five winter wheat varieties exposed to water deficits induced by different concentration of mannitol during germination

Fresh weight of coleoptiles and roots (Table 5) were differently affected by water deficits. Alcohol mannitol significantly reduced coleoptile fresh weight across treatments. Moreover, the varieties Bosanka and Nova Bosanka were the most sensitive against the lowest osmotic potential (-0.6 MPa). There was no significant difference in root fresh weight in all wheat varieties between control and -0.3 MPa mannitol treatments. Our results are in agreement with those of Demir *et al*. (2008) and Braga *et al*. (1999) who had examined the effect of polyethylene glycol on the germination of seeds of pepper and beans respectively. Wang et al. (2009) reported that the fresh weight, root length and the above-ground part in the two varieties of alfalfa were significantly inhibited by 35% PEG solution.

Table 6.Coleoptile dry weight (g) and root dry weight (g) of five winter wheat varieties exposed to water deficits induced by different concentration of mannitol during germination

	Coleoptile dry weight				Root dry weight			
Treatment	Mannitol							
	0 MPa	-0.3 MPa	-0.6 MPa	average	0 MPa	-0.3 MPa	-0.6 MPa	average
Bosanka	0.066^{d}	0.040^{h}	0.008^{j}	0.038^{C}	0.012^{g}	0.016^{cd}	0.007^{h}	0.011^{C}
Jelena	0.077^{c}	0.060^{e}	0.033^{i}	0.057^{A}	0.018^{b}	0.014^{ef}	0.017^{c}	0.016^{B}
Kristina	0.083^{b}	0.042^{gh}	0.042^{gh}	0.056^{A}	0.014^{f}	0.024^{a}	0.017^{bc}	0.018^{A}

Different letters indicate significant difference at P < 0.05 level.

The results showed that different mannitol concentration effected significantly the wheat coleoptile and root dry weight (Table 6). Coleoptile dry weight gradually decreased with water deficit increase, while the highest root dry weight was recorded under conditions of -0.3 MPa. The highest average result on shoot dry weight under the conditions of the highest mannitol concentration was observed in the variety Kristina. The variety Bosanka was the more sensitive to water stress and had the lowest shoot dry weight at -0.6 MPa. Root dry weight did not suffer any decrease until -0.6 MPa, and the variety Orion presented lowest result. According to Marur *et al.* (1994), the lack of water slows physiological and biochemical processes of soybean seeds and low water deficit affected poor growth and reduced the accumulation of dry matter.

Table 7. Root / coleoptile ratio of five winter wheat varieties exposed to water deficits induced by different concentration of mannitol during germination

Root /coleoptile ratio				
Treatment	Mannitol			
	0 MPa	-0.3 MPa	-0.6 MPa	average
Bosanka	0.179^{fg}	0.401^{d}	0.898^{a}	0.493^{A}
Jelena	0.231ef	0.236^{e}	0.513^{c}	0.327^{C}
Kristina	0.165^{g}	0.578^{b}	0.403^{d}	0.382^{B}
Nova Bosanka	0.170^{g}	0.230^{ef}	0.587^{b}	0.329^{C}
Orion	0.163^{g}	0.254^{e}	0.269^{e}	0.229^{D}
average	0.182^{C}	0.340^{B}	0.534^{A}	0.352

Different letters indicate significant difference at P < 0.05 level.

Root/coleoptile (RCR) ratio is one of the several ratios which give estimates of the distribution of dry matter between the different plant organs (Hunt 1990). It is a measure of distribution of dry matter between the root and the shoot systems and it is a good indicator for effects on root and shoot dry weights. Under mannitol treatment average of RCR raised from 0.182 (control) to 0.340 (-0.3 MPa) and to 0.534 (-0.6MPa). In relation to the other varieties, the variety Bosanka had the highest RCR under -0.6MPa. High ratio RCR in the germination of winter wheat is a good indicator of resistance to drought (Baalabaki *et al*., 1999).

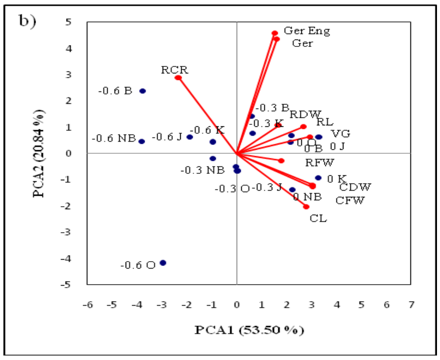

Figure 1. PCA analysis of trait association of winter wheat cultivars (Bosanka – B, Kristina – K, Jelena – J, Nova Bosanka – NB and Orion – O) grown under different levels (0 MPa – O, -0.3 MPa – -0.3 and -0.6 MPa – -0.6) of mannitol

The biplot of the principal component analysis (PCA) illustrates the relationships between the means of the studied traits in wheat cultivars grown under different levels of mannitol (Figure 1). The cultivar × treatment points and traits vector are placed on biplot according to their PCA scores. Biplot revealed similar interrelationship between the studied traits in wheat cultivars at different mannitol levels. Germination (Ger) and germination energy (GerEng) were highly and positive associated as indicated by acute angles. Moreover, root fresh (RFW) and dry weight (RDW) and coleoptile fresh weight (CFW) and dry weight (CDW) were highly associated under the influence of different mannitol levels. There was positive association between root and coleoptile weight (both dry and fresh). Root length was positively associated to GerEng, indicating that early germination improves root growth. An increase in root growth is an indicator of the ability of plants to withstand under water stress, It could be also used to screen plant cultivars for drought tolerance. Biplot showed that wheat cultivars grown under lowest osmotic potential (-0.6MPa) had higher values of root/coleoptiles ratio (RCR) compered to control at -0.3MPa treatment. This result indicates that coleoptile growth is more suppressed than root under condition of low osmotic potential.

Conclusion

Based on the results of this study it can be concluded that there are significant differences between the examined cultivars in their response to drought tolerance. Generally a gradual increase of mannitol treatments was followed by a reduction in all the analyzed parameters in selected cultivars. Highest decrease occurred at increased mannitol treatments (-0.6MPa) and it could be an indication of the tested varieties sensitivity to stressing conditions. In order to enhance plant tolerance to stressing environmental conditions, especially drought stress, studying the reaction of different cultivars in stressing environments is importance in improving the efficiency of breeding and selection. The limit value of water resources when a plant, under the influence of mannitol, can germinate quite well and have a good increase in seedling was at -0.3MPa, i.e. in low stress. Besides the standard techniques and commonly used data analysis, biplot offers additional options, preferably in the portion of a visual representation and understanding important interactions revealed in the present data sets from surveys of seed science research.

SOWING QUALITIES AND YIELDING PROPERTIES OF SUDAN GRASS (*Sorghum sudanense*) DEPENDING ON FRACTIONATION OF SEEDS AND SEEDING RATE

Tatiana KRIUKOVA *, Georgiy SHENTSEV

Voronezh State Agrarian University named after Emperor the Great Peter, Voronezh, Russia
*Corresponding author: selection_kr@mail.ru

Abstract

Currently, fodder production is important in providing livestock feed and has a huge impact on agricultural production in the Russian Federation.
To create a sustainable fodder base for meeting the needs of animal husbandry, an important forage crop is Sudan grass (*Sorghum sudanense*) – which is an annual plant. It has a high drought resistance, good aftermath, it is versatile to it, produces a high yield of forage with good fodder merits. Green crop reaches 35-40 tons per hectare (Shitikova, A.V., 2019).
With proper cropping practices, it produces record yields among fodder annual grasses.
Data on the optimal sowing rate during cultivation for feed and seeds vary from 0.5 to 5 million units per hectare (Shapsovich, S.N., 2013). In this regard, it is necessary to determine the optimal seeding rate for the Central Black Earth region. In addition, the lack of scientifically based recommendations on the preparation of seeds for sowing indicates the relevance of research aimed at improving the elements of agricultural technology of this crop.
When conducting research on Sudan grass Voronezh 24, data were obtained on the dependence of the quantity of the green mass of Sudan grass, on the seeding rate and fractionation of seeds.
In the conditions of the Central Black Earth region, seeds of the Sudanese grass of Voronezh 24 variety must be separated on an aerodynamic separator. For sowing, seeds of large fractions are use. The highest yield of green mass can be obtained by using the seeding rate of 2.5 million pcs / ha.

Keywords: *Sudan grass, annual grasses, seed fractionation, feed production, feeding animals*

Introduction

In modern conditions, fodder production is of decisive importance not only in the provision of animal husbandry with feed, but it also has a huge impact on agricultural production in the Russian Federation as a whole.
In solving the problem of creating a sustainable fodder base for increasing the productivity of animal husbandry, Sudanese grass is the most promising crop. It has not only high drought resistance, but also good aftermath, versatility of use, high yield of forage with good fodder merits.
Sudan grass is a high-yielding agricultural crop, which with proper cropping practices of cultivation, produces a record harvest of forage annual grasses (Muslimov, M.G., 2013).
Sudan grass forms a well-developed root system, extending to a depth of more than 2 meters (Fundamentals of programming crop yields, 2014). The stem is a cylindrical made. Plants are up to three meters high. The lower stem node is the tillering node. Sudanese grass can form up to 25 shoots in a bush. The leaf is wide-linear, up to 60 cm long, smooth, slightly rough along the edge. The leaf of sorghum consists of a vagina and a leaf blade, the length of which sometimes reaches 1 m. The surface of the leaf can be smooth or corrugated. Inflorescence is panicle of various shapes, densities and colors, size 15-70 cm (Private selection of field crops, 2016). Inflorescence is a panicle, about 40 centimeters long. The fruit is a caryopsis, tightly enclosed in spikelet scales. 4-5 grams of seeds are obtained from each panicle (Plant growing, 2015). It is undemanding to soils. It grows poorly in wetlands.

Sudanese grass is cultivated for green fodder, grass meal, hay, silage and haylage. It is included in the rations of cattle, sheep and pigs. It suffers from trampling a little and quickly grows when it is etched. Therefore it is of great importance as a pasture plant, especially for late grazing (Solovjev B.F., 1960).
The feeding value of green mass and hay is higher than other cereal grasses due to its high content of protein, carbohydrates, carotene, sugars and fiber. There is also a large number of macro-and microelements. The beneficial properties of Sudanese grass are also due to the presence of vitamins. The green mass and hay of Sudanese grass contain a lot of sugar, and are well eaten by animals (Kokonov, S.I., 2013).
It is of particular value in the second half of the growing season, as a reliable source of green fodder, and a promising link in the raw materials conveyor.
The objective is to establish the influence of the seeding rate and seed fractionation of Sudanese grass seeds on sowing qualities and yield of green mass.

Material and Methods

The object of the study was variety of Sudanese grass Voronezh 24, zoned by the Central Black Earth Region. The variety was created at the department of breeding and seed production of Voronezh State Agrarian University.
The experiments were carried out on the fields of Voronezh State Agrarian University in 2016-2018. The option without separation of seeds with a seeding rate of 2.5 million units per hectare was taken as the standard. The seeds were divided into five fractions using an aerodynamic separator. The mass of 1000 grains and seed germination were determined by standard methods. Field experiments were carried on plots with an accounting area of 4 square meters in fourfold repetition. Sowing was carried out by the SSFC-1.6 breeding drill with a seeding rate of 2 million pieces per hectare and 2.5 million pieces per hectare. Row spacing was 15 centimeters. Green mass harvesting was performed manually, the yield was taken into account by weighing.
Seeds of Sudanese grass Voronezh 24 were calibrated using the SAD-4 machine for 5 fractions. Clods of soil and other heavy impurities fell into the first fraction, seeds with the highest specific gravity in the 2nd and 3rd, the seeds with the lowest specific gravity in the 4th, and lightweight impurities in the fifth.

Results and Discussion

Sowing qualities (germination energy, field and laboratory germination) were determined from the seeds of the isolated fractions (Table 1).

Table 1 - Sowing qualities of seeds of Sudan grass

Seed fractions	Option	Mass 1000, g	Energy germination,%	Laboratory germination,%	Field germination,%
Control St	St	13,6	75,0	85,7	78
II fraction	1	15,5	84,6	90,0	80
III fraction	2	14,1	82,5	92,2	83
IV fraction	3	11,9	71,3	80,1	68

In the experiment on the determination of germination energy and field germination, the 1st and 2nd variants exceeded the control by more than 9%, and in laboratory germination the best result was noted on variant 2 (laboratory germination is 92.2%).
In general, it can be concluded that the size of the seeds has an effect on germination, but the largest seeds do not have the highest germination rates, which may be due to the fact that

large seeds are more severely injured during harvesting (Kryukova T.I., Goleva G.G. and Borovkova A.N., 2015).
To study the yield properties of seeds of different fractions, field experiment was carried out.
The average seed embedment depth was 4-5 cm, whereas in the condition of late sowing and arid spring, seeds were embedded more deeply. Sowing was carried out at the optimum time when the soil warmed to the temperature required for sowing.
In the field experiment, phenological observations were performed during the entire growing season (Table 2).

Table 2 - The number of days of the onset of development phases in Sudan grass

Seed fractions	The number of days from sowing to the onset of the development phases			
	seedlings	tillering	heading stage	flowering phase
Control St	12	31	36	47
II fraction	10	28	34	43
III fraction	12	31	34	43
IV fraction	13	34	38	50

It was noted that the plants grown from the seeds of the second fraction entered the initial phases of development faster, and the plants grown from the seeds of the third fraction grew slowly at the beginning of the growing season, and entered the heading and flowering phases faster than in the control. This may be due to the fact that these seeds were formed in the middle part of the panicle and were characterized by the highest specific weight, and, consequently, the highest biological value. Smaller seeds entered the flowering phase of the control after 3 days. Caring for crops included pre-emergence harrowing, hand weeding, applying potassium humate and loosening the row spacing.
Harvesting Sudan grass for hay and green fodder starts a few days before the beginning of the cutting phase. Later, the stems grow coarser, the quality of the feed decreases, and the animals eat it worse (Bogatyrev, V. M., 1951).
Before mowing for the green mass, the plants were counted according to productivity elements (Table 3). For this, 30 plants were selected from each plot.

Table 3 - The structure of the yield of green mass of Sudanese grass at different seeding rates, 2016-2018

Seed fraction	Plant height, cm	Stem diameter, cm	Quantity, pcs.		Size of the largest sheet, cm	
			shoots	leaves	length	width
2.0 million pieces per hectare						
Control St	150,0	0,75	6,2	6,2	45,6	3,1
II fraction	161,9	0,90	6,5	6,7	47,6	2,7
III fraction	165,5	0,82	6,5	7,0	58,4	2,9
IV fraction	138,4	0,65	7,0	5,3	43,1	2,7
2.5 million pieces per hectare						
Control St	148,8	0,39	6,0	5,9	49,4	2,5
II fraction	169,2	0,50	5,9	6,1	54,6	2,3
III fraction	164,5	0,48	5,8	6,8	52,9	2,6
IV fraction	132,5	0,35	6,7	5,2	42,0	2,5

It was established that the highest height was observed in plants grown from the seeds of the third fraction of 165.5 cm with a seeding rate of 2.0 million units / ha^{-1}, and 164.5 cm with a seeding rate of 2.5 million units / ha^{-1}. The remaining biometric indicators did not have significant differences depending on the density of standing plants.

The quality of the feed of Sudanese grass largely depends on the diameter of the stem and its foliage. As a rule, the thicker the plant stem, is the rougher the obtained green fodder and hay is.

It was established that the stem diameter depended on both the seeding rate and the size of the seeds. Plants with a reduced seeding rate formed a thicker stem. A direct dependence of the stem diameter on the size of the seeds was observed: the larger the seeds were, the larger the stem diameter was in plants. The thinnest stems were in the control variant and in plants grown from seeds of 4th fraction, and in terms of the number, size of leaves and bushiness, plants grown from seeds of the third fraction were the best. The plants grown from the seeds of the fourth fraction and 2.5 million pieces per hectare, formed stems with a diameter of 0.35 cm. Such tender food is well eaten by animals.

The yield of green mass at a seeding rate of 2.5 million units / ha^{-1} was higher in all variants (Table 4).

Table 4 - Green mass yield of Sudanese grass, 2016-2018

Seed fraction	Option	Green mass yield, kg / ha		
		seeding rate		increase
		2.0 million pcs.	2, 5 million pcs.	
Control St	St	278	308	30
II fraction	1	295	329	34
III fraction	2	325	340	15
IV fraction	3	226	252	27

The highest level of yield of green mass was noted in the second variant, where in the total for two cuttings the yield was 325 centners per hectare with a seeding rate of 2.0 million pcs / ha, 340 with a seeding rate of 2.5 million pcs / ha, which is 47 and 32 centners per hectare higher than in the control, respectively.

Small seeds (option 3) showed low yield properties, where the yield of green mass was only 226 centners per hectare with a seeding rate of 2.0 million pcs / ha, and 252 centners per hectare with a seeding rate of 2.5 million pcs / ha.

The largest increase in yield, depending on the increase in the seeding rate, was noted in variant 1, and amounted to 34 centners per hectare. Such an increase in the yield of green mass may be related to the fact that the seeds of the second fraction have low germination rate, and an increase in the seeding rate has a significant impact on the yield of green mass.

Conclusion

1. The best indicators of sowing qualities of seeds: 82.5% - germination energy, 92.2% - laboratory germination, 83% - field germination were marked on the option 2 (average size is fractions 3).
2. According to the number of days from sowing until the onset of the development phases, in variants 1 and 2, where the seeds are larger, it was observed that the *period of seedlings-the beginning of flowering* was for 4 days shorter.
3. The dependence of the yield of green mass of Sudanese grass on the seed fraction and seeding rate was revealed. The highest yield of green mass was obtained with a standing density of 2.5 million pcs / ha on the variant with seeds of the third fraction (340 centners per hectare), which is 32 centners per hectare more than the control. According to the biometric

parameters of the plants, a significant difference was noted in the stem diameter (with an increased seeding rate in all variants, the stem diameter was 0.5 cm thinner on average).

Thus, according to the results of the research, it was established that in the conditions of the Central Black Earth region, seeds of Sudan grass of variety Voronezh 24 should be divided into an aerodynamic separator, and sown with the seeds of the second and third fraction. With a seeding rate of 2.5 million pcs / ha, 330-340 centners per hectare of green mass can be produced.

Abstract
Marker assisted selection (MAS) significantly increases efficiency of conventional breeding. Molecular markers are utilized as selection markers for target genes (foreground selection) and also for identification of the genotypes (progenies) with the highest proportion of recurrent parent's genome (background selection). Maize Research Institute "Zemun Polje" has a breeding program with the aim to create lines with incorporated incompatibility dominant gene *Gametophytic Factor 1-S (Ga1-S),* using the integrated conventional and molecular breeding approach. *Ga1-S* is the most described gene belonging to the group of genes specific to the pollen development, germination and pollen tube growth. The *Ga1-S* system is the most commonly used to prevent the pollination of sweetcorn, popcorn and white kerneld hybrids by standard maize. The objectives of this study were identification of gene-specific molecular marker for foreground selection, as well as the set of SSR markers polymorphic between parental lines to be used in background selection. Genetic variability between two donor and three recurrent parental inbred lines was analyzed with 42 SSRs distributed over the maize genom. Total number of alleles detected with 30 informative markers was 83, average being 2.77. The genetic similarity values calculated on Dice coefficient ranged from 0.47 to 0.71. Among 12 gene-specific markers tested on parental lines, two showed distinct polymorphism for *Ga1-S*. These markers will be used as foreground selection markers for the incorporation of *Ga1-S* into our inbred lines which will be used for the creation of white kernel hybrids.

Keywords: *Gametophytic Factor 1-S, Maize, Molecular markers, Foreground selection, Background selection.*

Introduction
The inability of certain maize genotypes to successfully pollinate other genotypes is attributed to genes known as *gametophyte factors (ga)*. Gametophyte factors regulate the success of pollen-pistil interactions and affect the success of fertilization by causing the aberrant Mendellian genetic ratios in certain crosses (Nelson, 1994). These genes have two functions associated with them: a female function that produces a barrier to non-self-type pollen and a male function that enables self-type pollen to overcome that barrier (Lu *et al*., 2014). When present in pistil, they discriminate against or completely exclude pollen lacking the same allele (Nelson, 1994).
The *Ga1* was the first characterized gametophyte factor (Mangelsdorf and Jones, 1926) and has been intensively studied. It was mapped to the short arm of chromosome 4 in maize (Bloom and Holland, 2011; Lausser *et al.*, 2010; Liu *et al.*, 2014; Zhang *et al.*, 2012). *Ga1-s* is considered the "strong" variant of *Ga1*. In the *Ga1-s* barrier, pollen tubes do not grow straight and demonstrate heavy accumulation of clustered callose plug deposits (Lu *et al.*, 2014). The homozygous *Ga1-S/Ga1-S* genotype confers complete nonreciprocal cross-incompatibility (or unilateral cross-incompatibility) with *ga1* pollen (Kermicle and Evans, 2010; Zhang *et al.*, 2012).

Various strategies (e.g. physical barriers, temporal and spatial isolation) have been taken to reduce and avoid cross-fertilization among adjacent maize fields. Specialty types maize, such as sweet and waxy maize, popcorn, as well as the white kernel maize, are required to be free from foreign pollen due to the xenia effect. Seed production and non-GM maize fields require foreign- and GM-free pollen to maintain high hybrid purity and avoid contamination. The *Ga1-S* might be used as a biological reproductive barrier for the containment of gene flows between different types of maize (Liu *et al.*, 2014).
The incorporation of *Ga1-S* from popcorn to non-crossable maize elite lines has been performed using marker assisted selection (MAS) that greatly improve the efficiency and reliability of the backcrossing process by eliminating difficulty of phenotyping of the segregating population (Zhang *et al.*, 2012). Also, *Ga1-S* was introgressed by MAS into parental lines of an elite white waxy maize hybrid by six generations of backcrossing and one generation of selfing (Liu *et al.*, 2014). Maize Research Institute "Zemun Polje" (MRI) has a breeding program aimed at incorporation of the incompatibility gene *Ga1-S* into parental components of the hybrids with specific traits (white kernel). The main objectives of the research presented herein were to identify: 1) the SSR marker specific to the *Ga1-S* gene that will be used in foreground selection and 2) the set of SSR markers polymorphic between parental lines that will be used in background selection.

Material and Methods

Plant material

Two inbred lines (provided by the gene bank in Illinois, USA) were used as the donor parents (D_1 and D_2) of the favourable allele of the *Ga1-S* gene. Three MRI commercial inbred lines adapted to the local environmental conditions in Serbia were used as the recurrent parents (R_1, R_2 and R_3). These lines are components of the white kernel MRI hybrids.

DNA extraction

Total DNA was isolated from the kernel bulk according to Doyle and Doyle (1987). Bulks were prepared by pooling an equal amount of flour obtained by grounding 10 kernels per sample. The DNA was quantified using biospectrometer BioSpetrometer kinetic (Eppendorf, Germany) and diluted to a working concentration of 20 ng/µL.

Identification of molecular markers for foreground selection

Twelve gene-specific primers were chosen according to Liu *et al.*, (2014) and Zhang *et al.*, (2012). Polymerase chain reaction was carried out in 25 µL reaction volume containing: 1×DreamTaq Green Buffer (Thermo Scientific, USA), 100 µM dNTP (Thermo Scientific, USA), 0.5 µM of each primer, 1U DreamTaq DNA Polymerase (Thermo Scientific, USA) and 20 ng DNA template. Amplifications were performed in thermocycler Biometra TProfessional Standard 96 (Biometra, Germany) with the following program: an initial denaturation at 95ºC/5min, followed by 35 cycles each of denaturation at 95ºC/1min, annealing at 55ºC/30s and extension at 72ºC/1min with final elongation at 72°C for 10 min. The amplified fragments were separated by electrophoresis on 8% polyacrylamide gel in 1xTBE buffer. Gels were run on small format vertical gel system (Mini Protean Tetra-Cell, BioRad, USA), at 80 V for 1.5 h. After staining with ethidium bromide, they were visualized under UV transilluminator and documented in gel documentation system BioDocAnalyze (Biometra, Germany). Allele designations were made and approximate size range for the amplification products for each SSR locus was determined based on the positions of the bands comparing to the 100 bp molecular weight ladder (Thermo Scientific, USA).

Identification of molecular markers for background selection

Simple sequence repeat (SSR) analysis was done with 42 primer pairs spanning over the whole genome, selected from the maize database (www.maizegdb.org). Polymerase chain reaction (PCR) was carried out in 25 µL reaction volume containing: 1×DreamTaq Green Buffer (Thermo Scientific, USA), 200 µM dNTP (Thermo Scientific, USA), 0.5 µM of each primer, 1U DreamTaq DNA Polymerase (Thermo Scientific, USA) and 20 ng DNA template. The following touch-down program in the thermocycler Biometra TProfessional Standard 96 (Biometra, Germany) was performed: an initial denaturation at 95ºC/5min, followed by 15 cycles each of denaturation at 95ºC/30 s, annealing at 63.5ºC/1min (-0.5ºC/cycle) and extension at 72ºC/1min; another 22 cycles of 95ºC/30 s, 56ºC/1min and 72ºC/1min with final elongation at 72°C for four min. The PCR products were separated by electrophoresis on 8% polyacrylamide gel, with 20 bp molecular weight ladder (Thermo Scientific, USA) as a marker. After staining with ethidium bromide, they were photographed under UV light using BioDocAnalyze gel documentation system (Biometra, Germany). SSR profiles were converted into a binary matrix based on the presence (1) or the absence (0) of a specific allele. Genetic similarity (GS) was calculated in accordance with Dice (1945): GS_{ij} = 2a/2a+b+c; where: a is the number of fragments present in both variety *i* and *j* (1,1), b is the number of fragments present in *i* and absent in *j* (1,0), c is the number of fragments absent in *i* and present in *j* (0,1). Marker data analyses were performed using statistical NTSYSpc2 program package (Rohlf, 2000).

Results and Discussion

The main advantages of the marker assisted selection for simply inherited traits are direct selection of target gene with specific SSR markers (foreground selection) and fast recovery of recurrent parent's genome (background selection). Properties such as high polymorphism, co-dominant inheritance, random and frequent distribution throughout the genome, simple detection at any stage of plant development, independence of environmental conditions, high reproducibility, as well as cost-effectiveness, characterize SSR markers suitable for wide implementation into modern grain breeding programs (Semagn *et al*., 2006).

In our research, 12 gene-specific markers were tested on parental lines. Ten markers failed to give scorable bands due to absence of amplification product or poor amplification, while two markers showed distinct polymorphism for *Ga1-S* (Table1). The PR1 amplified ~410 bp fragment in donor parents (DPs) and ~390 bp fragment in recurrent parents (RPs). The PR2 amplified ~550 bp fragment in DPs and ~450 bp fragment in RPs. Amplification with these gene-specific SSR markers is given in Figure 1. These markers will be used as foreground selection markers for the incorporation of *Ga1-S* into our inbred lines which will be used for the creation of white kernel hybrids.

Table 1. Primers identified for foreground selection for the *Ga-1* gene

Primer	Reference	Sequence
PR1 F	ID2 F in Liu *et al*., (2014)	5′-CAAATTGAGCCCATTACC-3′
PR1 R	ID2 R in Liu *et al*., (2014)	5′-TTCATTCTATTGCGGGTC-3′
PR2 F	SD9 F in Zhang *et al*., (2012)	5′-GAGAGCTACGCACGACTTAT-3′
PR2 R	SD9 R in Zhang *et al*., (2012)	5′-CAAGACTTGCACAATCGAGG-3′

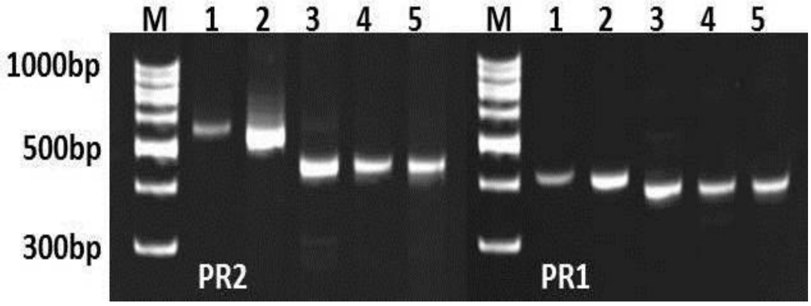

Figure 1. Parental polimorphism with the *Ga-1*-specific markers. M: 100 bp DNA ladder, 1-2: donor parents D_1 and D_2, 3-5: recurrent parents R_1, R_2 and R_3.

Genetic variability between two donor and three recurrent parental inbred lines was analyzed with 42 SSRs distributed over the maize genom. Total number of alleles detected with 30 informative markers was 83, average being 2.77, which is similar to those previously reported in maize inbreds (Bante and Prasanna, 2003; Legesse *et al.*, 2007; Kostadinovic *et al*., 2018). These SSR markers that showed polymorphism between parental lines will be employed for identification of the genotypes with the highest proportion of recurrent parent's genome in BC_2 generation. The genetic similarity values calculated on Dice coefficient ranged from 0.47 to 0.71 (Table 2). These results can be useful for identifying the most appropriate parental lines to be crossed, i.e. predicting the yields of crosses between lines (Ribaut and Hoisington, 1998).

Table 2. The pairwise genetic similarity values calculated on Dice coefficient between donor (D_1 and D_2) and recurrent parent lines (R_1, R_2 and R_3).

	D_1	**D_2**
R_1	0.52	0.47
R_2	0.56	0.49
R_3	0.71	0.56

As concluded by Zhang *et al*., (2012), the introduction of *Ga1-S* performed by backcrossing without markers is laborious, lengthy and inefficient because of the difficulty of phenotyping of the segregating population. Since 50% individuals of the backcrossing population do not contain *Ga1-S* allele, the tightly linked markers can greatly improve the efficiency and reliability of the backcrossing process by eliminating those without *Ga1-S* allele prior to pollination, reducing the size of the breeding population and saving both time and money. Also, background selection accelerates recovery of the recurrent parent's genome. According to Hospital *et al.* (1992), two generations can be saved by conducting marker assisted background selection.

Conclusions

Among 12 gene-specific SSR markers tested on parental lines, two markers showed distinct polymorphism for *Ga1-S*. These markers will be used as foreground selection markers for the incorporation of *Ga1-S* gene. Also, the set of 30 SSR markers polymorphic between parental lines is chosen for the background selection. The identification of these markers represents the first step towards the incorporation of the incompatibility gene *Ga1-S* into parental components of the white kernel hybrids.

Abstract

The okra (*Abelmoschus esculentus* L. Moench.) is less-known vegetable species in Slovak Republic. The goal of experiment was to evaluate the yield potential and antioxidant activity of okra grown in conditions of Slovak Republic. The field experiment was established at the Slovak University of Agriculture in Nitra in 2018. Within experiment, seven okra cultivars with different fruit color were tested (Cajun Delight F1, Clemson Spineless, Burgundy, Blondy, Baby Bubba, Jing Orange, Pure Luck F1). Okra seedlings (18 of each cultivar) were planting in spacing 0.60 x 0.40 m on 23th May 2018. The harvest of okra fruits was realized according to fruit production from 3rd July 2018 to 27th August 2018. The antioxidant activity was measured in fresh pulp and seeds of okra fruits by method of DPPH. The yield of okra fruits per plant were ranged from 293.2 (Burgundy) to 470.7 g (Clemson Spineless). The average weight of okra fruits was varied from 25.6 (Cajun Delight F1) to 36.1 g (Jing Orange). The okra yield per hectare, counted according to yield per plant, was ranged from 12.22 (Burgundy) to 19.61 $t.ha^{-1}$ (Clemson Spineless). The antioxidant activity of okra fruit pulp was ranged from 77.9 (Clemson Spineless) to 84.2 %DPPH (Baby Bubba). The antioxidant activity of okra seeds was only slightly varied, concretely from 98.3 (Cajun Delight F1) to 99.0 %DPPH (Pure Luck F1). Obtained results indicate that okra can be considered as a crop with good yield potential in the Slovak Republic. The important factor, influencing on the yield and quality of okra, is its cultivar.

Keywords: *Okra, Cultivar, Yield, Antioxidant activity*

Introduction

Okra (*Abelmoschus esculentus* (L.) Moench., syn. *Hibiscus esculentus* L.) belongs to the *Malvaceae* family (George, 2011). The exact origin of okra is unknown, but it is thought to have come from Africa, where it has been grown as a crop for centuries. Some evidence suggests it was grown in Egypt as long ago as 2,000 BC (Chanchal *et al.*, 2018). Okra is known and marked by various names in the world (Singh et al., 2014), e. g. lady's fingers (English speaking countries), bhindi (India), krajiab kheaw (Thailand), ochro, okoro, quingumbo, kacang bendi (South East Asia), bamya (Middle East), quiabo (Angola), quimbombo (Cuba), gombo, gumbo (France), mbamia, mbinda (Sweden), okura (Japan) or qiu kui (Taiwan). According to the database of Faostat (2019), average world production of okra in period 2008-2017 was 8.682 mil. tonnes. The highest share of okra was produced in Asia (69.18%) and Afrika (30.06%); Europe production of okra was presented only by 0.1% share from total world production. The highest okra producers are India, Nigeria, Sudan, Pakistan or Ivory Coast.

Okra is an annual or perennial, dicotyledonous plant related to species such as cotton, cocoa and *Hibiscus* (Jain *et al.*, 2012). According to Singh *et al.* (2014), okra plays an important role in the human diet - it is a food source of protein, carbohydrates, vitamins, calcium, potassium and enzymes which are often lacking in the diet, mainly in developing countries. Its medicinal value was reported in curing of ulcers and relief from haemorrhoids. Okra has found medicinal application as a plasma replacement or blood volume expander and it is also useful in genito-urinary disorders, spermatorrhoea and chronic dysentery.

Okra is a multi-purpose crop due to its various use of fresh leaves, buds, flowers, pods, stems and seeds. Young, immature fruits can be used in salads or soups. Fruits offer a mucilaginous consistency after cooking (Gemede *et al.*, 2015). Okra mucilage has the potential for use as food, non-food products and medicine (Haruna *et al.*, 2016). It is used to modify the food quality in terms of food stability, texture, and appearance properties by acting as an emulsifier, thickener, gelling agent, or texture modifier (Noorlaila *et al.*, 2015). Okra mucilage also contributes to improved functionality, especially water-binding, emulsifying, and foaming properties of food products (Jideani and Bello, 2009). Okra seeds may be roasted and ground to form a caffeine-free substitute for coffee (Calisir *et al.*, 2005). Okra leaves can be harvested and used as a cooked green vegetable (George, 2011). The okra plant consists of stalk fibre and bast fibre and it can be an effective alternative for paper production (Jahan *et al.*, 2012).

The goal of experiment was to evaluate the yield potential and antioxidant activity of okra grown in conditions of Slovak Republic. This study was supported by the grant VEGA 1/0087/17.

Material and Methods

The field experiment was established at the Slovak University of Agriculture in Nitra in 2018. The climate of experimental area is characterized by warm and dry summer and slightly warm, dry or very dry winter. According to the climatic normal 1951 - 2000 for Nitra, annual mean temperature is 9.9 °C and mean rainfall total is 548 mm (Šlosár *et al.*, 2016). Within vegetation period (May - August), the average air temperature was 18.1 °C and the rainfall total was only 89 mm. Individual experimental month were evaluated as hot-very hot and dry-extremely dry.

Within experiment, seven okra cultivars with green (Baby Bubba; Cajun Delight F1, Clemson Spineless; Pure Luck F1), red (Burgundy; Jing Orange) and creamy (Blondy) fruit colour were tested. Okra seedlings were planting in spacing 0.60 x 0.40 m on 23th May 2018. The variant of each okra cultivar was divided to three plots with 6 plants, thus, 18 plants of all okra cultivars were planted. Within fertilization strategy, nitrogen was only applied because phosphorus and potassium content in soil before experiment establishment was evaluated as sufficient for okra production (Table 1).

Table 1 Agrochemical soil characteristics before experiment establishment in 2018

pH_{KCl}	Humus (%)	Nutrient content (mg.kg^{-1} of soil)					
		$N_{min.}$	P	K	Ca	Mg	S
7.04 N	32.9 G	6.4 L	140.5 H	368.0 H	6350.0 H	763.4 VH	26.3 M

Note: N_{min} - N mineral (N inorganic); N - neutral; G - good; L - low; M - medium; H - high; VH - very high.

The harvest of immature okra fruits was realised according to fruit production from 3rd July 2018 to 27th August 2018 (12 dates). The yield of okra fruits per hectare was (t.ha^{-1}) was calculated according to the yield of okra fruits per one plant. Within calculation, density of 41667 plants per hectare was used. The plant density was calculated according to the plant spacing (0.6 x 0.4 m) used in this experiment.

The antioxidant activity of okra was determined in fruits harvested on the 10th August 2018. After harvest, seeds were divided from okra fruits. The antioxidant activity was separately

measured in fresh pulp and seeds of okra fruits by method of DPPH (Hegedűsová *et al.*, 2018).
The statistical analysis of obtained results was performed by using of the Statgraphic Centurion XVII (StatPoint, USA). Results were evaluated by analysis of variance (ANOVA) and average values were tested by LSD test performed at the significance level of 95% ($p < 0.05$).

Results and Discussion

Yield per plant

Most of differences in the yield of fruit per plant among tested okra cultivars were evaluated as statistically significant (table 2). The yield of okra fruits per plant was ranged from 293.2 (Burgundy) to 470.7 g (Clemson Spineless). Similar values of okra yield per plant (320.0 - 433.3 g) were showed in the field experiment in Bangladesh (Saha *et al.*, 2016a). Saifullah and Rabbani (2009) realised the extensive study focused on the effect of genotype to the yield of okra fruit per plant in Bangladesh. Values of okra yield per plant in 121 genotypes were ranged from 92.16 to 641.42 g. Singla *et al.* (2018) also presented significant variability of okra yield per plant (299.1 - 496.7 g), dependent on cultivar, in the field experiment realised in India. Results of our experiment are in the range found by mentioned authors.

Table 2 Yield parameters and antioxidant activity of okra

Cultivar	Yield/plant (g ±SD)	Average weight (g ±SD)	Yield ($t.ha^{-1}$ ±SD)
Baby Bubba	396.2 ±8.8^{c}	29.6 ±0.7^{c}	16.51 ±0.37^{c}
Blondy	467.7 ±7.8^{d}	32.0 ±0.5^{d}	19.49 ±0.33^{d}
Burgundy	293.2 ±7.7^{a}	32.9 ±0.9^{de}	12.22 ±0.32^{a}
Cajun Delight F1	307.6 ±8.4^{b}	25.6 ±0.7^{a}	12.82 ±0.35^{b}
Clemson Spineless	470.7 ±9.2^{d}	33.4 ±0.7^{e}	19.61 ±0.38^{d}
Jing Orange	462.6 ±5.4^{d}	36.1 ±0.4^{f}	19.28 ±0.22^{d}
Pure Luck F1	398.3 ±8.2^{c}	27.3 ±0.6^{b}	16.60 ±0.34^{c}

Note: SD - standard deviation; Note: Values with different letters among rows are significantly different at $p < 0.05$ by LSD in ANOVA.

Average weight of fruits

The statistical analysis of obtained results showed statistically significant differences of average fruit weight among tested okra cultivars (table 2). The average weight of okra fruits was ranged from 25.6 (Cajun Delight F1) to 36.1 g (Jing Orange). Saha *et al.* (2016b) found weight of okra fruits in the range from 19.0 to 24.4 g in Bangladesh. Within another study in Bangladesh (Saifullah and Rabbani, 2009), the weight of fruits was also influenced by okra cultivar (15.3 - 26.2 g). Singh *et al.* (2018) examined the effect of cultivar on the okra fruit weigh in India. Authors found variability of its values from 11.68 to 14.09 g. In mentioned studies, values of fruit weight were lower in comparison with results found in our experiment. In US Virgin Islands, Nandwani (2012) found comparable weight of okra fruits in cultivar 'Clemson Spineless' (32.6 g) to our experiment.

Yield per hectare

The statistically significant differences of yield per hectare among tested okra cultivars were found. The yield per hectare was ranged from 12.22 (Burgundy) to 19.61 $t.ha^{-1}$ (Clemson Spineless). According to Chanchal *et al.* (2018), value of 10 $t.ha^{-1}$ can be considered as a good yield and yield over 40 $t.ha^{-1}$ can be reached only under optimal conditions. According to Faostat database (2019), average yield of okra in the world during 2008-2017 was 4.81 $t.ha^{-1}$. It is significantly lower value compared to results of our experiment with okra.

In Bangladesh experiment, Saifullah and Rabbani (2009) compared the yield of okra fruits in 121 cultivars and its values were ranged from 2.76 to 19.24 $t.ha^{-1}$. The yield of okra fruits, reached in our experiment, was varied in the range presented by authors. Similarly, the significant variability of okra yield, dependent on its cultivar, was also presented by Singh *et al.* (2018) in India (8.18 - 13.67 $t.ha^{-1}$). On the contrary, Saha *et al.* (2016a) found lower yield of okra fruits per hectare (9.28 - 12.56 $t.ha^{-1}$) in Bangladesh. Abubaker *et al.* (2012) tested the effect of plant density on the yield of okra fruits in Jordan. In 'Clemson Spineless' okra cultivar and comparable plant density (40000 per hectare), the significantly lower yield (2.57 $t.ha^{-1}$) was found compared to the same okra variety tested in our experiment.

Antioxidant activity (AOA)

The statistical analyses of AOA values in pulp or whole fruit were showed among tested okra cultivars. The AOA of okra pulp was ranged from 77.9 (Clemson Spineless) to 84.2 %DPPH (Baby Bubba). The average AOA value of whole fruit (pulp+seeds) was ranged from 88.0 (Cajun Delight F1) to 91.6 %DPPH (Baby Bubba). Differences of AOA in okra seeds among tested cultivars were evaluated as a statistically non-significant.

Ahiakpa *et al.* (2013) analysed AOA in whole fruits of 25 okra cultivars in Ghana and its values were ranged from 16.74 to 55.97 %. In okra cultivar 'Clemson Spineless', AOA of fruits was 45.27 %. All okra cultivars were showed by lower AOA compared to cultivars tested in our experiment. Petropoulos *et al.* (2018) determined the AOA of fruits in eight okra cultivars by method of DPPH and results were expressed in EC50 values (sample concentration providing 50% of AOA or 0.5 of absorbance in the reducing power assay). Authors found significant variability of AOA in dependency on the okra cultivar. The AOA was ranged in the interval 0.66 - 1.27 (small fruits) or 0.70 - 1.18 $mg.ml^{-1}$ (large fruits). Differences between the lowest and highest AOA were presented by 92.4 % or 68.6 %.

The antioxidant activity of okra seeds was only slightly varied, concretely from 98.3 (Cajun Delight F1) to 99.0 %DPPH (Pure Luck F1). Graham *et al.* (2017) found significantly lower AOA of seeds in six okra cultivars (36.9 - 60.4 %) in comparison with cultivars tested in our experiment.

Table 3 Antioxidant activity of okra

Cultivar	Antioxidant activity of okra (%DPPH ±SD)		
	pulp	seeds	fruit
Baby Bubba	84.2 ±0.7^{c}	98.9 ±0.4^{a}	91.6 ±0.4^{c}
Blondy	80.4 ±0.6^{b}	98.4 ±0.4^{a}	89.4 ±0.2^{b}
Burgundy	80.6 ±0.7^{b}	98.7 ±0.5^{a}	89.7 ±0.5^{b}
Cajun Delight F1	79.3 ±1.2^{ab}	98.3 ±0.4^{a}	88.0 ±0.7^{ab}
Clemson Spineless	77.9 ±1.2^{a}	98.9 ±0.5^{a}	88.4 ±0.7^{a}
Jing Orange	83.0 ±0.6^{c}	98.7 ±0.5^{a}	90.9 ±0.3^{c}
Pure Luck F1	83.2 ±0.7^{c}	99.0 ±0.4^{a}	91.1 ±0.6^{c}

Note: SD - standard deviation; Note: Values with different letters among rows are significantly different at $p < 0.05$ by LSD in ANOVA.

Conclusions

The okra is less-known vegetable species in Slovak Republic, or Middle Europe generally. The goal of experiment was to evaluate the yield potential and antioxidant activity of okra grown in conditions of Slovak Republic. Results of this study indicate that okra has a promising yield potential in Slovak Republic, despite of its tropic origin. The okra cultivar 'Clemson Spineless' was expressed by the highest yield of okra fruits per plant or hectare. Generally, all tested okra cultivars were showed by yield quantity comparable to studies realized in countries where its cultivation has a long-term tradition. The okra fruits and seeds were also showed by high antioxidant activity which was significantly influenced by tested cultivar.

Abstract

The main goal of sowing the narrow-row crops is to make the seed distribution even more uniform in the vegetation space. Specifies of sowing the narrow-row crops in interaction with the effects of sowing aggregate operations significantly influence the profitability of production, bearing in mind the fact that failures in the sowing process cannot later be corrected. The paper presents the results of testing the quality of work of various sowing aggregates on two tillage systems during sowing of narrow-row crops. The tests were carried out in the vicinity of Knjaževac, and the quality of sowing aggregates effects included the determination of the longitudinal, transverse and seed distribution along the depth of the seed bed in the sowing of winter wheat of the Sosthena variety on the reduced tillage of the Amazone D9 4000 Super sowing machine, and on the conventional tillage of the seedling machine OLT Gama 18. The obtained results showed that the planting aggregate Amazone D9 4000 Super performed better and achieved a more even seed arrangement. The highest content of grain in the transverse distribution of 67% was grouped at a group distance of 120.1 - 140 mm, while the longitudinal seed content of over 64% was in the group distance of 40.1-60 mm. The second tested aggregate obtained the uneven distribution of seeds, bearing in mind that in the group distribution 120.1 - 140 mm there were 45% of the grains, while in longitudinal 55% of the grains were within the group distance of 40.1 - 60 mm. Distribution of seed at depth with both sowing aggregates was moderately satisfactory.

Keywords: *Sowing aggregate, Quality, Seed, Distribution, Wheat.*

Introduction

Wheat production can be carried out by using conventional and conservational tillage, as a substitute for classical tillage due to numerous advantages, especially in sowing the winter crops (Kovačević *et al.*, 2005; Rusu *et al.*, 2011; 2013). The basic goal of wheat sowing is the balanced seeding to optimal depth and even distribution in vegetation, which is not satisfactorily obtained with the existing solutions of universal wheat sowing machines and tillage systems (Šumanovac *et al.*, 2005). Successful sowing in precise agriculture is difficult to achieve without the use of appropriate sowing aggregates, and knowing their performances (Auernhammer, 2004; Wiesenhoff and Koller, 2004). The performance of aggregates for sowing is significantly influenced by crop remains (Doan *et al.*, 2005). Conventional tillage does not provide a good soil structure, so the quality of sowing is inadequate. Distribution of wheat seeds at the soil surface in different tillage systems and direct sowing was not satisfactory, while the distribution results were satisfactory in depth (Šumanovac *et al.*, 2006). At the planned depth by wheat sowing machine "Vederstad Rapid 400S Super XL", 75% of the plants were analysed, and 15% at depths bigger or smaller than 1 cm from the set depth, while the seeders "Lemken Solitaire 9" and "Amazone RP AD 403" set depth of seeding achieved in 85% of analyzed plants (Mehandžić *et al.*, 2006). Choosing the wrong tillage system and seeding aggregate adversely affects moisture conservation, yield and production costs (Boydas *et al*., 2007; Farkas *et al*., 2009; Sarauskis, 2009). The assessment of the quality of the work of the seeders is being reflected in the fulfillment of the requirements related to the achievement of the desired sowing norm and the uniform distance of seeds in a row (Marković *et al*., 2009). Seed drills are equipped with sowing devices for every row or central sowing device that distributes seed to all drill's depositors. In comparison with individual metering, the central metering apparatus has higher values of non-uniformity coefficient over seed depositors and higher values of variation coefficient (i.e. more expressed non-uniformity) of longitudinal and transverse seed distribution over the plot (Malinović *et al*., 2001; 2003; Barać *et al*., 2015). The research was carried out in order to determine the effects of labor and qualitative indicators of the work of various sowing aggregates in the reduced tillage and winter wheat sowing under the test conditions.

Material and Methods

In the conditions of production in the vicinity of Knjaževac 43°35'30.2"N 22°12'56.0"E during 2017/18 we examined sowing aggregates for reduced tillage and seeding the winter wheat of the Sosthena variety. The tests included an assessment of the quality of the work of two types of seeding aggregates: Amazone D9 4000 S with RoTeC-Control applicators (Type A) in the variant of reduced tillage and sowing and seeding aggregate OLT Gama 18 (Type B) in the variant of conventional tillage and sowing. Seedlings were distinguished by the construction of the seeding device, the installed seed applicators as well as by the additional equipment for the soil preparation for winter wheat seeding. The Type A seeder was equipped with a seeding device for single seeding, combined with multiple working devices groups of 4 m the working width. The first working organ is a rotary harrow with the pins, the next working is a steel-toothed roller, and behind the bladed barriers for seeds covering, and its end with pressing wheels. The Type B seeder was a standard seed drill with a central seeding device for seeding and standard discs. The seeders were aggregated with tractors of an appropriate power of 147 kW, or 46.5 kW. In both tillage varieties, the pre-culture was corn. In the conventional tillage variant, plowing was done with ram plows, then harrowing and pre-sowing preparation, after which seedlings with OLT Gama 18 were done. In the variant of reduction tillage, the plate was made at an angle of 10^o in relation to the direction of the pre-culture lines, and then the preparation of the soil and sowing was done with the Amazone D9 4000 S. Seed quantity was 220 kg ha $^{-1}$, the planned distance in the row was 5 cm, and sowing depth 3-5 cm, and inter-row distance 12 cm. The analysis of the effects of the seedlings was done after the wheat crop, and it was introducing and including the assessment of the longitudinal, transversal as well as the seed distribution by depth. The longitudinal seeds arrangement was determined when the plants had 2-3 leaves, by counting the plants in every second row at 3 m in length, while the transversal distribution of wheat seeds was determined by measuring the spacing between the rows on the working width of the seeders. The depth of sowing was determined by picking up the plants and measuring the etiolated part of the plants up to the transition to dark green color. Taking into account the slipping of the soil, and all the values were read in 5 repetitions. The obtained results were processed using the Microsoft Office Excel 2007 package.

Results and Discussion

Figure 1, 2 and 3 show the results of the longitudinal and transversal distribution as well as the one by the depth of winter wheat seeding of the Sosthena variety according to the treated variants of reduced and conventional tillage (Type A and Type B).

The obtained results show that the Amazone D9 4000 S sowing aggregate has a higher operating quality and has achieved more even distribution of the seeds compared to the second sowing aggregate. Analysing the longitudinal distribution of wheat seeds by group

spacing, it is observed that in the first variant (Type A) the highest average grain content of wheat grains of 64% was in the group spacing of 40.1 - 60 mm, which was considered very satisfactory, while in the other variant type B), in the group distance of 40.1 - 60 mm, the share of grains was significantly lower and amounted to an average of 55%.
It is important to note that in both examined variants there was no higher presence of wheat grains in the group distance of 0-10 mm, which was 2% - Type A and 3% - Type B, while in group distance 10.1 - 20 mm it was recorded 5% of winter wheat seed in both tested variants. In the group spacing 30.1 - 40 mm, wheat grain content ranged from 14% (Type A) up to 23% (Type B). In the other group intervals, there were no major deviations between the examined variants (Figure 1).

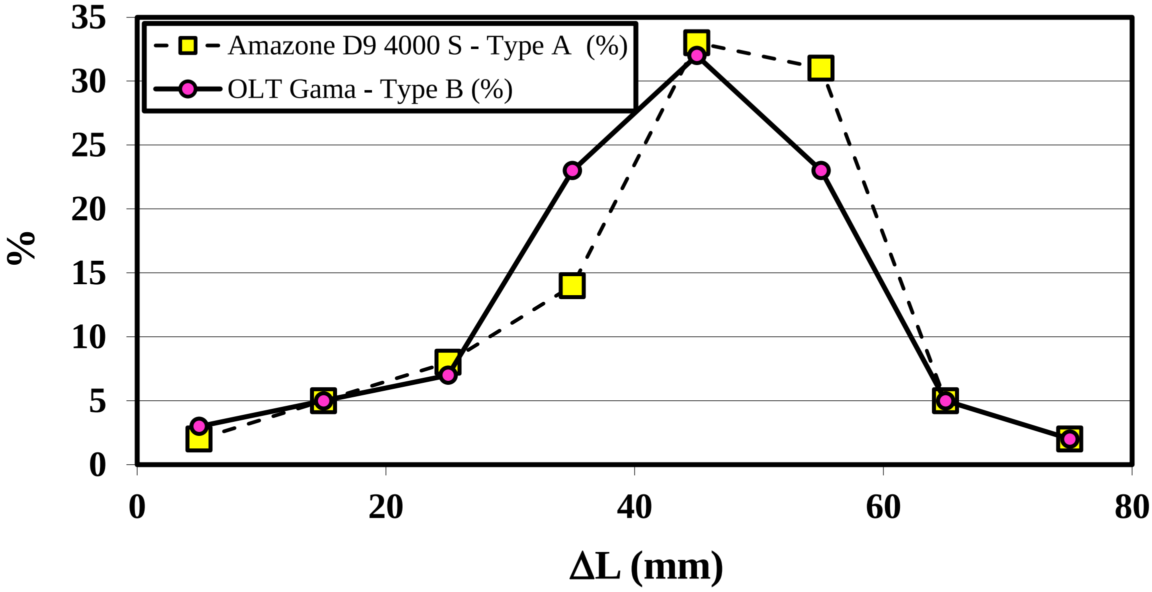

Figure 1. Relative frequency of longitudinal distribution of wheat seed by group spacing and examined variants

Figure 2 shows the results of cross-distribution of wheat seed according to treated variants. The results shown in Figure 2 indicate that the Amazone D9 4000 S seeder obtained more uniform cross-section density of wheat grain compared to the second variant. Thus, for variant A, in the group distance of 120.1 - 140 mm, there were 67% of wheat grains, which can be considered very satisfactory, while at the same group distance, for variant B, 45% of wheat grains were recorded, which is not within satisfactory limits. In the group distance of 0-100 mm, a negligible share of wheat grains was recorded. Namely 1% - Type A and 2% - Type B.
The wheat grain content in the group spacing of 110.1-120 mm ranged from 7% in the Type A seeder up to 9% in the Type B seeder. At a group spacing of 140.1-150 mm, 15% of wheat grains (Type A) or 21% (Type B), while in the group distance of more than 150 mm, the content ranged from 6 to 20%.

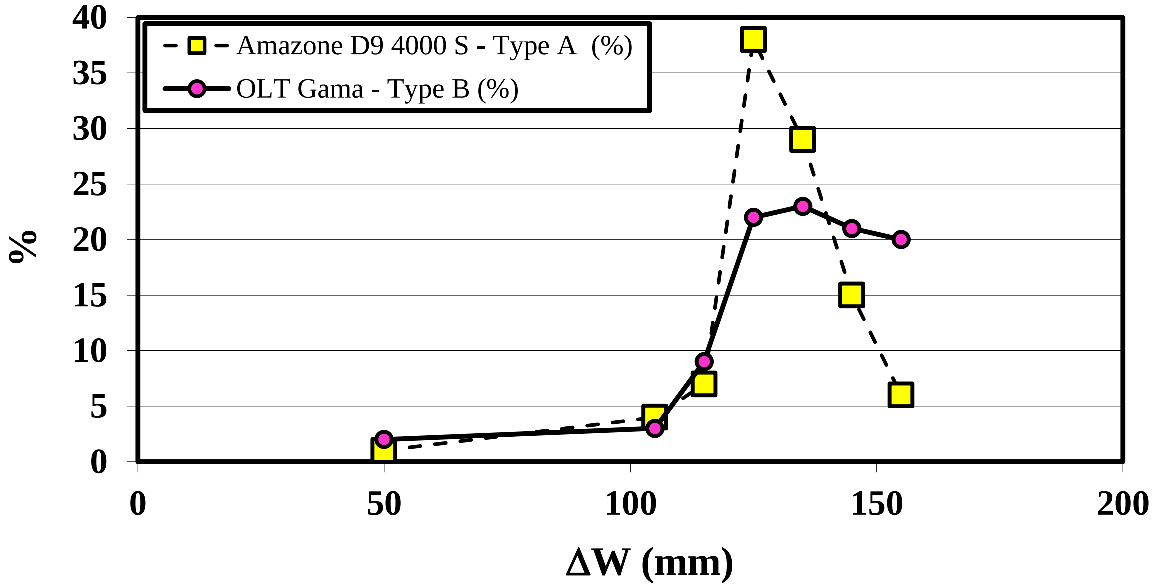

Figure 2. Relative frequency of cross-seed distribution by group intervals and examined variants

More evenly longitudinal and transversal arrangement of wheat seed with seeder Amazone D9 4000 S is primarily explained by the characteristics of the seeding device that performs better seeding and RoTeC-Control seeding depositors in comparison to the seeder OLT Gama 18 with a central sowing machine that achieves unsatisfactory seeding as it groups seeds into piles and standard disc depositors, as well as pre-seeding soil preparation..

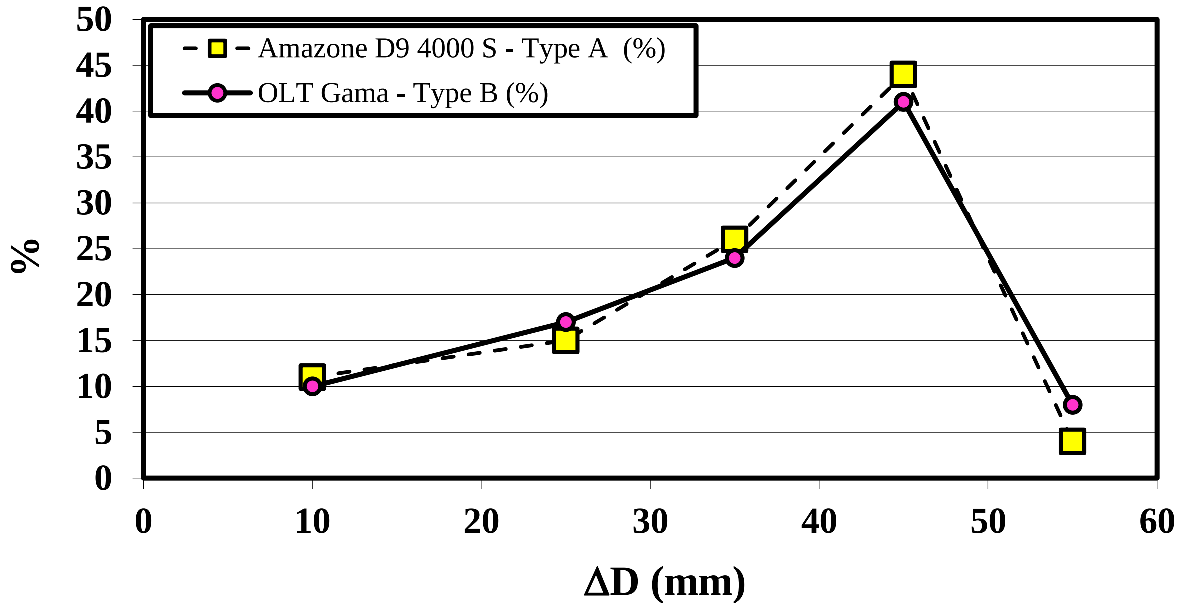

Figure 3. Relative frequency of seed distribution in group distances by the depth

Figure 3 shows the results of wheat seeding by depth, depending on the variants of the seeders aggregates examined. On the basis of the results shown, it can be noticed that in terms of the depth of winter wheat seed of the Sosthena variety, significant differences were not observed at the analyzed group intervals in both types of tested seed aggregates. Thus, the type A seeder, in the group spacing of 10.1-20 mm, sowed 11% of the seed, while in the group

distance 20.1-30 mm, 15% of wheat seed was seeded. In the group spacing of 30.1 - 50 mm, a total of 70% was seeded, while at a depth of more than 50 mm, only 4% of wheat was seeded.
During the examination of Type B seeders, similar values were obtained for observed group intervals. Within the group distance from seeding depth of 10.1 - 20 mm was recorded 10%, while 17% of wheat seeds were sown within a depth of 20.1-30 mm. 65% of wheat seeds were sown on the depth of sowing of 30.1 - 50 mm (Figure 3).
Other authors came up with similar results in their research (Malinović et al., 2003; Wiesenhoff *et al*., 2004; Šumanovac *et al*., 2006; Mehandžić *et al*., 2006; Marković *et al*., 2009; Rusu *et al*., 2013; Barać *et al*., 2015).

Conclusions

Based on the obtained results, it can be concluded that the examined seed aggregates obtained the different quality of work on two tillage systems during winter wheat sowing. The sowing aggregate of type A, operated better and achieved an evener distribution of wheat seed in relation to the second seeding aggregate, since in the longitudinal distribution at group intervals the highest average grain content of wheat grain from 64% was in the group distance of 40.1 - 60 mm which is considered to be very satisfactory, while in the other examined variants - type B in the group distance of 40.1 - 60 mm the grain share was significantly lower and amounted to an average of 55%. It is important to note that in both examined variants there was no higher presence of wheat grains in the group spacing of 0 - 10 mm, which was 2% - type A and 3% - type B. In the case of an aggregate type A, it was more uniform than the transversal distribution of wheat grains compared to the second variant, while for the total examined variant in the group distance of 120.1 - 140 mm, which is very satisfactory, while for the same group distance, for wheat variant B, 45% of wheat grains were recorded, which is not within the satisfactory values. In the group spacing of 0 - 100 mm, a negligible share of wheat grains was recorded, namely 1% - Type A and 2% - Type B. The more uniform longitudinal and transversal distribution of wheat seeds with the Amazone D9 4000 S seeder is explained by the characteristics of the planting apparatus that carries higher quality seed deposers, and RoTeC-Control seed depositors compared to the OLT Gama 18 seeder with a central sowing device that achieves unsatisfactory sowing because it drops seeds into piles, and standard disc deposers as well as pre-seeding soil preparation. In terms of the depth of seeding the winter wheat, the examined seed aggregates did not obtain significant differences in analyzed group distances so that seed distribution by depth can be considered relatively satisfactory. The seeding aggregated Type A, in a group spacing from 30.1 - 50 mm seeded 70%, while the Type B seeding aggregate at a depth of sowing of 30.1 - 50 mm sowed 65% of wheat seeds.

Abstract

Yields of wheat and rapeseed in the Republic of Serbia in the period 2011-2018 were analyzed on the basis of data on sown areas and yield taken from the Statistical Yearbook of the Republic of Serbia. The trends of planted areas and yields in the Republic of Serbia and by region of analyzed meteorological stations (Novi Sad, Kraljevo, Negotin, Valjevo, Vranje and Kragujevac) have been determined, in order to analyze the impact of climate on yields of crops. The average sown area of wheat in the period 2011-2018 was 558,823 ha, and of rapeseed 12,679 ha. A slightly better eight-year average yield of wheat was achieved in Region I (4.76 t ha^{-1}); while in Region II the yields were 3.5 t ha^{-1}. The average yield of rapeseed from one hectare of sown area on the basis of the eight-year production in Serbia was 4.27 t ha^{-1}.

Keywords: *climate, wheat, areas and yield, rapeseed*

Introduction

Primary The climate is variable in its nature and this variability has been increasing in recent years. Climatic extremes are becoming more and more frequent, more intense and more costly. In addition to the significant impact on yield, they significantly affect both the sown area and the total quantities produced. However, science and the profession in agriculture are working to improve new technologies. Breading by creating stress-tolerant varieties also tries to reduce the impact of climate variability on yields. However, in the changing climatic conditions, a different response to the yield of certain species should be expected, which will also condition the cultivation perspective.

Wheat belongs to the family *Poaceae* genus *Triticum*. Over 70% of the population of the globe is fed with wheat bread making it world's most important bread plant. At the same time, Europe is the main production center where the highest yields per unit area are achieved. In the agroecological conditions of Serbia, the sensitive stages in the production are germination and grain-filling. The germination process requires a minimum temperature of 1^{o}C, but under such conditions germination runs slowly, while the optimal temperature for germination is 15-20^{o}C. During the grain-filling process, the grain passes through the milk and dough state. In the milk state, the grain reaches its full length, the color is green, and the plants at that time have their green color, with the lower leaves fading. In the dough state the grain is full and glossy; the plants at that stage become more yellow, although the green color is mostly preserved only by the peak leaves. In agroecological conditions of Serbia the grain filling lasts 16-22 days. The wax maturity phase lasts 6-8 days and sometimes more and grain moisture is 35-25%. Plants at the end of waxy maturity become yellow, leaves die off, and grain moisture is 21-24%. The duration of this phase differs from 3-4 days in arid conditions, while in humid conditions it can be extended to about 20 days, which can significantly affect the yield mainly through the hectolitic weight of the grain. Full maturity occurs at a moisture of 16-17%, which can be reduced to 14-15%. All these stages of wheat development and growth are followed by climatic conditions. From the phase of filling the grain to the maturation in the wheat vegetation, temperatures ranging from 25 to 30°C are considered high. Temperatures above 30°C are considered high and harmful to wheat. A very high temperature above 35°C in the presence of dry winds destroys photosynthesis in plants, slows the growth, and can cause death of plants, but in agroecological conditions this is characteristic of the ripening phase. High temperatures combined with low relative humidity lead to poor grain fulfillment, i.e. its leanness and premature maturation. This is then called a forced maturation that inevitably leads to low yields (Statistical Yearbook of the Republic of Serbia 2012-2018).

Rapeseed belongs to the family *Brassicaceae*, the genus *Brassica*. Rapeseed is grown for seeds that contain 40 to 49% of oil, and 18 to 25% of protein. The refined oil is used for food or technical purposes for the production of lubricants, biodiesels or as a raw material in pharmaceutical, textile and others industries. In Central and Western Europe, rapeseed is increasingly important for the production of bio-diesel. The largest producers of rapeseed in the world are the European Union, and China as an individual country. The optimal period of sowing of rapeseed is at the end of August-early September, with enough moisture in the soil, there are seedlings appearing in 4-6 days (*Crnobarac et al*., 1999). But in this period, there is often a lack of precipitation which in some years prevents successful germination where in addition to the temperature soil moisture is needed in order to initiate the metabolic processes necessary for germination. In the dry autumn conditions characteristic for rapeseed, is that even during the sowing the insufficiently humid soil germination is lagging till the rain falls, and the sprouted seedlings enter the period of autumn frosts in the phase of the cotyledon, which can cause the uneven germinated crops or complete destruction of newly-formed crops (*Gašparov et al*., 1988). The uniformity of germination of rapeseed may also be affected by the color of the seed (*Knežević et al.,* 2019). In the production of rapeseed, the collecting-harvesting process belongs to a more fragile phases since involves at this stage fruits of rapeseed are prone to cracking and seed dispersal, which is particularly pronounced in combination with weather conditions such as winds with periods of rainy and sunny weather.

The aim of this paper was to analyze the impact of climatic conditions that accompany production by regions, areas under cultivation and yield per unit area of wheat and rapeseed in Serbia for the period from 2011 to 2018.

Material and Methods

Yields of wheat and rapeseed in the Republic of Serbia in the period 2011-2018 were analyzed on the basis of data on sown area and yield taken from the Statistical Yearbook of the Republic of Serbia (G2012, G2013, G2014, G2015, G2016, G2017 and G2018). Trends in planted areas and yields in the Republic of Serbia and by regions (Region I - North of Serbia and Region II - Šumadija, western, southern and eastern Serbia) were determined. In order to analyze the influence of observed climate change trends on yields of examined cultures, average annual temperatures and precipitation amounts in the Republic of Serbia and at regions in which the analyzed meteorological stations are located (Novi Sad, Kraljevo, Negotin, Valjevo, Vranje and Kragujevac) are calculated.

Results and Discussion

Graph 1 shows the average annual air temperature in Serbia in the period from 2011 to 2017. The average air temperature in Serbia during the seven-year period was 12°C and was higher by 0.95°C compared to 2011, by 0.18°C compared to 2012, by 0.21°C compared to 2013 and by 0.43°C compared to 2016 year, while it was lower by 1.5°C compared to 2017. The average air temperature in 2014 and 2015 was approximately the average for Serbia. The highest average seven-year temperature value was established in Negotin (13^{o}C) and the lowest in Vranje (11.9^{o}C). Based on the data from Graph 1, it can be concluded that two years ago, out of seven tested, had a slightly higher average temperature than the perennial average for Serbia. Various stress abiotic factors (high and low temperatures, drought, acid and saline soil) in various stages of wheat development limit the expression of maximum genetic potential. Drought has become the main limiting factor in global plant production reducing yields in developed agricultures in the world. The drought-stress is usually followed by high temperatures, which additionally increases the effect of stress (*Đekić et al*., 2017, *Terzić et al.,* 2018). Global climate changes condition increasingly warmer summers and milder winters, which in the future will shift the dates of sowing and spiking, as well as the growing areas of stubble grain cereals (*Đekić et al*., 2019).

	2011	2012	2013	2014	2015	2016	2017	Prosek
Novi Sad	11.7	12.5	12.2	12.9	12.8	12.3	12.6	12.4
Kraljevo	11.6	12.5	12.6	12.5	12.5	12.2	12.4	12.3
Negotin	12.2	13.1	12.8	12.7	13.7	13.1	13.1	13
Valjevo	11.9	12.6	12.7	12.8	12.9	12.5	12.6	12.6
Vranje	11.2	12	12.3	12.4	11.5	12	11.8	11.9

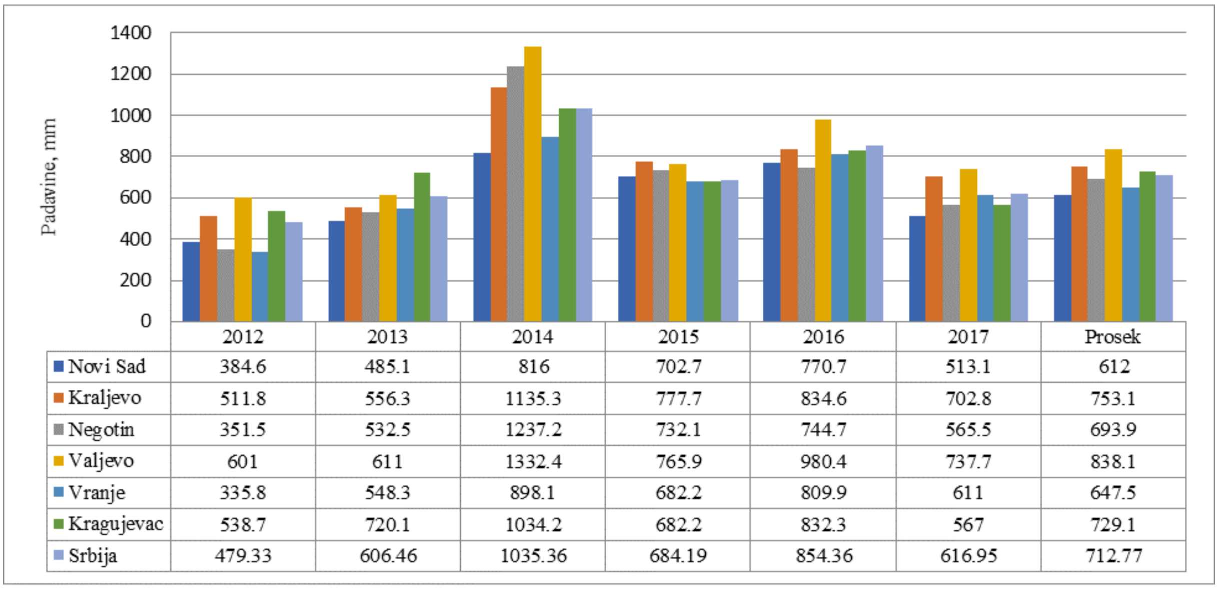
Graph 1. Average annual air temperature in Serbia (2011-2017)

The data shown in Graph 2 for the studied vegetation period clearly indicate that the average annual rainfall varied from the seven-year average for Serbia. The average annual rainfall was lower than the seven – year average of 233.44 mm, in 2012, 106.31 mm, in 2013, 28.58 mm in 2015 and 95.82 mm in 2017 while the distribution of rainfall was uneven. The average rainfall was greater by 322.59 mm in 2014 and by 141.59 mm in 2016. The average amount of precipitation compared to the studied cities was 40.33 mm higher in Kraljevo, 125.33 mm in Valjevo and 16.3 mm in Kragujevac. Slightly lower than seven-year average values for precipitation compared to Serbia were in Novi Sad, Negotin and Vranje. The average yield of wheat above 4 t ha^{-1} was achieved in 2013, 2015, 2016, 2017 and 2018 (Table 1), which shows that they were favorable both for wheat and rapeseed cultivation. *Đekić et al.,* (2017) and *Terzić et al*. (2018) pointed out that the total amount of precipitation is important at the annual level, but the arrangement of it, especially in critical phases of plant development, is significantly disturbed. The same authors point out that in addition to the necessary reserves for the spring part of the vegetation, winter precipitation greatly influences the distribution of easily accessible nitrogen in the soil. In terms of wheat growing fields, wheat is the second crop in Serbia. Rapeseed is highly variable by the areas on which it is grown. Wheat and rapeseed are botanical and usable cultures, but they are very competitive in the areas they occupy.



Graph 2. Average annual precipitation in Serbia (2012-2017)

Table 1. Areas and realized yields of wheat and rapeseed in Serbia

Year	Wheat						Rapeseed	
	Region I north Serbia		Region II Šumadija, western, southern and eastern Serbia		Average in Serbia Region I + II		Average in Serbia Region I + II	
	Areas sown ha	Yield t ha^{-1}	Areas sown ha	Yield t ha^{-1}	Areas sown ha	Yield t ha^{-1}	Areas sown ha	Yield t ha^{-1}
2018	363570	5.42	284513	3.64	648083	4.74	-	-
2017	314480	4.62	245222	3.40	557702	4.08	19934	4.11
2016	329187	5.78	265931	3.69	595118	4.85	13476	4.83
2015	325766	4.79	363997	3.29	589763	4.12	12226	4.12
2014	308398	4.30	240334	3.49	548732	3.94	9815	3.96
2013	320923	4.64	236473	3.55	557396	4.18	9686	4.33
2012	268241	4.33	214372	3.52	482613	3.97	8258	4.01
2011	270514	4.17	220660	3.39	491174	3.82	15357	4.23
Average	312635	4.76	258938	3.50	558823	3.84	12679	4.27
(CV)	9.377	11.93	17.40	3.819	9.11	8.979	31.77	6.949

For the analyzed period and both regions, wheat was grown on the smallest areas in 2012 (482,613 ha) and also in 2011 it was grown on the areas of less than 500,000 ha. In the remaining of the analyzed years, it was cultivated on the areas greater than 500,000 ha. For the analyzed period for wheat in both regions, the area variability expressed in the coefficient of variation (CV%) was 9.11%, while for the rapeseed the area variability was much higher (CV=31.77%). (Table 1).

In the analyzed period, wheat produced the total yield per unit area of 3.82 t ha^{-1} (in 2011) to 4.85 t ha^{-1} (in 2016) (the region average I + II) with the variability expressed in the coefficient of variation CV=8.979%, In rapeseed the corresponding values ranged from 3.96 t ha^{-1} (in 2014) to 4.83 t ha^{-1} (in 2016) and with lower variation (CV=6.949%).

Observing the achieved yields of wheat by years and regions in all the years north of Serbia (Region 1 Belgrade and Vojvodina) compared to the south of Serbia (Šumadija, western

Serbia, southern Serbia and eastern Serbia) generated higher yields of 1.26 t ha^{-1}, the yield variability was higher in the region I (CV=11.93%) than the variability in the region II (CV=3.819%), (Table 1).

Đekić et al. (2019) and *Terzic et al.* (2018) point out that grain yield shows a tendency of growth in years with higher intensity and better precipitation patterns during critical stages of plant development. They also concluded that the sowing structure should be based on more than one variety in order to reduce the risk bearing unpredictability of each vegetation, regardless to the reliability of the selection criteria for the seed sorting in a particular year of research.

Conclusions

The paper presents an analysis of the production of wheat and rapeseed in the Republic of Serbia in the period 2011-2018. With regard to the yield of wheat and rapeseed, the record year for the period 2011-2018 was 2016, with an average wheat yield of 4.85 t ha^{-1} and a 4.84 t ha^{-1} of rapeseed. In 2016, the largest production of wheat and rapeseed in the last decade was recorded. When it comes to total production, it can be said that there is a tendency of growth with smaller fluctuations. Grain yield shows a growth tendency in years with higher levels and better rainfall pattern during critical stages of plant development.

Abstract

Grain yield and quality components were evaluated in four ('Novosadski 448', 'Novosadski 456', 'Dinarac' and 'Dunavac') two-row spring barley cultivars. Comparative studies were conducted during the 2008-2010 year period on the experimental field of the Small Grains Research Centre, Kragujevac. The experiment was laid out in a randomized block design with three replications on a Vertisol soil. At tillering, 50 kg ha^{-1} nitrogen was applied. Calcium ammonium nitrate (CAN) with a nitrogen content of 27% was used for top dressing. The cultivars showed significant differences in grain yield, thousand kernel weight and germination energy, and no substantial differences in protein contents. Grain yield was highest in cv. Dinarac and lowest in cv. Dunavac. The analysis of the effect of the cultivar-year interaction reveals a specific response of each cultivar to germination energy. All cultivars were found to have germination energy of above 90%. Environmental conditions had no significant effect on grain protein content. This suggests that all of the tested cultivars can serve as equally valuable raw materials in the brewing industry.

Keywords: *Spring barley, grain yield, thousand kernel weight, germination energy, protein content*

Introduction

The most important traits that a barley genotype should possess is the yield and quality of the grain. Grain yield has changed during the last century, with yield increases mostly resulting from the development of plant selection and breeding techniques that lead to the genetic yield potential of newly created spring barley cultivars of above 11 t ha^{-1} (Pržulj *et al.* 2010).
Yield increase is associated with improvement of the genetic basis of cultivars and use of adequate production technology. Temperature and rainfall are not necessarily the most important factors that govern the level of production and grain quality in malting barley, since the harvested grain is often of poor quality when these factors are close to optimal (Pržulj *et al.* 2014).
Apart from high yield, thousand kernel weight and good biotic and abiotic stress resistance, malting barley cultivars should have a low content of chaff and proteins and a high starch content. Thousand kernel weight is not just a component of yield, but also a very important component of quality malting barley grains (Ullrich, 2002; Madić *et al.* 2016). Pržulj and Momčilović (2008) stated that the brewing grain quality should have a mass of thousand grains of 45 to 50 g. Grains of greater weight usually has more starch and less protein (Lagassé *et al*. 2006; Marquart *et al.* 2007). Thousand-kernel weight and test weight are among initial major indicators of grain quality (Fox *et al.* 2006, Fox *et al.* 2007). The malting barley varieties divided into groups on the basis of 1000-kernel weight: >45 g large grain, 41 to 44 g medium grain, 37 to 40 g small grain (Malcev, 1967). Protein content is the initial indicator of qualitative analysis of barley grain. Malting barley should have a low content of proteins (below 11.5 %), soluble ones in particular, since a high content of soluble proteins

gives a saturated taste to the beer produced and makes the colour and taste of beer difficult to control.

Apart from the genetic factors (choice of cultivar), an increase in protein content was substantially affected by environmental factors such as inadequate use of nitrogen fertilisers, water deficiency, high temperatures during the kernel filling stage, etc. (Maksimović *et al.* 2001). Furthermore, many studies suggest differences in grain yield stability and adaptability of cultivars to environmental and growing conditions, as well as different cultivar responses to biotic and abiotic stresses (Mirosavljević *et a*l. 2015).

Production technology should be strictly applied adhered to in order to fully implement the genetic potential for grain yield and quality in malting barley (Pržulj and Momčilović 2002; Madić *et al.* 2006; Paunović *et. al.* 2008).

Materials and Methods

Four cultivars of two-row spring barley, (Novosadski 456, Novosadski 448, Dinarac and Dunavac) were analysed for grain yield and quality components. The research was conducted during the 2008-2010 year period on the experimental field of the Small Grains Research Centre, Kragujevac, on a Vertisol soil. According to the analysis, this is a soil of medium acid reaction (pH $_{KCl}$ 4.9), poor in organic matter (2.68 %), very poor in readily available phosphorus (P_2O_5 < 1 mg*100^{-1} g soil), and medium provided with easily accessible potassium (K_2O 10.5 mg*100^{-1} g soil).

The experiment was laid out in a randomized block design with three replications. Each treatment was planted in plots of 5.0 m^2 area, consisting of ten 5.0 m long rows, spaced 0.1 m between rows, 0.5 m between plots and 1.0 m between blocks.

Seeds were sown by hand into the experimental plots in all three years on mid-March, at a seed rate of 450 germinating seeds m^{-2}. Maize was the preceding crop in each experimental year. During the growing season the standard measures of plant protection were used. At tillering 50 kg ha^{-1} nitrogen was applied. Calcium ammonium nitrate (CAN) with a nitrogen content of 27% was used for top dressing.

Grain yield was determined on each plot and expressed in t ha^{-1} at 14% moisture content. Thousand-kernel weight, germination energy (%), protein content was assessed four months upon harvest under laboratory conditions.

Grain protein content (% d.m.) was determined by Kjeldahl method. Results were subjected to a two-way ANOVA (year, cultivar) for the experimental period using the statistical package SAS/STAT, 2000. User's Guide, Version 9.1.3. The significance of difference between the means was assessed by LSD test at the 95% level.

Results and Discussion

Grain yield of barley is a complex trait of tremendous economic importance resulting from the effect of genotype and the environment during the entire plant life cycle. It is difficult to create a variety that has all the positive properties in different cultivation conditions and resistant to biotic and abiotic stress factors (Pržulj *et al.* 2010; Knežević *et al.* 2015; Madić *et al.* 2016). The analysis of variance for grain yield showed significant differences among the cultivars, with the highest and lowest yields being obtained with cvs. 'Dinarac' and 'Dunavac', respectively (Table 1).

The yield was significantly influenced by the conditions of growth (years), and there was also a significant interaction effect between the genotype and the year.

An analysis of the interactive effects between genotypes and year reveals a similar tendency of cvs. 'Novosadski 448', 'Dinarac' and 'Dunavac'. The variety 'Dunavac' had a significantly lower grain yield in the first year. In the third year the yield of cv. 'Dunavac' was at the level of the second year, so it can be concluded that the cv. 'Dunavac' does not react to improved environmental conditions (Table 1).

Table 1. Grain yield (t ha^{-1}), 1000-kernel weight (g), germination energy (%) and grain protein content (%) of barley cultivars over a three-year period

		Grain yield	1000-kernel weight	Germination energy	Grain protein content

*NS - non-significant; ** F - test significant at the 99% level; * F - test significant at the 95%

Thousand kernel weight is not only a yield component, but also a very important component of grain quality in malting barley. Malting barley is of good quality if its 1000-kernel weight is above 38 g (Gaćeša *et al.* 1992). The analysis of variance for 1000-kernel weight suggested significant differences among cultivars (Table 1). The highest 1000-kernel weight had cv. 'Dinarac' and the lowest cvs. 'Novosadski 448' and 'Novosadski 456'. Environmental conditions over the years also produced statistically significant effect, with significant interaction effects between cultivar and year being observed. Thousand kernel weight was substantially lower in cvs. 'Novosadski 456', 'Novosadski 448' and 'Dunavac' during the first year of the study as compared to cv. 'Dinarac', but showed an increasing tendency in the second and third years. Cultivar 'Dinarac' had a significantly larger thausand kernel weight in all years in relation to other varieties (Table 1).

The strongest response to variable environmental conditions was exhibited by cv. 'Dunavac', whereas the least variations, irrespective of the conditions, were observed with cv. 'Dinarac'. Substantial effects of production conditions on technological quality parameters were reported by Lookhart *et al. (*2001), Knežević *et al.* (2004) and Pržulj *et al.* (2014). Malt is defined as the germinated barley, and the maltsters expect the bar to be 365 days regardless of the storage conditions (Pržulj *et al.* 2000).
The grain yield of barley can be improved by selecting plants of medium plant height with thousand kernel weight above 41.0 g and grain protein content of about 11.0 g 100^{-1} g dm (Mirosavljević *et al.,* 2015). Certain grain traits, such as dormancy and hydrosensibility, are desirable agronomic traits though undesirable in technological terms; therefore, breeders are required to satisfy production and storage requirements, on the one hand, and malting requirements, on the other (Pržulj *et al.* 2010). The highest germination energy had cv. 'Novosadski 448'. Between the varieties there was no difference in the energy of germination except in cv. 'Novosadski 448', also the impact of the year did not have a significant effect. All cultivars were found to possess the required germination energy of above 90%. The lowest variation across years was observed in cv. 'Novosadski 448'. Conversely, cvs. 'Dinarac' and 'Novosadski 456' exhibited significantly higher values in the second and third years. The analysis of the cultivar-year interaction effect indicates a specific response of each cultivar to germination energy.
Grain protein content of barley grains is one of the limiting parameters of malting barley. To be good raw material for beer industry, barley grains should be balanced uniform in size, with the absolute weight over 40 grams and with the total protein below 12% (Maleševic *et al.* 2010). The cultivars tested did not significantly differ in the grain protein content, nor did environmental conditions produce any significant effect (Table 1). This suggests that all of the tested cultivars can serve as equally valuable raw materials in the brewing industry. The choice of the most favourable cultivar can be determined by other production traits.

Conclusion

The grain yield of all of the cultivars tested was above 6 t ha^{-1}, being the highest in cv. 'Dinarac' and lowest in cv. 'Dunavac'. The environmental conditions (year), as well as the genotype-year interaction significantly influenced the grain yield and thousand kernel weight. All cultivars in the first year had significantly less thousand-kernel weight, compared to the second and third year. The strongest response to variable environmental conditions was exhibited by cv. 'Dunavac', whereas the least variations, irrespective of the conditions, were observed with cvs. 'Dinarac' and 'Novosadski 456'. All cultivars were found to have germination energy of above 90%. The analysis of the effect of the cultivar-year interaction reveals a specific response of each cultivar to germination energy. Environmental conditions had no significant effect on grain protein content. This suggests that all of the tested cultivars can serve as equally valuable raw materials in the brewing industry.

Abstract

Crop rotation is considered to be an instrument of sustainable cropping system assisting in varying the set of soil nutrients. Thereby reducing the likelihood of soil erosion, building soil organic matter, increasing carbon sequestration, improving soil quality, water holding capacity, nutrient availability, soil structure and minimizing greenhouse gas emissions. Additionally, reducing the outbreak of pests, weeds and other diseases on the farmland, reducing the reliance on chemical fertilizers, minimizing agricultural crop production dangers and heighten crop yield in comparison with monoculture practices. Crop rotation is an agricultural practice of growing different or non-similar crops on the same farmland in different seasons. Also, this cropping system has the potential to increase the diversity of cropping systems, to maximize resiliency of the cereals-based system under variable weather conditions. Higher cereal yields have been gained by including legumes in the rotations. Legume crops could play an important role by delivering multiple services in line with sustainability principles. Crop type can impact soil temperature and water content by affecting shade intensity and evapotranspiration. Crop residues returned to the soil are the main input in maintaining soil organic carbon (SOC), which generally seems to increase with the diversified crop rotation compared to the mono-cropping. Especially, crop rotation and grazing system can affect crop residue mineralization, root and microbial respiration, so as to play a major role in regulating soil surface GHG emissions.

Keywords: *rotation, legumes, cereals, productivity.*

Introduction

Rotations are an important part of any sustainable agricultural system. Yields of crops grown in rotations are typically 10% higher than those of crops grown in monoculture in normal growing seasons, and as much as 25% higher in droughty growing seasons. When you grow a grain or vegetable crop following a forage legume, the extra supply of nitrogen certainly helps (Chuan, 2013; Paul *et al*., 2014). However, yields of crops grown in rotation are often higher than those of crops grown in monoculture, even when both are supplied with plentiful amounts of nitrogen. Research in Iowa found that even using 240 pounds of N per acre when growing corn after corn, yields were not as good as corn grown following alfalfa with little or no N applied. In addition, following a non legume crop with another non legume produces higher yields than a monoculture using recommended fertilizer rates. For example, when you grow corn following grass hay, or cotton following corn, you get higher yields than when corn or cotton is grown year after year. This yield benefit from rotations is sometimes called a *rotation effect.* Another important benefit of rotations is that growing a variety of crops in a given year, spreads out labor needs and reduces risk caused by unexpected climate or market conditions. Other benefits may occur when perennial forages (hay-type crops) are included in the rotation, including decreased soil erosion and nutrient loss (Craig *et al*., 2006; Abdul Quddus *et al.*, 2017).

In Mediterranean-type ecosystems, given the low rainfall, the practices followed in the context of modern agriculture have often led to a deterioration in the quality of resources. Soil

quality must be maintained and resource exhaustion limited. Consequently, the adoption of multiple crop systems, such as the economy, continued productivity and environmental security, must be a primary objective of the corresponding agricultural policy. Among these systems, rotation and green fertilization of legumes, contributing to plant health, controlling the population of enemies, pathogens and weeds, the availability of nutrients, the improvement and rational use of soil, the protection of flora and fauna and, more generally, their impact on future crops. (Bao-Luo, 2016; Lampurlanes *et al.*, 2009).
It is known that 75% of the nitrogen contained in legume biomass comes from conventional nitrogen sequestration (Grath and Wohlrab 1992, Wendland *et al.*, 1993). Beans and peas are always associated with a significant nitrogen gain. Legumes fix the atmospheric nitrogen, release in the soil high-quality organic matter in the soil and facilitate soil nutrients' circulation and water retention (Neugschwandtner *et al.*, 2015; Ghanem *et al.*, 2011). Legumes could be competitive crops and, due to their environmental and socioeconomic benefits, could be introduced in modern cropping systems to increase crop diversity and reduce use of external inputs. Field pea and faba bean accumulate about 130 and 153 kg Nha^{-1} in their aboveground biomass, respectively and significant quantities (30–60% of the accumulated total N) may also be stored in belowground biomass. Faba beans can contribute large amounts of nitrogen to the soil (up to 100kg N/ha over an extended period), while helping to control crown rot and improving overall soil health. Field pea varieties developed provide a viable pulse alternative for grain growers. (Sallaku *et al.*, 2016; Denton, 2013).
The purpose of this article is to present a brief review about the advantages and applications of the crop rotation technique, so that restoring this 'old' method which has been forgotten despite the great prospects in both agronomic and environmental science.

Literature review

Literature review is a thorough study into the already existing knowledge of a topic selected by researchers. This literature search concerns the Crop rotation. The information was obtained from the main online scientific sites including Science Direct, Google Scholar and Scopus. Searches were also undertaken in the University of Thessaly library, dissertation and thesis search engines like ProQuest, Open-thesis and National Documentation Centre.

Experimental results

The switching of fallow crops is considered the oldest and most basic agricultural practice of payment for agriculture, basic procedures before the emergence of modern cultivation techniques. The final succession option is a management decision based on the desire to optimize economic, agricultural or environmental goals. The key to economic goals is to optimize profit, for agricultural purposes, maximize production from a variety of crops, and for the environment, minimize the use of chemical inputs.
The succession of a row of crops in crop rotation is likely to face problems with government regulations - or regulations agro - ecological conditions (such as climatic conditions, topographical and climatic conditions) soil), the presence of insects, weeds, diseases or their varieties cultivation and available mechanical equipment (Castellazi *et al*., 2008).
According to Tillman *et al*. (2004) winter crop rotation with spring crops helps to preserve biodiversity by offering shelter and food to a beneficial effect insects. Also, the use of legumes and soil cover plants in general crop rotation systems reduce the likelihood of crop failure by diseases and enemies, due to lack of insults or reduction of numbers of the pathogens during their development.
Crop rotation combined with reduced soil treatment (or non-cultivation) increases the population of worms and therefore improves the quality of the soil, reduces oxidation rates,

improves the percentage of organic matter so long-term availability and supply of macro- and micro-elements in crops (Francis, 2005).

A modern rotation system was first applied in England in the 18th century, in Rothamsted, England, for 100 years (since 1843). Some of experiments are still ongoing. In addition, 30-year experiments in America showed that the yield of wheat increased by three years crop rotation corn and oats by 140%, 86% and 64%, respectively on the above species (Karlen *et al*., 1994).

The results showed that wheat as monoculture is lagging behind in crop yield over two years crop rotation and especially those that included legumes. Of these, pea (*Pisum sativum*) helped to obtain higher yields of wheat without the addition of any chemical fertilizer while the use of chemical fertilizers gave higher yields on cereals. There are very few long-term studies which have quantified the effect of different crop systems in soil conditions. One of these studies in Cyprus showed that long-term crop rotation leads to impeccable, environmental cultivation system perspective, with higher productivity (Papastylianou, 1993), better income for farmers (Papastylianou & Panayiotou, 1993), as well as lower nitrogen fertilizer requirements (Papastylianou, 1993).

Unless chemical fertilizers are used, green lubrication, using in particular the pea incorporated in the soil, is considered to be the most productive crop rotation for wheat, because it achieves rapid stability of its yields at high levels. "Maintenance is used in almost 40% of cultivated area in the South US, while winter plant, cover crops play an important role in farming systems with regard to the protection against erosion as well as the improvement of the soil productivity (CTIC, 2004).

In an experiment in Alabama, US three-year crop rotation: cessation - corn and tropical legumes (sunny hemp) – corn found that N content in maize seed was much higher in the yields followed by the legumes after the set-aside. Or the contribution of nitrogen fertilization to the segments that received it and preceded the pulp, ranged around 58 kg N ha^{-1} based on biomass production and about 33 kg N ha^{-1} (16.3 kg N ha^{-1} higher than set-off) based on the seed content. Maize production after oil compared to set-aside was 85% higher (Balcom & Reeves, 2005).

A rotational experiment with legumes was conducted in the southwest England. The results showed that the organic matter of the soil was maintained, improving both its physical and chemical characteristics, providing the soil with additional N and reducing surface erosion due to intense winter rainfall (Boquet & Dabney, 1991). Also, Oyer and Touchton (1990) have shown experimentally that an increase in N after winter-leguminous cultivation has led to an increase in successive cotton and sorghum crops without fertilization in spring crops but a decrease in organic soil content.

Table 1. Comparison of Monoculture, Fixed-Sequence Rotations, and Dynamic Cropping Systems (Source: Modified from Hanson *et al.*, 2007).

	Monoculture	**Fixed-Sequence Rotations**	**Dynamic Cropping Systems**
Numbers and types of crops	Single crop	Multiple crops: number depends on regionally adapted species, economics, farmer knowledge, infrastructure.	Multiple crops: number depends on regionally adapted species, economics, farmer knowledge, infrastructure.
Crop diversity	N/A	Diversity depends on length of fixed sequence.	Diversity high due to annual variation in growing conditions and marketing opportunities, as well as change in producer goals.
Crop-sequencing flexibility	N/A	None, although fixed-sequence cropping systems that incorporate opportunity crops increase flexibility.	High. All crops, in essence, are opportunity crops.
Biological and ecological knowledge	Basic knowledge of agronomy	Some knowledge of crop interactions is necessary.	Extended knowledge of complex, multiyear crop and crop-environment interactions.
Management complexity	Generally low, though variable depending on crop type	Complexity variable depending on length of fixed sequence and diversity of crops grown.	Complexity inherently high due to annual variation in growing conditions, markets, and producer goals.

Advantages

The advantages of such a farming system are related to:

- Maintaining or increasing soil fertility, which is achieved through more efficient use of soil nutrients, increased organic matter and nitrogen (N), erosion protection and preservation or improvement of the physical composition of the soil.
- The fight against plant pests, which in combination with other factors combat weeds, pets and plant diseases.
- Increasing performance, qualitatively and quantitatively.
- Addressing economic and technical problems (Selim, 2019).

The rotation system that we will follow and maximize our profit over a period of many years depends on the following factors:

- The species and varieties included in the crop rotation, as well as the crop rotation cycle (number of years).
- The ratio of the total area to be occupied by each crop.
- The succession of crops in the crop rotation cycle (Chongtham *et al.*, 2016).

Conditions for successful crop rotation

In determining the above factors, account should be taken of the following:

- the adaptability of plants to the soil and climate conditions of each region, as well as the economic and technical conditions determining the competitiveness of crops (product prices, cost, demand for products, allocated production facilities and capital);
- the existence of water resources and their better management,
- the presence of pests (weeds, enemies and diseases) and the possibility of dealing with them,
- the existence and distribution of working hands and mechanical equipment,
- the effect of one crop on the next. (Bulldock 1992; Charles *et al*., 2009).

Examples of crop rotation

A simple rotation of a broadleaf and a narrow-leaf is a **two-year** crop rotation.
Potatoes - Winter rye
Sugar beet - Summer barley
Cotton - Winter wheat
Tobacco - Winter wheat
Under certain conditions of the regions we can make three-year, four-year and five-year crop rotation, consisting of a broad leaf and two consecutive narrow-leafs, etc.

Three-years
Corn - Winter wheat - Winter barley
Cotton - Winter wheat - Oats
Sugar beet - Summer wheat - Winter barley

Four Years
Potatoes - Winter wheat - Winter barley - Oats
Corn - Oats - Winter wheat - Summer Barley
Potatoes - Potatoes - Winter wheat - Winter barley - Oats - Winter rye

Five Years
Potatoes - Winter wheat - Winter barley - Summer rye - Oats
Beans - Winter wheat - Summer wheat - Summer barley - Oats
Dual plant rotation can be made from two broadleaves and two narrow leaves:
Potatoes - Sugar beet - Winter wheat - Summer wheat
They can be grown for two consecutive years of broadleaf leaves and followed by a narrow leaf:
Sugar beet - Potatoes - Oats
Corn - Corn - winter wheat

It is reported that diversified crop rotations have also greater energetic productivity from above-ground biomass (grain / seed yield and by-products) if compared with crops grown in repeated sowings or in monoculture. Crop rotation in combination with different tillage methods (conventional tillage, reduced or minimum tillage and no-tillage) is the way to improve soil quality, but it is not clear whether the soil treatment method has a significant impact on the overall crop rotational energy productivity.

The most nitrogen-demanding crop, corn, followed the pasture, and grain was harvested only two of every five to seven years. A less nitrogen-demanding crop, oats, was planted in the second year as a "nurse crop" when the grass-legume hay was seeded. The grain was harvested as animal feed, and oat straw was harvested to be used as cattle bedding; both eventually were returned to the soil as animal manure. This rotation maintained soil organic matter in many situations, or at least didn't cause it to decrease too much. On prairie soils, with their very high original contents of organic matter, levels still probably decreased with the below rotation.

Year 1. Corn Year 2. Oats (mixed legume–grass hay seeded) Years 3, 4, and 5. Mixed grass–legume hay Years 6 and 7. Pasture (Hanson *et al.*, 2007).

There are literally dozens of rotations that might work well on a particular farm. The specific selection depends on the climate and soils, the expertise of the farmer, whether there are livestock on the farm or nearby, equipment and labor availability, family quality-of-life considerations, and financial reality (potential price minus the cost of production). (However, vegetable farmers will sometimes include low-return crops in their rotations because customers expect to find them in the mix at a farm stand or farmers' market.)

Conclusions

The introduction of new cultivation techniques has enabled the same field to be cultivated continuously refined with the same crop culture. This practice leads to the loss of fertility in the fields, increases weed problems and diseases, thereby augmenting the cost of producing more fertilizers and pesticides. This concomitant waste of natural resources as well as the uncontrolled use of chemicals are leading ecosystems to environmental degradation. The concept of crop rotation is known to farmers from the earliest stages of agricultural development on the planet. As has been the case with many practices, industrialization and changing lifestyles have made producers withdraw from this environmentally beneficial of this cultivation technique. Crop rotation is a method that begins to be applied again after a year of negligence. The advantages of crop rotation systems can help solve some of the major problems of modern agriculture such as maintaining or increasing soil fertility to improve plant health, increase yields and income for farmers in combination with environmentally friendly practices. Agriculture is one of the most anthropogenic activities with the greatest negative environmental impacts, so scientific research on methods that reduce contamination is imperative in order for agriculture to become environmentally friendly sector.

INTERCROPPING – MAY BE AN OLD PRACTICE BUT TIMELESS: A SHORT REVIEW

Elpiniki SKOUFOGIANNI*, Kyriakos D. GIANNOULIS, Dimitrios BARTZIALIS, Georgios CHARVALAS, Nicholaos G. DANALATOS

Abstract

Intercropping is known as the achievement of a high and stable production that not only raises complementary products in the area but also reduces the harmful effects of diseases and pests, prevents pollution and results in effective use of resources. Intercropping is an agricultural practice of cultivating two or more crops in the same place of land at the same time which is commonly practiced in many parts of the world in order to increase the productivity per unit area of the land. The crops are not necessarily sown at the same time and their harvest time may be quite different, but they are simultaneously grown for significant growing periods. In this review study, we are informed about the use and importance of the intercropping system which is mainly based on very old ones and which is of great importance in recent years in agricultural production. There are several intercropping systems such as mixed, strip and row intercropping patterns. Supplemental effects in models of resource use should be taken into consideration so as to get better yield and quality in intercropping systems. Cereal/legume intercropping increased dry-matter production and grain yield more than their monocultures. The N transfer from legume to cereal increased the cropping system's yield and efficiency of N uses. The taller cereal reduces biological N fixation and yield of the associated legume. Also, intercropping can be a method of improving diversity in agricultural ecosystem. It provides farmers with the chance to simulate natures´ principle of diversity on their farms. Complementarities in models of resource use should be considered to get better productivity in intercropping systems.

Keywords: *intercropping, productivity, legumes, agricultural practice.*

Introduction

As a result of the rapid population growth, the demand for food production is increasing, but unfortunately the availability of cultivated land remains the same or decreases. Thus, the only way to increase agricultural output is to increase yields per year (Odedina *et al.*, 2014).
Intercropping has a very old history and it is define as the agricultural practice of cultivating two or more plant species in the same area at the same time. Sowing time and harvest time may not be the same but most of the times are time-matched (Ghanbari and Lee, 2003; FAO, 1983). In an intercropping system it is possible to combine annually with annual plants, annual with perennials and perennials with perennial plants without any problem (Eskandari *et al*., 2009; Mousavi and Eskandari, 2011).
The intersection provides territorial coverage throughout the year or at least for longer than monocultures in order to protect the soil from dehydration and erosion. By cultivating more than one crop at a time in the same field, farmers maximize the efficiency of water use, maintain soil fertility and minimize soil erosion, which are serious disadvantages of monoculture. It also reduces the peak of seasonal work as a result, of different planting and harvesting time between crops. In addition, it could serve to increase production per unit area, in particular with low levels of external input, since a mixture of species better uses the available nutrients and water in the soil(Waktola, 2014).

Several scientific studies have been carried out on cereals and legumes interconnection systems and prove their success compared to monocultures. Some studies have shown that intercropping culture was more productive than the monoculture due to the complementary effect of the intercrops of such studies included, cucumber-cowpea, amaranth-cowpea (Bhatti *et al*., 2013) cowpea-corn (Waktola, 2014) and cowpea mushrooms (Gomez and Gomez, 1983).
In this review study, we are informed about the use and importance of the intercropping system which is mainly based on very old one practices and which is of great importance in recent years in agricultural production.

Mechanisms

Complementarity is a general term describing the positive effects that can result from intercropping. There are two mechanisms that contribute to complementarity: resource allocation and facilitation. Resource allocation, also known as segregation and position differentiation, describes the fullest use of available resources from combining crops compared grown separately. The choice of plants for the method of mating depends on the depth of rooting, phenology and plant architecture between the cultivated species at a junction can minimize competition and increase resource allocation. A classic example is the combination of corn seeds (*Zea mays* L., *Phaseolus vulgaris* L. and *Cucurbita pepo* L. respectively) (Litrico and Violle, 2015). In this case, the allocation of resources depends on the differences in the characteristics between the beans that determine the nitrogen, the low growth of bean which covers the soil and suppresses the weeds and the tall corn that serves as a pergola for the beans (Pleasant and Burt, 2010).
The facility refers to processes whereby one type of crop provides a limiting resource or improves the environmental status of another crop. A classic example is the supply of nitrogen from legumes to the soil. Another example is when a deep-rooted species provides water to species difficult to absorb groundwater by hydraulic lifting. As an indirect facilitation, you also consider the beneficial change in the rhizosphere through the terrestrial microorganisms that can grow a plant species thus improving the availability and transport of nutrients from one plant to another (Brooker *et al.*, 2015).

Types of intercropping

Cultivations can be grown together in a variety of ways. **Mixed** intercropping is the practice in which two or more species simultaneously develop in a field without the use of any particular spatial configuration. In this type of intercropping, there are no distinct rows of plant species.
Opposite, the **strip** intercropping is the practice of cultivating two or more crops in separate but adjacent rows at the same time close enough to each other to interact. While these types of intercropping vary depending on spatial configuration, crops can also be inserted in different ways that change in time. The **relay** intercropping comprises the step-by-step planting of two or more cultivations together so as to overlap only parts of their life cycles (Altieri, 1995; Brooker et al., 2015).

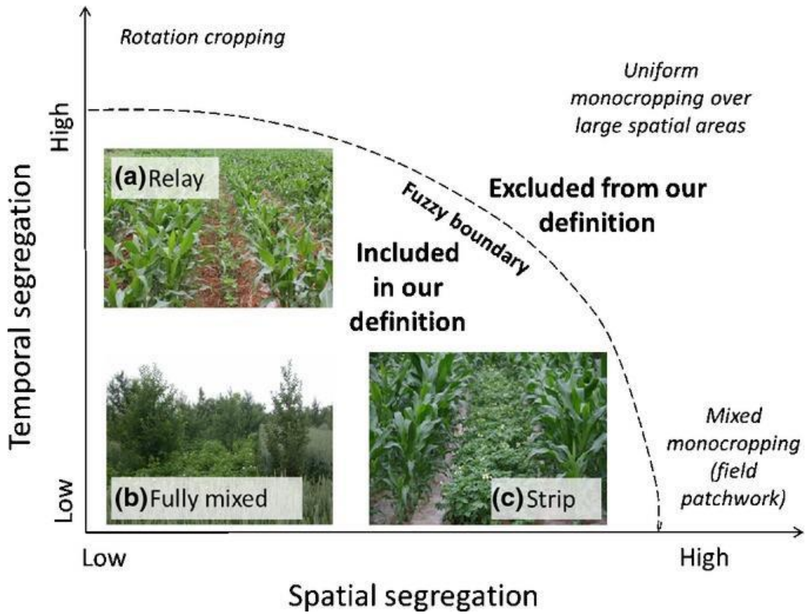

Figure 1. Presentation of the distinction according to degree of both spatial (x-axis) and temporal separation (y-axis) two (or more) cultivars using different intercropping types (Brooker *et al.*, 2015).

Advantages of intercropping

Intercropping is used to gain the most benefit. The advantage of intercropping is that increases productivity by reducing external inputs. It has a low cost that's why is very useful for low income farmers (Eskandari, 2012). There are many reports on the positive results and the superiority of intercropping than the monoculture. The most important advantages of intercropping are:

- **Increased crop production**

One of the main reasons for the use of intercropping is that increased crop production more than a pure cropping(Caballero and Goicoechea, 1995).Intercropping has been shown to reduce the risk of crop failure by increasing crop yield stability over time and in all locations (Bybee *et al*., 2016; Raseduzzaman and Jensen, 2017). Sustainability of crop yield can be increased by decreasing the variation of years at the same site or the increase of production coherence across the region year (Williamson, 2018).For example, experiments have determined that the wheat and bean combination increases production and stability as compared to pure culture (Ghanbari and Lee, 2002). We also, obtained the same results from the bean stew with barley (Martin and Snaydon, 1982).

- **Better resource management**

Increased crop productionoften seen at intercropping compared to unique crops was the result of the full exploitation of natural resources such as solar energy, soil nutrients and water (Szumigalski and Van-Acker, 2008).

- **Management of weeds**

It is known that weeds interact with crops, causing problems through competition (for light, water, nutrients and space) or allopathy. Intercropping is more effective than monoculture to suppressing weeds, but their efficacy varies greatly (Girjesh and Patil, 1991). The benefits of weed control over pure cultivation are two ways. First, there may be weed suppression or may provide yield advantages without suppressing weed growth below the levels observed in net harvesting of components, if the intersections use resources that are not exploitable by the weed (Matt and Dyck, 1993; Hauggaard *et al.* 2003).

- **Reduction of pests, diseases**

An important advantage of the interaction is that it mitigates harmful organisms and diseases (Willey, 1990). Generally strategies to reduce pest infestations can be divided into three groups:

1) By breaking down the ability of a pest to attack the host due to the many existing cultivations(Watiki *et al.*, 1993).
2) Residual trapping of parasitesor pathogens to prevent damage to the main species.
3) Remediation of parasites from natural enemies present in the species (Danso *et al*., 1987).

Though the junction does not happenalways reduce parasites or pathogen, most reports delay the reduction of parasite and disease populations in the region(Fujita *et al.,* 1992).

Example of successful intercropping (*Panicum miliaceum – Pisum sativum*)

Panicum miliaceum, also known as proso millet, belongs to the family of *Poaceae*, and it is considered one of the oldest domesticated plants. Nowadays, the *Panicum miliaceum* is mainly grown in India, China, Russia, USA (McDonald and Dowey, 2003). It has a superficial root system. The height of plants ranges from 30 to 100 cm depending on genotype and environmental conditions. Its stems are internally hollow and the stem diameter ranges from 20 to 50 mm. Oftenlaterally branches develop at αsufficient height from the ground surface. The leaves are lanceolate, about 30 cm long, with a small tongue. Strains and leaves are covered with light fluff (Chai, 1999). It does not have high nutrient requirements, withstanding drought and high temperatures with low water requirements compared to cereal crops (Lyon *et al*., 2008; Rajput *et al.,* 2016).

Pisum sativum is an annual herbaceous plant. It is known fresh as vegetable and dryas legume. It thrives in cold areas of the beloved areas up to 670 north width and height up to 2,000m. The root system consists of a strong pile root and a rich networklateral roots. The root can reach a depth of 1m or more. The stem is thin, tender, has an angular or round cross section and is hollow internally.

The length of the shoots ranges from 45 to 120cm, but the plants usually do notshow this height because they are sloping. The pea can be adapted to a variety of soils, however it prefers fertilizer clay with very good drainage pH 5.6 -7.5 (Pavek, 2012).

Generally, the intercropping of cereals and *Pisum sativum* L. leads to the reduction of external inputs. The nitrogen produced by the plants covers some of the grain needs, resulting in greater productivity and growth of plants by reducing the use of compound fertilizers. In addition, the combination of the two plant species improves plant health (Jensen *et al.,* 2006; Kadziuliene *et al.,* 2011).

Intercropping had increase in the protein content of cereals, increasing their nutritional value to a high level (Sarunaite *et al.,* 2012). This is also shown by experiments carried out by intercropping millet with *Fabaceae* family species like (cowpea) which have an increase in protein content compared to monocultures. The content of crude fiber are lower in intercropping experimentthe fiber content is low in intercropping system in relation to monocultures which areconsidered positive because it facilitates the digestion of lives. Percentof ash is higher in sole millet (Islam *et al.,* 2018). Finally,intercropping helps to control weeds because the combination of plant species gives very good results having a suppressive effect on weeds (Bellwood, 2005).

Conclusions

Intercropping is a useful tooland has been recognized through numerous scientific studies. Farmers can achieve an increase in production of the main crop combined with additional income from the second or third crop, making maximum use of agricultural land. The concentration does not only increase the farmer's revenue due to the increase in production but also reduces his costs in fertilizers, herbicides and water. This is a major asset and can improve the financial situation of small farmers in particular. Finally, it is a friendly method for environments that reduces the negative impacts of modern agriculture and can contribute to sustainable intensification of industrialized agricultural landscapes.

Abstract

Grain legumes, also called pulses, are crops of the botanical family *Fabaceae*.Genus *Lupinus*spp. isalso included in this family.There are over 150 different species of lupines. Some of them are ideally suited to agricultural production due to their nature as nitrogen fixing grain legumes that develop seeds with high protein and high energy contents, which can be grown effectively in northern and southern climates. There are three lupine species of agricultural significance at present: narrow-leafed (*L.angustifolius*), white (*L. albus*) and yellow (*L. luteus*).The inclusion of lupine in crop rotation positively influences biodiversity and soil fertility as the bacteria at the root of lupine symbiotically absorb nitrogen (N) from the air. Lupine plant residues provide the next culture with 32–96 kg N/ha, while the accumulation of nitrogen in lupine biomass ranges from 199–372 kg N/ha, 86% of which is the result of symbiotic fixation.Lupine can be grown on less fertile, acidic and sandy soils where other crops produce lower yield. This is also very important for crop rotation, especially in organic agricultural production, due to its positive impact on the yield of subsequent crops, mainly cereals.Lupine seeds are of low price and non-genetic modified ingredients that constitute of good protein sources (ca. 40%), fiber (ca. 28%), healthy fatty acids, vitamins, minerals and other metabolites with recognized antioxidant properties (e.g., polyphenols). Despite the low European production of grain legumes, European countries exhibit suitable soil-climatic conditions in order for this crop to be cultivated.Measures towards increasing their local production have already been purposed by the European Commission as a way of decreasing the external dependence on soybeans.

Keywords:*lupine, cultivation, animal feed, nutritional value.*

Introduction

The value of lupine in recent centuries has grown considerably over the past few years. As a legume, Lupine provides nitrogen to the soil by setting a very good choice for crop rotational systems.Legumes are a very promising category of plants that grow without the need of special irrigation, which fits perfectly mainly in the dry-heat conditions of the less fertile areas (Naumkin *et al.*, 2015). Although humans have been consuming lupines for many years, beneficial properties in human and animal body have become known in recent years through scientific research. The lack of knowledge regarding the great benefits of lupines for dairy products has led to a global decline in world production (Naumkin *et al.*, 2015**;** Tan *et al.*, 2014).

Nowadays, lupine cultivation has begun to grow again by creating new varieties that eliminate the disadvantages of cultivation. Lupine plant residues contain about 32-96 kg N/ha, while in its biomass the nitrogen content is 199-372 kg/ha. (Unkovich et al., 1994).

Lupine is one of the best choices for animal feedingdueto the high protein and carbohydrate content and the low starch levels. Soluble and insoluble non-starch polysaccharides positively influencefood quality, allowing proper absorption of other nutrients. In terms of seed composition, lupine has a high level of protein (40%), fat (28%), antioxidants and vitamins that increase their nutritional value (Curti*et al.*, 2018; Melde *et al.*, 2016). However, some

varieties contain alkaloids which can cause stomach upsets in animals and humans (Magalhã es*et al.*, 2017).
In addition, production costs in relation to other feeds are particularly competitive, making it a good choice for a ruminant. Finally, the lupine is easy to store and manage so it can be easily used by livestock units.
Although the lupine is one of the best choices as a feed with nutritional value equals and sometimes can be better than other feeds.It is not used widely due to lack of knowledge and information. The purpose of the work is to inform the scientific community about the advantages of lupine and to try to solve some misunderstanding of previous years.

Climate, Soil, Yield and Cultivars

Despite the low European production of grain legumes,European countries present suitable edapho-climatic conditions to cultivate lupines. Guidelines toincrease local production have already been proposed by the European Commission as a way to reduce soybean external dependence.
Yellow lupine (*L. luteus*) breeding is restricted in Europe. Despite the fact that it is extremely resistant to drought and that it can withstands pH=4, due to the low resistance to diseases,it is not cultivated.In Poland, the yields of this variety were 1.5-2.5 t/ha on sandy soil(Gresta *et al*., 2017).
Narrow-leafed lupine (*L. angustifolius*) is grown in northern Europe and requires a wide range of pH values between 5 and 6.8(Gresta *et al*., 2017).The largest yields in Germany over the period 2009-2011 were 3.5-5 t/ha and related to the 'Boregine', 'Haagena' and 'Sonate' varieties. On the other hand, the cultivation of the same varieties on sandy soil produced 2-3.5 tn/ha (Guddat *et al*., 2011).
White lupine (*L. albus*) is well adapted to different soil types, with greater preference for loamy and light clay soils. Furthermore, lupine has excellent calcium resistance and a biological cycle of many days (140-200 days; Gresta *et al*., 2017).

Sowing time

In Mediterranean areas,lupines' sow is usually carried out in autumn as to be able to get higher yields compared with yields of different sowing time (Annicchiarico and Carroni, 2009). White lupine has a temperature resistanceup to -8 ^{0}C while the narrow-leafed lupine can withstand up to -10^{0}C. Therefore, narrow-leafed lupinehas a higher temperature resistance and is recommended for early sowing in spring. In North areas, sowing is not recommended in autumn, as the prolonged low temperaturesof winter have negative effects on growth (Prins, 2014).

Fertilization

Potassium sulphate fertilization in Dutch had a positive effect on the final quality of the lupine and reduced the levels of alkaloids, while there was not observed any differences on the harvested yield (Prins, 2014; Prins and Nuijtnet, 2015). Finally, nitrogen fertilization had not any effect on crops in northern Europe (Prins, 2014).

Weed Control

There is a high competition between weeds and lupines. Weed control or restriction can be achieved in two ways; either by applying high planting density (Herbert *et al*., 1978; Isaac *et al*., 2000) or by using chemical-mechanic weed control.The application of chemical control is limited to lupine cultivation (Prins, 2014) due to its sensitivity to herbicides.Weed population decreased significantly with grubbing 4-5 times in the first two months (Jensen *et al*., 2004a).

Irrigation
According to previous studies, irrigation (at the required levels) increased crop yield, while *Botrytis cinerea* Pers. infestation has led to a yield decrease (Jensen *et al*., 2004b).

Alkaloids in lupines
Lupines contain nine alkaloid compounds with quinolizidine: lupinine, sparteine, angustifoline, α-isopolinone, lupanine, 11,12-dehydrolupanine, 13α-hydroxylupanine, piperidine (smipine) and indole (gamine). Sparteine is the most dominant alkaloid of the mentioned above in Yellow Lupine, while in White and Narrow-leafed lupines lupanine is the major one (Magalhães *et al*., 2015).
Lupine is used extensively in livestock farming. According to its high protein content,lupine is used for the nutrition of the ruminants and the monogastric animals. The prolonged use of such foods for ruminants increases the resistance to the harmful effects of alkaloids. However, lupine varieties with alkaloid content greater than > 1000 mg/100 g dry matter must be avoided (Magalhães *et al*., 2015).
Consequently, sweet white and yellow lupine are suitable for animal feeding, while in case of other varieties a debittering process before using these is necessary (Magalhães *et al*., 2015).

Tolerance to biotic stress
White lupine is predominantly attacked by an insect called *Phorbiaplatura*. The infestation occurs in the roots and hypocotyls of the larvae have a higher incidence during autumn sowing. The control can be done in two ways, either by application of soil insecticides or by coating of systemic seeds insecticides. Regarding fungal diseases, white lupine is affected by 3 fungi (Huyghe, 1997). *Pleiochaetasetosa* is characterized mainly by the appearance of brown spots on the leaves of the plant and, secondly, by the destruction of the roots of *L. angustifolius.* The use of winter-hardy progenitors had positive results on increasing the plants resistance to fungi (Cowling, 1988).
Uromyceslupinicolus occurs in hot and dry periods such as in summer period. The reduction in biomass production and leaves premature fall can be treatedby the application of triazole group fungicides (Huyghe, 1997).
Colletotrichum gloeosporioides, known as Anthracnose, primarily affects the seed. Consequently, the appearance of the symptoms (cankers on the stems) occurs in the early stages of the plant's life cycle resulting in its destruction before flowering (Von Baer and Hashagen, 1996)

Tolerance to abiotic stress
Abiotic stress is mainly due to drought, high pH and frost (Huyghe, 1997). The varieties sown in autumn are highly resistant to frost (Huyghe and Papineau, 1990).Primarily, when sowing takes place in the early autumn, the plants have a better developed and larger root system and therefore have greater resistance to soil cooling.White lupine is cold-tolerant, but temperatures of -6^{0}C to -7^{0}C are harmful at germination. Cool temperate weather conditions are important during the vegetative stage. Temperatures lower than 10^{0}C and short days are required to induce flowering (Putnam, 1993). It appears that bitter cultivars tolerate cold and disease stress better than sweet ones.(Jansen, 2006). Finally, it has been found that the resistance is inherited (Huyghe, 1997).
A second abiotic factor is water logging, which can cause root damage resulting in *Fusarium* and *Botrytis cinerea* infection. The solution to this problem is the early sow (Huyghe, 1997).White lupine thrives on soils with pH ranging from 4.5-7.5. However, aluminium toxicity and iron chlorosis have been observed at valuesbelow 4.5 and above 7.5.Lupine is susceptible to alkalinity due to free lime. In high alkaline, *L. pilosus* has shown high

resistanceto other white lupine varieties. This sensitivity is mainly due to the mechanisms of phosphorus and iron uptake by the roots (Gerke *et al*., 1994).Plant nutrition becomes impossible (Huyghe, 1997) as calcium citrate is destroyed in the presence of free lime (Dinkelaker *et al*., 1989).

Drought remains an abiotic stressor. It is important during the blooming and the formation of the pod to avoid droughtand to complete its flowering. Consequently, the completion of the biological cycle of lupine must be completed before drought period. The choice of autumn sowing and early flowering varieties contributes significantly to this. In Western Europe, the choice of such varieties results in reduced photosynthetic ability. However, temporary stresses may occur during the development of the pod (Rodrigues *et al.*, 1995; Chaves, 1994).

Conclusions

Lupine is a plant that has long been known for its nutritional potential and its cultivation is gaining ground throughout Europe.Lupine is a promising crop of livestock legumes for world livestock. It is a low cost crop with a protein content equal to that of soy (30-42%), making it one of the best animal nutrition options.

The process of converting raw materials into alternative animal feeds has become imperative because of global concern over genetically modified products.Lupinecould be a solution in GMOs problem by limiting the production of soybean, due to its advantages.

Finally, further research for the creation of new varieties as well as cultivation processing practices should be carried out in order to improve the efficiency of the lupine.

Abstract

Because of the various environment conditions yield, quality and other agro-physiological parameters in cereal species vary based on genotype, environment and its interaction. The experiment was carried out to assess bread wheat, durum wheat, barley and triticale cultivars for grain yield, agronomic parameters, physiological and quality parameters under rainfed conditions. In this experiment a total of 17 cultivars (5 bread wheat, 4 durum wheat, 4 barley, and 4 triticale) were evaluated during 2017-2018 growing season. The experiment was conducted in the randomized completely blocks design with four replications. Grain yield, days of heading, plant height, number of spike per square meter, aboveground biomass (NDVI), chlorophyll content (SPAD), canopy temperature, 1000-kernel weight, test weight, and protein ratio were investigated. Analysis of the variance revealed that there were significant differences among cereal species and cultivars for the parameters tasted. Mean grain yield for bread wheat was 6643 kg ha^{-1}, for barley 5588 kg ha^{-1}, for durum wheat 5193 kg ha^{-1} and for triticale 4914 kg ha^{-1}. According to results, bread wheat cultivars had higher grain yield and aboveground biomass, barley cultivars had higher number of tiller per square meters, and chlorophyll content. Triticale cultivars had higher plant height and barley had short plant height. Barley cultivars had higher 1000-kernel weight followed by bread wheat. Bread wheat had higher test weight and durum wheat had higher protein ratio. Result of the study showed that bread wheat had higher grain yield and desirable parameters tested than durum wheat, barley and triticale cultivars, so bread wheat has more advantageous than the other cereals crops.

Keywords: *Cereals species, cultivars, yield, agro-physiological traits*

Introduction

Almost all breeding programs in the world aim to improve varieties with stable yields. The yield stability is generally grouped as static or dynamic stability (Pfeiffer and Braun, 1989). Cereals crops play an important role in the agricultural system. Its grain yield and quality varies based on environment factors, agronomic practices and cereals crops. Various factors are considered responsible for better yield. Selection of improved and high yielding genotypes of different cereals having a wide range of adaptation to agro climatic conditions is essential to increase the yield (Shah *et al*., 2002). Different varieties of cereals respond differently to agro-climatic conditions of a particular area (Behara, 1994). Apparently, morpho-physiological traits of growth and development have the greatest impact on the adaptation of plants to the target environments with the aim of achieving a maximum productivity. Selection criteria based on morphological, physiological and biochemical traits have been suggested for screening drought tolerance in wheat (Araus *et al*., 2002). The adaptation strategies of the plants to drought stress include drought escape, drought avoidance and drought tolerance. Among these strategies, escaping drought involves the completion of the life cycle before the onset of the drought period. Therefore, early maturity has been known as a major drought escaping mechanism, particularly in terminal drought stresses (Levitt, 1980; Chaves *et a*l., 2002).

Bread wheat (*Triticum aestivum* L.) and barley are the most important and widely producing cereal crops throughout the Thrace region of Turkey (Öztürk and Korkut, 2017). Although the amount of the rainfall during growing season is enough for wheat production, the distribution of this rainfall is not regular. This fluctuation of rainfall causes reducing grain yield and quality in cereal crops (Öztürk and Korkut, 2018). Therefore, the objective of this study was to evaluate the performance and compare of the cereal crops cultivars to investigate their yield quality and agro-physiological character under rainfed condition in Trakya region, Turkey.

Material and Methods

The experiments were conducted during 2017-2018 growing years in Edirne locations, Turkey. Five bread wheat, four durum wheat, four barley and four triticale cultivars were studied in a randomized complete block design (RCBD) with four replications. Each plot was 6 meter long and had 6 rows, spaced 0.17 meters apart. A planting rate of 500 seeds m^2 was used. In this experiment a total of 17 cultivars were evaluated during 2017-2018 growing cycle. The experiment was conducted in randomized completely blocks design with four replications. Grain yield, days of heading, plant height, number of spike per square meter, 1000-kernel weight, test weight, and protein content were investigated. The Zadoks Decimal Code (Z) was used to describe plant growth stages (Zadoks *et. al*., 1974).

Grain yield, days of heading, plant height was taken from plot in each replication. In the experiments, 1000-kernel weights and test weight (Blakeney *et al*., 2009), protein ratio, (Köksel *et al*., 2000; Perten H, 1990; Pena, 2002) were determined. In the research; biomass (Gutierrez-Rodriguez *et al*, 2004), canopy temperature (Babar et al, 2006; Blum 2000; Jackson et al, 1981; Reynolds et al., 2001), chlorophyll content (Babar *et al*, 2006; Adamsen *et al*., 1999) were investigated. Physiological characters canopy temperature (CT), chlorophyll content (SPAD), and aboveground biomass (NDVI) were measured at heading stage of the plant development. Canopy temperature measurements were taken when the sky was clear and there was little or no wind and plant surfaces are dry. Canopy temperature measurements were made between 11:00h to 14:00h (Pask *et al*., 2012).

The analysis of variance for each character was measured followed by LSD to test significance difference between means (Steel and Torrie, 1980), and simple correlation coefficient and path analysis, which is the direct and indirect effects of each character was performed as per method of Dewey and Lu (1959). Data were analysed statistically for analysis of variance following the method described by Gomez and Gomez (1984). The significance of differences among means was compared by using Least Significant Difference (L.S.D. at a %5) test.

Results and Discussion

Trakya region has various environment conditions, so mainly issue for plant breeders in improving yield across variable environments. The analysis of variance for yield and quality components was performed and given in Tables 1 to 6. The results of variance analyses showed that there were significant differences ($P<0.01$) among genotypes based on locations. Grain yield in bread wheat ranged from the highest 6948 kg ha^{-1} to the smallest 6535 kg ha^{-1} Table 3. The mean grain yield was 6645 kg ha^{-1}. The highest grain yield performed by cultivar Gelibolu. Mean aboveground biomass of the cultivars was 0.74, 0.79 and 0.75 at Z30, Z45 and Z55 growth stages, respectively. Mean chlorophyll content of the cultivars was 46.9, and cultivar Tekirdağ had higher chlorophyll content. Canopy temperature was measured at Z55 growth stages and cultivar Gelibolu had the lowest canopy temperature under rainfed condition.

Selimiye was the early cultivars, while Pehlivan was late. Cultivars Gelibolu and Pehlivan had higher tillering capacity. Cultivars Selimiye and Pehlivan had higher thousand kernel weight and test weight (Table 3). Grain protein content is among the key determinants affecting of both end use and market value in wheat (Pena, 2002) also, protein quality and quantity is the most important components of wheat grains governing end-use quality (Pena, 2008; Niu et al., 2010). In the research cultivar Saban had higher protein ratio.

Grain yield in durum wheat ranged from the highest 5589 kg ha^{-1} to the smallest 4990 kg ha^{-1}. The mean grain yield was 5193 kg ha^{-1}. The highest grain yield performed by cultivar Ç1252. Mean aboveground biomass of the cultivars was 0.64, 0.68 and 0.57 at Z30, Z45 and Z55 growth phase. Mean chlorophyll content of the cultivars was 46.9, and cultivars Eminbey and Mirzabey had higher chlorophyll content. Canopy temperature was measured at Z55 growth stages and cultivar Mirzabey had the lowest canopy temperature. With regard to genotypic effects, cultivar Ç1252 exhibited the highest plant height (95.3 cm), on the other hand, Mirzabey, which was showed the lowest plant height (88.3 cm). Cultivar Kızıltan had higher spike number per square meter and Ç1252 had higher 1000-kernel weight (TKW) and test weight (TW) (Table 4).

Grain yield in barley cultivars ranged from the highest 6256 kg ha^{-1} to the smallest 5199 kg ha^{-1}. The mean grain yield was 5589 kg ha^{-1}. The highest grain yield performed by cultivar Hasat. Cultivar Hasat had also higher biomass (NDVI) at Z30, Z45 and Z55 growth stages. Mean chlorophyll content of the barley cultivars was 50.4, and cultivars Sladoran had higher chlorophyll content. Cultivars Hasat and Bolayır exhibited the highest plant height and, also Cultivar Bolayır and Hasat had higher spike number per square meter. Among cultivars 1000-kernel weight ranged from 40.0 g to 45.7 g and, mean was 42.0 g. Cultivar Harman had the highest 1000-kernel weight. Test weight varied among cultivars from 72.9 kg to 74.9 kg and the highest test weight was determined in cultivar Harman (Table 5).

Based on grain yield in triticale cultivar MİKHAM had the highest (5312 kg ha^{-1}) yield and followed by Tatlıcak-97. The mean grain yield was 4913 kg ha^{-1}. The highest biomass was performed by cultivar Tatlıcak-97. Cultivar MİKHAM had the highest chlorophyll content and lower canopy temperature. Cultivars Presto and Tatlıcak-97 had the highest spike number per square meter. The highest thousand kernel weight was determined in cultivars MİKHAM (Table 6).

Note: **: P<0.01, *: P<0.05, GY: Grain yield (kg da^{-1}), NDVI: Aboveground biomass, SPAD: Chlorophyll content, CT: Canopy temperature (^{o}C), PH: Plant height (cm), DH: Days of heading, SNM: Spike number per square meter, TKW: 1000-kernel weight (g), TW: Test weight (kg), PRT: Protein ratio (%)

Correlation coefficients based on the investigated parameters for bread wheat, durum wheat, barley and triticale were determined by Pearson's correlation analysis (Table 7). In bread wheat, it was found significant negative correlation between grain yield and NDVI at Z30 growth stage (r=-0.875*), canopy temperature at Z55 (r=-0.891*) and protein ratio (r=-0.930**). Grain yield was positively correlated with number of spike per square meter and slightly correlated with test weight. Correlation coefficients for durum wheat cultivars showed that, it was found positive correlation between grain yield and NDVI at Z30 growth stage, and Z45 growth stage. There was a negative relation between grain yield and days of heading (p=-0.931*) in durum wheat. Grain yield was positively correlated with plant height, TKW and TW. In the research, in barley cultivars it was found positive association between grain yield and biomass (NDVI) at Z30 (r=0.683) and Z45 (r=0.833). Grain yield was slightly positively correlated with plant height, 1000-kernel weight and test weight. There was a negative relation with grain yield and days of heading (r=-0.931*). In triticale cultivars, it was found positive association between grain yield and biomass (NDVI) at Z30 (r=0.640) and Z45 (r=0.812). Grain yield was positively correlated with chlorophyll content at Z55, 1000-kernel weight and test weight. There was a negative relation with grain yield and canopy temperature (r=-0.770).

Conclusions

Because of the various environment conditions yield, quality and other agro-physiological parameters varied in cereal crops based on genotype, environment and its interaction. Analysis of the variance revealed that there were significant differences among cereal crops and among cultivars for the parameters tasted. Bread wheat had the highest grain yield than other cereal crops. According to results, bread wheat cultivars had higher biomass, barley cultivars had higher number of tiller per square meters, and chlorophyll content. Triticale cultivars had higher plant height and barley had short plant height. Barley cultivars had higher 1000-kernel weight followed by bread wheat. Bread wheat had higher test weight and durum wheat had higher protein ratio. Result of the study showed that bread wheat had higher grain yield and desirable parameters tested than durum wheat, barley and triticale cultivars. Results also showed that physiological parameters such as biomass and canopy temperature could be used in cereal breeding programs for selection of the higher yielding genotypes.

Abstract
The experiment was established at the experimental field of the Small Grains Research Centre in Kragujevac (Serbia) during the two growing seasons. The objective of the research was to evaluate the effect of fertilization and the environment on the yield of winter barley. The following characteristics were analysed: grain yield, 1000 grain weight and test weight. The average grain yield and 1000 grain weight of all treatments in 2010/11 growing season was significantly greater than in 2009/10, mostly as the result of highly favourable weather conditions at major stages of plant development. The grain yield of the barley was significant lower in control (treatment without fertilizer). Barley yield was the highest in the NP_1K and NP_2K (4.199 and 4.290 t/ha) treatments. Variance analysis showed statistically very significant differences for grain yield, 1000 grain weight and test weight between the vegetation seasons and very significant differences for grain yield and 1000 grain weight between the effects of fertilization. Variance analysis showed very significant differences for 1000 grain weight between the interaction of the vegetation seasons and variants of fertilization.

Keywords: *barley, fertilization, nitrogen, yield*

Introduction
Barley is one of the oldest agricultural species, which has gone through genetic alterations during the process of domestication. The basic purpose of the barley usage has been changed during thousands of years of the cultivation, i.e. from the main grain in the human diet to the very important animal nutrient. The grain quality of barley is affected by genetic and environmental factors as well as their interaction. Because of this, the same cultivar in different years can behave like brewing or feeding barley, according to the content of grain nutrients, which determines end-use (Đekić *et al.*, 2017). It is known that individual or mutual influence of abiotic stress factors (high and low temperatures, drought, acidic and saline soil) in different barley growth stages limited expression of the maximum grain yield potential (Đekić *et al.*, 2019). The length and intensity of the stress period vary from the environment to the environment, as well as between years in the same environment (Bratković *et al.*, 2018).
Cultivars of the new generation exhibit the high degree of the tolerance against temperatures shocks during the phase of the forming and filling of grain as well as against drought. To achieve high and stable grain yields, newly cultivars are demand more precisely and more complex NPK nutrition (Jelić *et al.*, 2015). The role of the fertilization before basic tillage become more important in the global warming condition. Furthermore, a good soil supply with P_2O_5 and K_2O is very important, since barley need to absorb the same or higher amounts of these elements for a short period of time (Jelić *et al.*, 2014). Efficacy of the nitrogen utilization from mineral fertilizers is decreasing with increasing of the nitrogen fertilizing level (Đekić *et al.*, 2014; Jelić *et al.*, 2015; Terzic *et al.*, 2018). Nutrient utilization from fertilizers and yield forming are under the important influence

of weather conditions and specific characteristics of the location (Popović *et al.*, 2011; Đekić *et al.*, 2014, 2019; Pržulj *et al.*, 2014; Bratković *et al.*, 2018; Terzic *et al.*, 2018).
Because of appearance of new demanded cultivars at permanent changes in soil fertility level and environmental conditions, still exist need to researches fertilization of barley, as well as determine optimal rates and balanced nutrition ratios in concrete agro ecological conditions. The main goal of this research was to investigate the effect of long-term applications of identical amounts and ratios of nitrogen, phosphorus and potassium on the yield components of winter barley cultivar „Grand".

Material and methods

Meteorological conditions

Kragujevac area is characterized by a moderate continental climate, which general feature is uneven distribution of rainfall by month. Data in Table 1 for the investigated period (2010-2011) clearly indicate that the years in which the researches were conducted differed from the typical long-year average for Kragujevac region, regarding the meteorological conditions. The average air temperature in 2009/10 growing season was higher by 0.37°C and 2010/11 was higher by 0.16°C than with the perennial average. The sum of rainfall precipitation in 2009/10 growing season was higher by 612.1 mm, where the sum of rainfall in 2010/11 growing season was 86.2 mm lower than the perennial average and with a very uneven distribution of precipitation per months. During the April and May in 2009/10 growing season it was 142.2 mm and 116.7 mm of rainfall, what was 90.3 mm and 59.1 mm more compared with the perennial average. During the June in 2009/10 it was 196.7 mm of rainfall, what was 126.3 mm more compared with the perennial average.
In addition to the necessary reserve for the spring part of the vegetation, winter precipitation greatly influences the distribution of easily accessible nitrogen in the soil (Jelic *et al.*, 2015; Đekić *et al.*, 2015; Terzic *et al.*, 2018).

Table 1 *Precipitation sum and average monthly temperature in Kragujevac, Serbia*

Months	Mean monthly air temperature (^oC)			The amount of rainfall (mm)		
	2009/10	2010/11	Average	2009/10	2010/11	Average

Experimental design and statistical analysis

Effects of mineral nutrition efficiency of barley have been studied at the stationary field trial of the Small Grains Research Centre in Kragujevac (Serbia) for two growing seasons (2009/10 and 2010/11). The experiment was laid out in a randomised block design with five replications and a plot size of 10 m^2 (5 m x 2 m). In all years, winter barley was sown in the second half of October at a row spacing of 12.5 cm. The rate of nitrogen application were 80 kg/ha N. The barley cultivar used in the experiment was Grand. Six variants of mineral nutrition: control, N (80 kg/ha N), NP_1 (80 kg/ha N and 60 kg/ha P_2O_5), NP_2 (80 kg/ha N and 100 kg/ha P_2O_5), NP_1K (80 kg/ha N, 60 kg/ha P_2O_5 and 60 kg/ha K_2O) and NP_2K (80 kg/ha N,

100 kg/ha P_2O_5 and 60 kg/ha K_2O). The following traits were analysed: grain yield, 1000 grain weight and test weight. Grain yield was measured for each plot and calculated as grain yield in t/ha at 14% grain moisture. Then, a sample was taken for 1000 grain weight and test weight determination.
The soil used in the trial was vertisol having a very acid reaction (pH in KCI: 3.92-4.27), the content of total nitrogen was medium (0.12-0.15%), while the content of affordable phosphorus (26.9 mg P_2O_5/100 g soil) and potassium (21.0 mg of K_2O/100 g of soil) is high.
On the basis of achieved research results the usual variation statistical indicators were calculated: average values, standard error and standard deviation. Statistical analysis was made in the module Analyst Program SAS/STAT (SAS Institute, 2000).

Results and discussion

The average grain yield, 1000-grain weight and test weight of all treatments was significantly higher in 2010/11 growing season (Table 2).

The highest grain yield had application of NP_2K in a quantity of 80 kg/ha N, 100 kg/ha P_2O_5 and 60 kg/ha K_2O (4.290 t/ha). The grain yield of the barley was significantly lower in control (treatment without fertilizer). Average grain yield of treatments ranged from 0.575 t/ha (control) to 3.407 t/ha (NP_1K) in 2009/10 growing season and 0.909 t/ha (control) to 5.202 t/ha (NP_2K) in 2010/11 growing season. In all years, NP_1K and NP_2K treatments produced significantly higher grain yields compared in the other treatments. Considerable variation in yield depending on years of research have established Popović *et al*. (2011), Jelić *et al*. (2014), Madić *et al*. (2014) and Đekić *et al*. (2019).

The average 1000 grain weight of all treatments in the 2010/11 growing season was significantly greater than in the 2009/10 growing season, mostly as the result of highly favourable weather conditions at major stages of plant development. Averaged across years, significantly higher values for 1000 grain weight were found in NP_1K and NP_2K treatments (43.51 g and 44.60 g).
During the 2009/10 growing season, test weight was significantly greater in N treatment (66.15 kg/hl) than in the other treatments. During the 2010/11 year, NP_2K treatment (68.41 kg/hl) had significantly higher values for test weight compared to the other treatments.
Table 3 shows the impact of the year, fertilization and interaction of year x fertilization on yield, 1000 grain weight and test weight. Analysis of variance was found highly significant effect of year on the grain yield ($F=18.358^{**}$), 1000 grain weight ($F=13.237^{**}$) and test weight ($F=10.234^{**}$). Based on the analysis of variance, it can be concluded that there are very significant differences in grain yield, 1000 grain weight and test weight regard the treatments of fertilization (Table 3).

Table 3 *The analysis of variance for the traits analyzed in Kragujevac, Serbia*

Effect	df	Mean sqr Effect	Mean sqr Error	F	p-level
The analysis of variance for grain yield					
Year, (Y)	1, 58	33.494	1.824	18.358	0.0002
Fertilization, (F)	5, 54	16.480	1.054	15.635	0.0000
Year x Fertilization, (YxF)	5, 48	0.865	0.398	2.173	0.0726
The analysis of variance for 1000 grain					
Year, (Y)	1, 58	55.296	4.177	13.237	0.0006
Fertilization, (F)	5, 54	35.945	2.183	16.468	0.0000
Year x Fertilization, (YxF)	5, 48	0.678	1.233	0.550	0.7376
The analysis of variance for test weight					
Year, (Y)	1, 58	53.941	5.271	10.234	0.0022
Fertilization, (F)	5, 54	26.835	4.175	6.427	0.0001
Year x Fertilization, (YxF)	5, 48	9.961	2.536	3.928	0.0046

The grain yield was in a positive correlation with the 1000 grain weight as well as with the test weight (Table 4). Barley yield in 2009/10 growing season was positively and highly significant correlated with 1000 grain weight (0.718^{**}), but in the 2010/11 vegetation season grain yield in was positively and highly significant correlation with the 1000 grain weight (0.720^{**}) and test weight (0.666^{**}). The present results confirm the statement of many authors that the traits analyzed and their correlations are genetically determined but are strongly modified by the nutrient status of the environment and weather conditions (Popović *et al.*, 2011; Madić *et al.*, 2014; Jelic *et al.*, 2015; Đekić *et al.*, 2017; Jamil *et al.*, 2017; Terzic *et al.*, 2018).
Table 5 shows the correlation coefficients between the studied fertilization treatments and analysed traits. Positive correlations were observed between grain yield and thousand grain weight in all treatments. Positively and strong correlations were observed between grain yield and thousand grain weight in the NP_2 ($r=0.725^{*}$), in the NP_1K ($r=0.836^{**}$) and treatment NP_2K ($r=0.711^{*}$). Positively and medium strong correlations were observed between thousand grain weight and test weight in the unfertilized control ($r=0.669^{*}$), in the NP_1K ($r=0.698^{*}$) and treatment NP_2K ($r=0.649^{*}$).

^{ns}-non significant; *-significant at 0.05; **-significant at 0.01

Conclusion

As the result of favourable weather conditions i.e. sufficient amounts of precipitation at major stages of plant development and moderate temperatures at the end of the growing season, the average grain yield of all treatments was significantly higher in 2010/11 than in 2009/10. Averaged across treatment, thousand grain weight and test weight were significantly greater in 2010/11 than in the previous year. Averaged across years, grain yield and 1000 grain weight was significantly greater in NP_1K and NP_2K than in the other treatments. Regardless of year, NP_1K and NP_2K treatments had significantly higher values for 1000 grain weight compared to the other treatments. Across years, there was considerable inconsistency in differences in traits among the treatments (fertilization x year interaction).

Abstract

The experiment was established at the experimental field of the Small Grains Research Centre in Kragujevac (Serbia) during the two growing seasons. The objective of the research was to evaluate the effect of genotype and the environment on the grain yield of winter wheat cultivars (Takovčanka, Kruna, Planeta and Vizija). The following characteristics were analysed: grain yield, 1000 grain weight and test weight. The average grain yield of all cultivars in the 2010/11 growing season was significantly greater than in the 2009/10 year, mostly as the result of highly favourable weather conditions at major stages of plant development. Takovčanka and Kruna gave significantly higher grain yields in all years compared to Planeta. Averaged across years, significantly higher values for 1.000 grain weight were found in Planeta and test weight was found in Takovčanka. Different responses of cultivars to variable agroenvironmental conditions in terms of grain yield and 1.000 grain weight and test weight require the use of a number of cultivars in the crop structure.

Keywords: *cultivars, grain yield, wheat, quality characteristics*

Introduction

Wheat productivity and grain quality in Central Serbia are governed by a range of factors, notably climate, soil, genetics and crop nutrition. Soil acidity in wheat fields in Central Serbia has become a severe problem that leads to a significant decline in grain yield and quality of wheat (Đekić *et al*., 2013, Jelic *et al*., 2015). The yield per unit area is the result of the action of factors of genotypic factors and their interaction with environmental factors. Therefore, yield is a relative term and is determined by the variety, environmental conditions and the level of applied technology. Yield is largely dependent on the genetic potential, which could be defined the yield of variety which was grown in conditions on which it had been adapted, with adequately amounts of water and nutrients and efficient control of pests, diseases, weeds and other stresses (Đekić *et al*., 2014; 2019). Yields considerably vary primarily as a result of agro-ecological conditions during the growing season (Hristov *et al*., 2011; Đekić *et al*., 2012; Jelić *et al*., 2014; Djuric *et al*., 2018; Jordanovska *et al*., 2018; Terzić *et al*., 2018b).
In the production of wheat, the correct reonization (regional distribution) of varieties is very important, and it can contribute to a lesser variation in realized yields and achieving better average results (Dodig *et al*., 2008; Luković *et al*., 2014; Jordanovska *et al*., 2018; Terzić *et al*., 2018b; Đekić *et al*., 2019). Bearing all this in mind, it is necessary that climatic conditions are in accordance with the biological requirements of the plants. In the last few years, extreme temperatures and disturbances in the amount and distribution of precipitation have significantly affected the reduction in the total production of organic matter and yield reduction (Jelic *et al*., 2015; Perišić *et al.* (2016). In the continental climate, winter wheat has long been exposed to the influence of weather conditions, and hence the climate extremes.
Production of winter wheat with high grain yield and appropriate quality is possible only by choosing varieties of good quality with appropriate cultivation conditions and appropriate

production technology. The aim of this study was to determine the cultivars and the influence of ecological environmental factors on differences in stability and adaptability of cultivars regarding the grain yield, 1.000 grain weight and test weight of tested winter wheat cultivars, for the production conditions of Serbia.

Material and methods

Meteorological conditions

Kragujevac area is characterized by a moderate continental climate, which general feature is uneven distribution of rainfall by month. Data in Table 1 for the investigated period (2009-2011) clearly indicate that the years in which the researches were conducted differed from the typical multi-year average for Kragujevac region, regarding the meteorological conditions.

Table 1 *Precipitation sum and average monthly temperature in Kragujevac, Serbia*

Months	Mean monthly air temperature (^oC)			The amount of rainfall (mm)		
	2009/10	2010/11	Average	2009/10	2010/11	Average
X	11.7	10.2	12.5	102.6	86.9	45.4
XI	8.8	11.4	6.9	77.5	27.9	48.9
XII	2.6	2.4	1.9	194.2	50.1	56.6
I	0.9	0.9	0.5	57.0	29.1	58.2
II	3.2	0.5	2.4	150.5	48.5	46.6
III	7.2	7.2	7.1	43.3	20.4	32.4
IV	12.1	12.0	11.6	142.2	20.8	51.9
V	16.5	15.8	16.9	116.7	65.8	57.6
VI	20.2	20.9	20.0	196.7	32.3	70.4
Average	9.24	9.03	8.87	1080.1	381.8	468.0

The average air temperature in 2009/10 was higher by 0.37°C and 2010/11 was higher by 0.16°C than the average of many years. The amount sum of rainfall precipitation in 2009/10 was higher by 612.1 mm, whereas the respective rainfall in 2010/11 was 86.2 mm lower than the average of many years and with a very uneven distribution of precipitation per months. During the April and May in 2009/10 there were 142.2 mm and 116.7 mm of rainfall, and this was 90.3 mm and 59.1 mm higher compared to the perennial average. During June in 2009/10 it was 196.7 mm of rainfall, and this was 126.3 mm higher compared to the perennial average.

The total amount of precipitation is reflected on the multi annual average, but the distribution, especially at critical stages of development, is significantly disturbed in the 2009/10 year. In addition to the necessary reserve for the spring part of the vegetation, winter precipitation greatly influences the distribution of easily accessible nitrogen in the soil (Đekić *et al*., 2014; Jelic *et al*., 2015; Grčak *et al*., 2018; Milivojević *et al*., 2018; Terzić *et al*., 2018a).

Experimental design and statistical analysis

During the 2009/10 and 2010/11 cropping seasons, four cultivars of winter wheat (Takovčanka, Kruna, Planeta and Vizija) grown at the experimental field of the Small Grains Research Centre in Kragujevac (Serbia) were studied.

The soil used in the trial was vertisol having a very acid reaction (pH in KCI: 3.92-4.27), the content of total nitrogen was medium (0.12-0.15%), the content of affordable phosphorus was high (26.9 mg P_2O_5/100 g soil), and the content of affordable potassium was high ranging from 19.5 to 21.0 mg of K_2O/100 g of soil. The climate of the region was characterised by variable precipitation and an uneven distribution across months. A randomised block design with three replications and the plot size was 10 m^2 (5 m x 2 m) was used. In all years, winter wheat was sown in the second half of October at a row spacing of 12.5 cm. Along with

primary tillage, 400 kg/ha complex NPK (15:15:15) was incorporated into the soil, while during the spring fertilization the soil was supplemented with 300 kg/ha (KAN 27%N). During the growing season, common cultural operations were applied, without irrigation. The following traits were analysed: grain yield, 1000 grain weight and test weight. Grain yield was measured for each plot and calculated as grain yield in t/ha at 14% grain moisture. Then, a sample was taken for 1000 grain weight and test weight determination.
On the basis of achieved research results the usual variation statistical indicators were calculated: average values, standard error and standard deviation. Statistical analysis was made in the module Analyst Program SAS/STAT (SAS Institute, 2000).

Results and discussion

Table 2 shows the impact of the year, cultivar and interaction of year x cultivar on yield, 1.000-grain weight and test weight. The analysis of variance revealded a highly significant effect of year on the grain yield (F=17.913**) and 1.000-grain weight (F=60.540**). Based on the analysis of variance, it can be concluded that there are very significant differences in grain yield and 1.000-grain weight regarding the year of investigation, while among the investigated wheat cultivars the differences were not significant (Table 2).

Table 2 *Analysis of variance of the tested parameters*

Sources of variation	df	Mean squares		
		Grain yield, t/ha	1.000-grain weight, g	Test weight, kg/hl
Year	1	17.913**	60.540**	0.0002^{ns}
Cultivar	3	0.787^{ns}	0.132^{ns}	0.989^{ns}
Year x Cultivar	3	9.340**	1.216^{ns}	0.440^{ns}

** F –test significant at 0.01; * F –test significant at 0.05; ^{ns} –non-significant

As the result of favourable weather conditions i.e. sufficient amounts of precipitation at major stages of plant development and moderate temperatures at the end of the growing season, the average grain yield of all cultivars was significantly higher in 2010/11. Significantly lower yields were obtained in 2009/10 (Table 3).

Table 3 *Mean values for the tested parameters at winter wheat cultivars*

		GY (t/ha)	TW (kg/hl)	1.000GW (g)
Years	2009/10	3.897^{b}	71.20^{b}	37.63^{a}
	2010/11	4.602^{a}	77.36^{a}	37.64^{a}
Cultivar	Takovčanka	4.347^{a}	75.10^{a}	36.93^{a}
	Kruna	4.480^{a}	74.02^{a}	37.50^{a}
	Planeta	4.075^{a}	73.76^{a}	38.25^{a}
	Vizija	4.095^{a}	74.23^{a}	37.87^{a}

*Means within columns followed by different lowercase letters are significantly different according to the LSD test

The average grain yield of wheat cultivars ranged from 3.897 t/ha in 2009/10 to 4.602 t/ha in 2010/11. In all years, Takovčanka and Kruna produced significantly higher grain yields compared to Planeta. The average two-year value of test weight in Takovčanka cultivars was 75.10 kg/hl. The 1.000-grain weight of winter wheat varied across cultivars, from 36.93 g in cultivar Takovčanka to 38.25 g in cultivar Planeta. Thousand grain weight and test weight were significantly greater in 2010/11 than in the previous year.
The differences in the yields that were observed in the tested varieties in our experiment are the result of varietal specificities, which are mostly genetically conditioned. Thus, by

analysing the obtained results it can be concluded that there is a significant dependence of grain quality components on the genotype, and this is in agreement with the results of Đekić *et al.*, (2014), Perišić *et al*. (2016) and Terzić *et al*. (2018b).

Table 4 *Mean values for the tested parameters at winter wheat cultivars in two vegetation seasons*

		Grain yield (t/ha)	Test weight (kg/hl)	1.000-grain weight (g)
2009/10	Takovčanka	4.273[b]	72.52[a]	36.63[a]
	Kruna	4.007[a]	71.38[a]	37.10[a]
	Planeta	3.967[a]	71.08[a]	38.57[a]
	Vizija	3.340[a]	69.82[a]	38.23[a]
2010/11	Takovčanka	4.420[bc]	77.68[a]	37.23[a]
	Kruna	4.953[a]	76.67[a]	37.90[a]
	Planeta	4.183[c]	76.44[a]	37.93[a]
	Vizija	4.850[ab]	78.64[a]	37.50[a]

[*]Means within columns followed by different lowercase letters are significantly different according to the LSD test

Averaged across years grain yield was higher in Kruna and Takovčanka than in the other cultivars (Table 4). In two cropping seasons the average grain yield of the wheat cultivars ranged from 4.273 t/ha to 4.420 t/ha in Takovčanka, 4.007 t/ha to 4.953 t/ha in Kruna, 3.967 t/ha to 4.183 t/ha in Planeta and 3.340 t/ha to 4.850 t/ha in Vizija. Regardless of year, Takovčanka had higher values for test weight compared to the other cultivars. The 1.000 grain weight was higher at Planeta than in the other cultivars.

Table 5 *Correlation coefficients by studied environments in wheat*

	Grain yield	Test weight	1.000 grain weight
Correlations between the traits analysed in the 2009/10			
Grain yield	1.00	0.487	-0.366
Test weight		1.00	-0.073
1.000 grain weight			1.00
Correlations between the traits analysed in the 2010/11			
Grain yield	1.00	0.127	0.179
Test weight		1.00	0.202
1.000 grain weight			1.00
Correlations between the traits analysed in the 2009/11			
Grain yield	1.00	0. 708[**]	-0.121
Test weight		1.00	0.001
1.000 grain weight			1.00

[*] $p<0.05$; [**] $p<0.01$

The average values of the Pearson's coefficient of correlation (*r*) of investigated winter wheat traits are presented in Table 5. The established correlation coefficients between the grain yield and test weight in both vegetation seasons as well as during the two-year research were positive. The established correlation coefficients between the grain yield and the 1000 grains weight in both vegetation seasons as well as during the two-year research were negative, except in the second year of research in which a positive coefficient of correlation was noticed. The importance of these components in the formation of grain yield depends on the climatic conditions during the critical phases of growth and development, the applied agro-technology and the various combinations and relationships of NPK nutrients (Hristov *et al.*, 2011; Đekić *et al*., 2014; Jelić *et a*l., 2014; Djuric *et al*., 2018; Terzic *et al*., 2018a). Therefore, it is important to know the effect of these properties, i.e. yield components, as well as their interdependence on grain yield.

Conclusion

Based on the results during the two-year investigation in four Kragujevac's winter wheat cultivars, it can be concluded that the grain yield of wheat ranged from 4.075 t/ha (Planeta) to 4.480 t/ha (Kruna). The highest two-year average value of test weight was found in the cultivars Takovčanka (75.10 kg/hl). Winter wheat cultivars had test weight greater than 70 kg/hl. The highest 1.000 grain weight of investigation in winter wheat Planeta cultivar (38.25 g). During 2010/11 cropping season, statistically significantly higher grain yield per area unit, as well as 1.000 grain weight was obtained, compared to the 2009/10 cropping season.

On the base of studied parameters the wheat cultivars Takovčanka and Kruna were more tolerant to adverse chemical soil characteristics (low pH) and can be recommended as a suitable genotypes for wheat production on acid soils, especially after liming of soil. Different responses of cultivars to variable agroenvironmental conditions, particularly in terms of major grain quality indicators, require the use of a number of cultivars in the crop structure.

Acknowledgements

Investigations necessary for this paper are part of the project TP 31054 "Development of new cereals cultivation technologies on acid soils by usage of modern biotechnology", financed by the Ministry of Education, Science and Technology Development of Republic of Serbia.

PRODUCTIVITY AND BIOCHEMICAL COMPOSITION OF SOYBEAN GRAIN, DEPENDING ON THE MEANS OF PROTECTION

Tatyana ASEEVA*, Anna TISHKOVA, Natalia SAVCHENKO

Far Eastern Agricultural Research Institute, Russia
*Corresponding author: aseeva59@mail.ru

Abstract

The study was conducted in 2015-2017 in order to obtain experimental data on the impact of soybean protection technologies on the productivity and biochemical composition of soybean grain. Biological and chemical agents (TMTD, Immunocitofit, Zircon, Bisolbifit, Extrasol, Nutri-Veit with water softener Spartan, liquid humic fertilizer Optimo) were studied for plant protection on the example of *Ivan Karamanov* soybean cultivar. The experimental plots were laid in cereal-soybean crop rotation on meadow-brown heavy loamy soil on the base of the Far Eastern Agricultural Research Institute (Khabarovsk, Russia). The application of pesticides and biological agents in soybean crops contributed to a statistically significant increase in soybean yield compared to control (without treatments): 1.2, 1.03 and 0.8 tons ha^{-1} on the plots where seeds and crops were treated by Zircon, Extrasol and TMTD with Optimo, respectively. The highest protein contents were observed on plots with the application of TMTD (35.75 %); TMTD with Optimo (35.72 %); Zircon (35.56 %); Extrasol (35.47 %). The largest fat content was in grain obtained from plots where seeds and crops were treated by Zircon (16.5 %).

Keywords: *Soybean, productivity, protein, fat, plant protection.*

Introduction

"No other plant can compete with soybean by the amount of valuable nutritional products and substances produced per sowing area unit" – the words of V.A. Zolotnitskiy. Soybean uniqueness, versatility of use is determined by its chemical composition – the content of organic and inorganic matters in seeds and green mass (Vashchenko *et al*., 2010).

This crop plays a special role because of the need of producing high-protein food for the population. High nutrition value of soybean products is due to the presence of high-grade protein (30-50 % and more) and oil (15-26 %) in seeds (Dospekhov, 1985). Besides proteins and lipids, soybean seeds are rich in mineral elements: Fe, I, Cu, Zn, Mn, Co, Mo, Se, Cr, Ni, Sn, Si, F, V (Shchegorets, 2002).

The use of soybean and its products is carried out in three directions worldwide:

1. The improvement of nutrition and its therapeutic and preventive effects on humans. Currently, in many countries soybean becomes the main source of protein for the food industry. Soybean oil takes the first place in global production of all vegetable oils, and soybean products are classified as "healthy" having a preventive or therapeutic effect on a number of diseases (Shchegorets, 2002). It is also possible to produce full-fat or low-fat flour, margarine, mayonnaise, soy milk, tofu, dry soy base, soy sauce, soy mince, complex of soy milk products from soybean. From soybean seeds of small-seed cailtivars could be done seedlings, rich in biologically active substances (Shchegorets, 2002).
2. The improvement of productivity and efficiency of animal husbandry. It has been established that with regular feeding of animals with soybean the average daily gain in live weight doubles; feed consumption per unit of livestock production is reduced by 30-35 %; quality of livestock products rises (Shchegorets, 2002).

3. Industrial production. Construction plates, artificial fabrics and materials, fertilizers and other goods are produced from raw soybean materials that are not used in the food industry and animal husbandry (Shchegorets, 2002).

Natural and climatic conditions of the Russia's Far East are comparatively favorable for the cultivation of soybean. But the yield in recent years was 1.2-1.5 tons ha^{-1}, with a potential of 3.0-3.5 tons ha^{-1}. One of the main reasons of low grain yield of soybean is high fungal diseases occurrence. To reduce this impact we develop and test new strategies for the protection of this culture.

Materials and methods.

The study was conducted in 2015-2017 in the grain-soybean crop rotation on the experimental fields of the Department of breeding and seed production (Far Eastern Agricultural Research Institute, Russia). The soil of experimental plots was meadow-brown, heavy loamy, and has the following characteristics: humus content (by Tyurin) – 4.8; P_2O_5 (by Kirsanov) – 4.3 mg per 100 g of soil; K_2O (by Maslova) – 20 mg per 100 g of soil. The experiment was held according to the Methodology of field trials (Dospekhov, 1985) to determine the main indicators of biochemical composition of soybean (protein, fat). Soybean grain was sent to the analytical laboratory.

The objects of research were: chemical seed treater TMTD (thiram, 400 g per 1 litre); biological agents – Immunocytofit (arachidonic acid ethyl ester, 20 g per kg); Zircon (hydroxycinnamic acid 0.1 g per 1 litre); Bisolbifit and Extrasol (strain of *Bacillus subtilis* H-13, 100 millions of CFU per ml); liquid foliar fertilizer Nutri-Veit (28 % of phosphorus in form of PO_3 and 26 % of potassium) with water softener Spartan; liquid humic fertilizer (LHF), as well as the chemical fungicide Optimo (pyraclostrobin, 200 g per 1 litre). The implementation of different protective schemes was performed by dressing seeds and spraying plants during the growing season.

The experiment was arranged in a randomized complete block design with four replications on plots 50 m^2 in size, with the cultivar of soybean "Ivan Karamanov". Crops were grown according to conventional technology generally accepted in a region. Seeds were treated with water moistening 10 litres per ton, according to the experimental design, the day before sowing (Table 1).

Soybean seeds were sown on experimental plots in the first decade of June at a rate of 300,000 plants ha^{-1} (70 kg of seeds ha^{-1}) in moist well prepared soil to the depth of 3-4 cm on a profiled surface (ridge 140 cm).

Table 1. Experiment design (treatments of seeds and plants)

Variant	Seeds treatment	Plants treatment during growing season

7. Bisolbifit	Bisolbifit 2 kg/t	

8. Extrasol	Extrasol 2 l/t	Extrasol 2 l/ha during trifoliolate leaves and flowering stages
9. LHF	LHF 0,4 l/t	LHF 0,4 l/ha during trifoliolate leaves and flowering stages
10. TMTD + Optimo	TMTD 6 l/t	Optimo 0,5 l/ha with disease symptoms appearance

During the years of study hydrothermal conditions varied tremendously. During the first period of growing season of 2015 the weather conditions were unfavorable. Heat supply in this period was insufficient. Due to the low temperature regime, heat accumulation was slow. Soybean plants were stunted. Hydrothermal conditions of 2016 were close to average long-term indicators, but were not evenly distributed during the growing season. The accumulation of heat was slow, heat supply of plants was insufficient. The weather conditions of June 2017 were unfavorable for the growth and development of soybean plants. Further vegetation of plants took place under favorable conditions.

Results and discussion

Studied remedies combined fungicidal properties with growth regulating and anti-stress activity, which had a positive effect on growth, development, structural elements of yield and productivity of soybean.

Significant increase in yield by 1.2; 1.03 and 0.8 t ha^{-1} comparing to control was obtained by seed dressing and spraying of growing plants with Zircon, Extrasol, Spartan with Nutri-Veit (Table 2).

4. Immunocytofit	24.8	10.2	169.7	3.02
5. Spartan + Nutri-Veit	29.8	12.1	175.2	3.62
6. Zircon	31.4	12.9	173.6	3.88
7. Bisolbifit	25.9	10.6	170.1	3.18
8. Extrasol	26.8	12.4	179.6	3.71
9. LHF	24.6	10.4	172.6	3.13
10. TMTD + Optimo	26.8	11.3	177.4	3.48
$LSD_{0,5}$	4.4	1.5	12.9	0.42

It is not a secret that agrometeorological conditions of the growing season, system of treatments and protective measures have the greatest impact on the yield development. Under favorable weather conditions and high-quality agricultural technology, soybean plants grow and develop accumulating nutrients, which are later converted into protein and fat. The use of biological and chemical means of protection smoothed the negative impact of the adverse meteorological conditions and contributed to an increase in assimilation surface of soybean plants, which in turn affected the protein and oil content in grain.

Table 3. The influence of tratments on the protein and lipid content of soybean cultivar "Ivan Karamanov" (average for 2015-2017)

Variant	Protein, %	Fat, %
1. Control (without treatment)	35,37	14,8
2. Standard - TMTD	35,75	15,1
3. TMTD + Immunocytofit	33,92	15,0
4. Immunocytofit	35,42	14,7
5. Spartan + Nutri-Veit	34,40	15,2
6. Zircon	35,56	16,5
7. Bisolbifit	35,27	15,0
8. Extrasol	35,47	15,1
9. LHF	35,36	14,7
10. TMTD + Optimo	35,72	14,8

The highest protein content was observed in variants treated with: TMTD – 35.75 %; TMTD with Optimo – 35.72 %; Zircon – 35.56 %; Extrasol – 35.47 %. The highest fat content was in grain obtained from dressing seeds and spraying plants with Zircon – 16.5 %.

Conclusion

Among the diversity of cultivated crops, soybean exceeds others by its versatility of use (Dega, 2012). As a bean crop, soybean nutritionally surpasses all crops and feeds of natural meadows and pastures (Burlaka, 1965). The biochemical composition of its grain is unique. It contains 30-50 % easily digestible and balanced in amino acids protein, 16-26 % of oil, favorable in fatty acids composition, 20-25 % of carbohydrates, 5-6 % of salts and vitamins. With the improvement of advanced soybean processing technologies, the products made from it are widely used in bakery, confectionary, canning, meat and dairy, textile, paint and varnish, soap making, pharmaceutical, automotive, aviation and several other industries (Dega, 2012).

According to results of our research, significant increase in yield of soybean by 1.2; 1.03 and 0.8 t ha^{-1} was obtained in variants with seeds and plants treatments with Zircon, Extrasol, Spartan with Nutri-Veit. The highest protein and fat contents were observed in grain from plants treated with TMTD, TMTD with Optimo, Zircon, Extrasol; and Zircon respectively.

Abstract

The Far Eastern region is characterized by difficult soil and weather conditions, which have no analogues in the Russian Federation and neighboring countries. Currently, only 18 cultivars of spring triticale have been entered into the State Register of Protected Breeding Achievements and Approved for Use in the Russian Federation, therefore the expansion of the cultivated biodiversity of this crop in the area of high risk farming is undoubtedly an urgent task. In this regard, the purpose of research is to study the formation of spring triticale productivity in a monsoon climate. Field experiments conducted in the 2015-2018 year period. The object of research is testing of 10 cultivars of spring triticale of various ecological and geographical origins. The soil of experimental fields is a meadow-brown podzolized-gley heavily loamy. It was revealed that in the conditions of a monsoon climate, the need for heat and moisture in certain periods of organogenesis in spring wheat and spring triticale are diametrically opposed. The correlation dependences between the grain yeld of triticale cultivars and the parameters of environmental factors are established: the sum of the temperatures of the surface air layer and the amount of precipitation. Under the conditions of a monsoon climate, productive and promising genetic sources and donors of various ecological and geographical origins were identified for their involvement in the breeding process in order to expand the biological diversity of grain crops and increase the efficiency of rational use of natural agro-resources.

Keywords: *Far East region, crop productivity, crop cultivars, Russia*

Introduction

The most promising way of providing the world's population with a sufficient amount of healthy food can be done by the introduction of highly productive plants with valuable biochemical composition, which is especially important for Russia, where the variety of crops available for growing is limited (Kochetov *et al*., 2012). One of the most important reserves for increasing gross grain harvest is the use of uncommon for Russia culture in grain production - spring triticale. Triticale, occupying a certain niche in the structure of cultivated areas, expands biodiversity, thereby increasing the sustainability of crop production (Tylenko and Skatova, 2015). It is believed that the growth potential of its yield is significantly higher than that of wheat. Already at the present time, triticale ranks first in yield among cereal crops (Aydiev *et al*., 2016). Studies on the biological basis of triticale productivity and the creation of high-yielding forms of this promising culture are currently among the most promising areas in grain breeding (Emelyanova et al., 2018). Due to the specific genome, which includes the components of wheat and rye, triticale has a high potential for increasing productivity and is promising in the context of a lack of means of intensifying agricultural production.
Since 2009, triticale has been included in the list of grain crops in the final data of Rosstat. Amount triticale produced in Russia is insignificant if compared to other types of crops. According to the data, the share of this crop in the structure of the sown area of the country is 0.2-0.3% and the crops occupy an area of 165 to 251 thousand hectares. The average grain yield of triticale in the Russian Federation for 2009-2018 period reached 1.8-2.9 t/ha. Currently, 18 varieties of spring triticale have been entered into the State Register of Protected

Breeding Achievements and Approved for Use in the Russian Federation, which is not enough for use in various regions of the country, therefore expanding the varietal biodiversity of this crop in a monsoon climate is undoubtedly an urgent task.
The climate of the Far East sharply differs from the climate of the main agricultural regions of the Russian Federation and adjacent states. At the corresponding latitudes of the globe there are no analogues to it. According to the combination of soil and climatic factors, this region belongs to the zone of risk farming. Spring in all areas is late, long and cold. Rainfall in the spring and early summer periods, as a rule, is not enough. The second half of summer, on the contrary, abounds in precipitation and heat, and the relative humidity of air in this period reaches 100%. High humidity of the air and soil, combined with a rather high temperature during the period of ripening of cereal crops, contributes to the mass spread of diseases, including loose smut, Fusarium, dark brown spot and other diseases. All this has a negative effect on the realization of the genetic potential of productivity, especially in varieties of grain crops of foreign and foreign selection, which do not withstand water logging and high infectious load.
In this regard, the purpose of this research is to study the formation of spring triticale productivity in a monsoon climate.

Materials and Methods

The field experiments were conducted in the 2015-2018 year period. The object of research is 10 cultivars of spring triticale of various ecological and geographical origin. The standards – the zoned cultivar of spring soft wheat Khabarovchanka and the cultivar of spring triticale Ukro recommended for cultivation in this ecological zone. The soil of experimental fields is a meadow-brown podzolized-gley heavy loamy. Agronomyis common for the conditions of this region and they include: late autumn plowing, spring cultivation, harrowing in two wakes and sowing. Sowing of grain crops was carried out by the SSFC-7M seeder on plots with an area of 4 m^2 and randomized 3-fold with a seeding rate of 5.5 million viable seeds/ha. Accounting for the collection of spring triticale samples was carried out by the method of sub-section continuous threshing with the Hege-125 combine, followed by weighing and reduction to standard humidity and purity.
Field observations, measurements and biochemical analysis were carried out in full compliance with the field case methodology (Dospekhov, 1985), the state crop testing method (1985) and the methods of plant biochemical studies (Ermakov, 1987). Statistical processing of experimental data was performed using analysis of variance, correlation, and regression analysis using the Statistics v 10.0 software (Stat Soft, Inc., USA).

Results and Discussion

The Far Eastern region of Russia has sufficient natural and climatic resources for growing crops such as spring triticale. A main feature of meteorological conditions in recent years is a shortage of heat in the month of June with sharp amplitude of fluctuations in day and night temperatures of the surface air layer and rainy weather (Figure 1). Thus, the hydrothermal conditions during the years of research were diverse, rather fully reflecting the particularities of the monsoon climate, which made it possible to evaluate with a high level of confidence the influence of environmental factors on the growth, development and productivity of the samples of spring triticale under study.

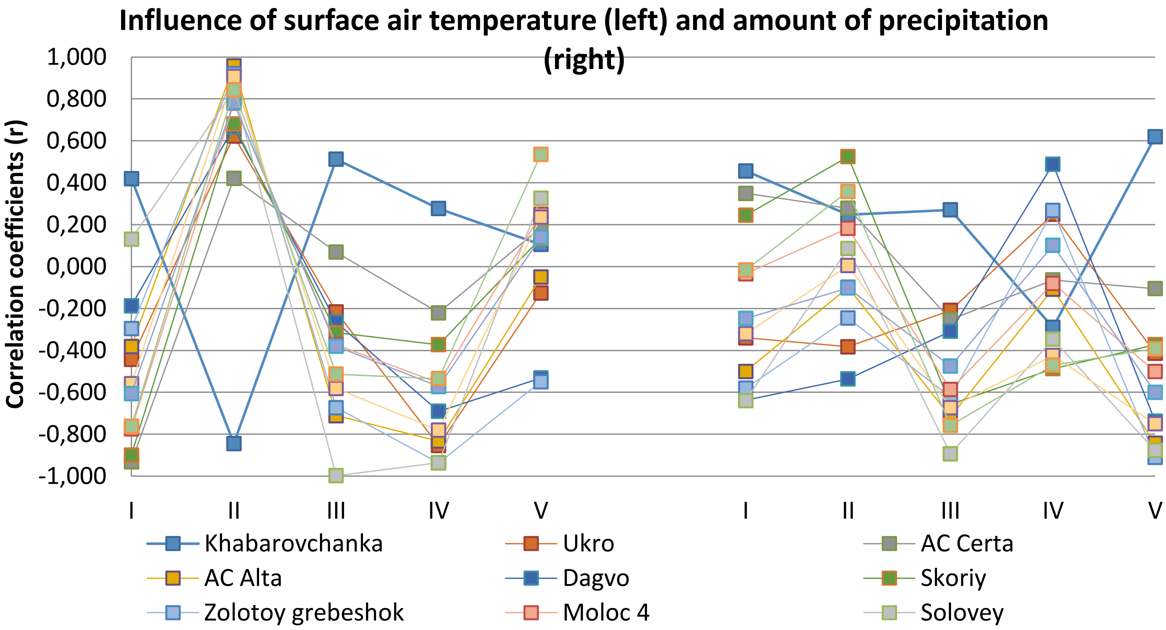

Figure 1. Agrometeorological conditions during research.

Main criterion of the economic value of a specific cultivar is grain yield. Overall grain yield of spring triticale cultivars AC Certa, Dagvo, Zolotoy grebeshok, Losinovske, Zgurivsky, exceeded the yield of standard varieties Khabarovchanka (spring wheat) and Ukro (spring triticale) by 0.1-0.6 t/ha (Table 1). Under the conditions of a monsoon climate, cultivar differences in productivity, according to the data in the table, were significant for triticale plants.

Table 1. Efficiency of spring triticale cultivars samples.

Cultivar	Productivity, t/ha		The protein content in grain, %		R	Linear regression equation	R^2
	X	lim	X	lim			
Khabarovchanka	2.2	1.5-2.9	15.5	13.9-16.2	0.80*	y=10.135+0.232*x	0.64
Ukro	2.2	1.4-2.6	15.0	13.3-15.9	-0.94*	y=18.665–0.183*x	0.88
AC Certa	2.8	1.7-3.6	14.9	14.1-15.6	-0.84*	y=16.511–0.059*x	0.70
AC Alta	1.9	1.5-2.4	15.0	13.1-17.0	-0.63*	y=20.504–0.289*x	0.40
Dagvo	2.3	1.1-2.9	15.0	12.9-18.1	0.04	y=14.767–0.011*x	0.01
Skoriy	2.2	1.9-2.3	15.5	13.9-16.9	-0.36	y=20.435–0.231*x	0.13
Zolotoy grebeshok	2.7	1.6-3.8	14.9	14.0-15.7	-0.28	y=15.521–0.024*x	0.08
Moloc 4	1.7	1.1-2.6	15.2	13.2-16.4	-0.62*	y =17.134–0.116*x	0.38
Solovey	1.9	1.1-2.8	14.9	13.7-16.9	-0.84*	y=21.231–0.287*x	0.71
Losinovske	2.6	1.5-4.1	14.9	14.1-16.4	-0.60*	y=16.388–0.056*x	0.36
Zgurivskiy	2.4	1.6-3.2	14.9	14.1-15.5	-0.62*	y=16.358–0.057*x	0.38
Brio	2.1	0.8-3.6	15.3	14.1-16.4	-0.69*	y=16.466–0.056*x	0.48

Note: X is the average value; lim is the minimum and maximum value; R is the correlation coefficient between yield and protein content in spring triticale grain.

A grain of valuable triticale class I according to GOST 34023-2016 (Russia) must contain at least 12% protein. A comparative assessment of quality indicators in the same environmental conditions shows that the protein content of spring triticale samples averaged 14.0-15.5%, which is at the level of the standard cultivar of spring wheat Khabarovchanka. Leadership in protein content in grain was noted in the cultivars AC Alta and Dagvo, in which the accumulation of protein substances in the grain in optimal hydrothermal conditions reached 17.0-18.0%. Varietal differences in protein content in the grain of spring triticale were revealed – higher quality grains were formed by the cultivars Skoriy and Brio. The variability of weather and climatic conditions is the main cause of instability in the quality of grain of cereals. In cool and wet conditions, the protein in the spring triticale grain accumulates less than in drier and warmer years. With an increase in yield, the protein content of the grains significantly decreases (R= -0.52), while the realization of the productive potential depends on the degree of compliance of the biological characteristics of an individual cultivars of agroclimatic and weather conditions of the region (Figure 2).

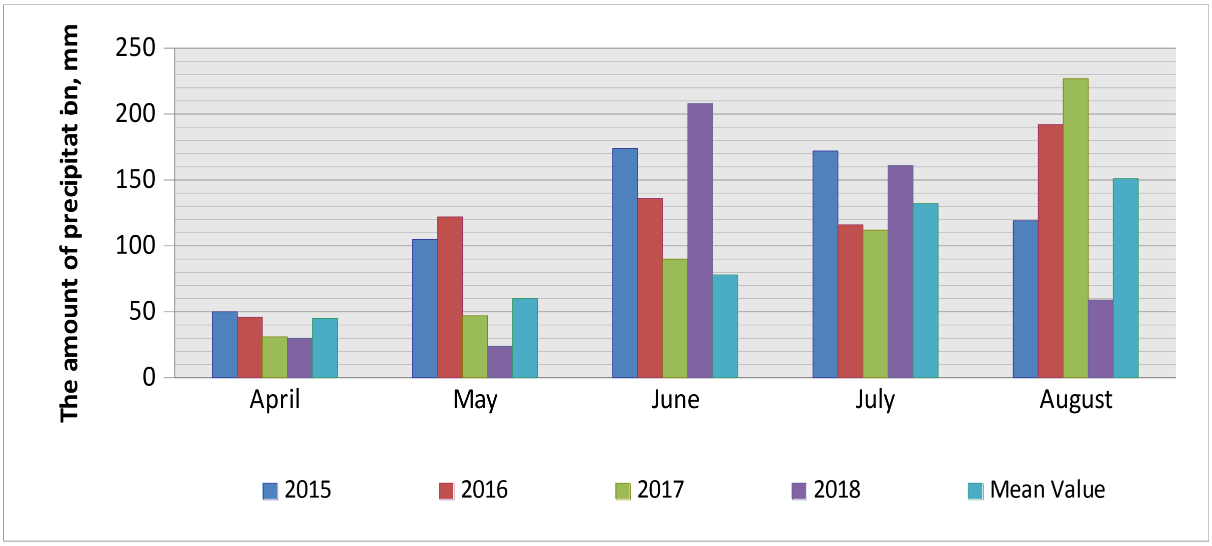

Fig. 2. The relationship between the yield of triticale and hydrothermal environmental conditions at different stages of organogenesis (I – Planting-sprouting, II – sprouting-tillering, III – tillering-jointing, IV – jointing-heading, V – heading-ripeness)

High temperature regime during the period of sprouting of spring triticale contributes to an increase of the tillering and the density of the productive stalk, while having a negative effect on the formation of spring wheat plants. Excessive water logging and the high temperature of the surface air layer during the period of jointing leads to a further loss of spikelets, higher levels of sterility and lower amount of grain per ear. Increased summary of temperatures and abundant rainfall in the reproductive period reduce the yield of triticale , but have a positive effect on the grain yield of spring wheat plants.

The magnitude of the multiple correlation coefficient indicates a close dependence of the yield and protein content in the grain of spring triticale on the agro-ecological conditions of the monsoon climate (R=0.78 and R=0.91, respectively). Combined effect of the temperature of the surface air layer, the amount of precipitation and moisture supply during the growing season determines the 61% of the yield variation and 83% of the variation in protein content in the grain of spring triticale. The remaining 39% and 17%, respectively, are attributed to factors unaccounted for in the regression model.

Conclusions

Thus, it has been established that in the conditions of a monsoon climate, different cultivars of spring triticale use different mechanisms in the formation of productivity. Cultivation of spring triticale in this ecological zone allows you to successfully harvest 2-3 t/ha of grain, but when exposed to stressful environmental factors, the yield varies from the average value by 2 times. According to the results of research, it has been established that the need for heat and moisture in certain periods of plant growth and development in spring wheat and spring triticale are diametrically opposed. At the same time, the productivity of triticale cultivars is depends on the cumulative effect of the temperatures of the surface air layer, the amount of precipitation and the level of moisture supply during the entire growing season.

FEATURES OF THE INFLUENCE OF CLIMATIC FACTORS ON THE CROP AND QUALITY OF GRAIN OF SPRING OATS

Tatyana ASEEVA*, Irina TRIFUNTOVA, Egor TOLOCHKO

Far Eastern Agricultural Research Institute, Russia
*Corresponding author: aseeva59@mail.ru

Abstract

The soil and climatic resources of the Far East of Russia from all grain crops, to the maximum extent corresponds to the biological characteristics of oats. Right now soybean prevails in the structure of sown areas of this ecological zone (72%), while grain crops occupy only 17%, which leads to possible environmental disaster of the natural environment with constant monoculture growing. The purpose of this research is to study the influence of climatic factors on the yield and grain quality of spring oats. The soil of is a meadow-brown podzolized-gley heavily loamy. The standard – zoned cultivar of spring oats Express in this zone was used. According to the economically valuable characteristics, 10 cultivars were selected and analyzed. As a result of research, the correlation between grain quality of different cultivars, meteorological conditions of the growing season and main phenological phases was determined in order to improve the adaptability of oats to environmental conditions. Correlation analysis of the data obtained in the study showed the dependence of the protein content in the grain of the hydrothermal conditions of the growing season. It was revealed that in most of the studied cultivars protein content decreases, while overall grain yield increases, as evidenced by the correlation coefficient ($r = –0.99$). Most cultivars demonstrated a significant positive correlation between completeness and grain size ($r = 0.95$). Grain inner hull in oat cultivar samples is a genetically determined trait with an indirect contribution of environmental conditions.

Keywords: *Spring oat, grain yield, grain quality, correlation analysis, Russia*

Introduction

An adaptive assortment of cultivated crops largely determines the competitiveness of a particular region and the country as a whole in the world grain market. The soil and climatic resources of the Far East of Russia from all grain crops, to the maximum extent correspond to the biological characteristics of oats. The cultivation of grain crops in the region is insignificant and in the last decade there has been a tendency to increase the acreage of soybeans. For 2018, soybean prevails in the structure of sown areas (72%), while grain crops occupy only 17%, which leads to incorrect type of crop rotations and, consequently, to an environmental disaster of the natural environment. The hydrothermal conditions of the cultivation zone have a decisive impact not only on the realization of the of the variety, but also on the quality of the harvest. A distinctive feature of the meteorological conditions in the Far East of Russia, including in the Khabarovsk Territory, is due to the monsoon nature of the climate, which is characterized by a significant amount of precipitation in the summer period. The winter in the region is harsh and long, with little snow, the average January temperature is -16 to -24 ^{0}C, which is why the soil freezes to 2.5-3.0 m. The summer is dry in the first half and rainy in the second. Over the warm period, the amount of precipitation varies by year over a wide range, 360-1048 mm. The sum of active temperaturesfor the period varies from 2460 to 2850 $^{\circ}$C. Accordingly, the air humidity in summer is much higher than in winter. On this basis, the study of the influence of the surface layer of air and the amount of precipitation in the main periods of organogenesis on the formation of yield and grain quality of spring oats is especially important in this ecological zone. In this regard, the purpose of this research is to study the influence of climatic factors on the yield and grain quality of spring oats.

Materials and Methods

Studies were conducted in the 2015-2018 year period in the Far Eastern Scientific Research Institute of Agriculture of Russia. The soil of crop rotation is a meadow-brown podzolized-gley heavy loamy. *Standard* - regionalized the cultivar of spring oats Express. The source material was taken as 100 samples of oats from the world collection of the Russian Institute of Plant Genetic Resources. N.I. Vavilova (VIR, Russia, St. Petersburg). According to the economically valuable attributes, 10 variety samples were isolated and analyzed: 14505 – Express, 14583 – Flamingsgelb, 15018 – Pg 17, 15053 – Nein, 15065 – Irtysh 22, 13717 – Alden, 14040 – Aurea 603, 14433 – Orpale, 14271 – Gallop, 14584 – Praefekt. All surveys and observations during the growing season were carried out in full accordance with the methodology of the field experiment (Dospekhov, 1985), methods of state variety testing of agricultural crops (1985) and the International Classification of the CMEA of the genus Avena (1984). Grain quality was determined using existing methods of biochemical studies of plants (Kazakov, 1987). Statistical analysis were performed using the "Statistics v. 10.0" software, to assess the influence of climatic factors on the grain quality of oats, a Spearman and Pearson correlation analysis was used.

Results and Discussion

The agrometeorological conditions in the years of research were varied, rather fully reflecting the characteristics of the region, which made it possible to evaluate with a high degree of certainty the influence of hydrothermal conditions on the growth, development and productivity of the cultivars. With the average long-year period norm of the amount of heat in April-August 2301.4 ^{0}C during the years of research, the amount of heat varied within 2291.2-2505.1 ^{0}C, the amount of precipitation - within 417-620 mm with a norm – 466 mm. A characteristic feature of meteorological conditions in recent years is a shortage of heat in the month of June with a sharp amplitude of fluctuations in day and night temperatures of the surface air layer and rainy weather. Under current hydrothermal conditions, the yield of the studied varieties during the years of research varied within wide limits – 1.6-6.7 t/ha and averaged 2.5-4.8 t/ha (Table 1). The highest realization of the productivity potential was observed in 2017 for the the cultivars Praefekt and Galop– 6.6 and 6.7 t/ha, respectively.

Table 1. Comparative characteristics of oat cultivars by yield and quality indicators.

Note: min is the minimum value of the attribute, max is the maximum value of the attribute, X is the average value of the attribute.

As a result of our previous studies, a close relationship was found between the yields of grain crops and the hydrothermal conditions of the Far Eastern region of Russia not during the growing season, but during the main periods of growth, development and yield formation (Aseeva and Melnichuk, 2017). According to Sazonova and Sartakova (2006), the quality parameters of oat grains are varietal hereditary traits, which makes it possible to further improve them, but they are subject to strong variability and under the influence of environmental conditions.
Correlation analysis between the quality indicators of oats and environmental conditions in certain periods of growth and development revealed a high degree of dependence between them. It was found that the majority of the studied cultivars, the protein content in the grain decreases with increasing yield, as evidenced by the correlation coefficient (r= -0.991*).
The varietal specificity of the dependence of the protein content in grain on the hydrothermal conditions of the growing season (Table 2) was revealed.

Table 2. The relationship of the protein content in the grain of oats with hydrothermal conditions at different stages of phenological phases

14271	0.61	0.99*	-0.78	0.38	0.32	-0.71	-0.63	-0.15	-0.43	0.09
14584	0.84	0.96	-0.53	0.66	0.74	0.70	-0.99*	0.37	0.86	0.64

Note: * – 95% significance level, ** – 99% significance level, I – the sum of the temperatures of the surface air layer, II – the amount of precipitation.

In most samples, high temperatures of the surface air layer during the periods from sowing to tillering and at the stage of seed loading and ripening cause a decrease in protein in the grain. A negative relationship was also found with the amount of precipitation in the period from sowing to tillering. Only in the period of tillering - heading, high temperatures of the surface air layer contribute to the accumulation of protein. In the same period, precipitation, on the contrary, restrain this process.
All studied cultivars have an inverse relationship between the amount of heat and moisture in the period of sowing-seedlings (Table 3). For several numbers, this relationship persists until the heading stage. Only during the period of grain ripening, the increase in heat contributes to the increase in grain weight. Excessive moisture in fact throughout the growing season reduces this figure.

Table 3. The relationship of the content of the natural weight of the grain of oats with hydrothermal conditions at different stages of development.

Note: * – 95% significance level, ** – 99% significance level, I – the sum of the temperatures of the surface air layer, II – the amount of precipitation.

The mass of 1000 grains is one of the most important components of the productivity and technological value of grain (Batalova *et al*., 2017). Oat grain inner hull have a low nutritional value. Therefore, the cultivars of the new generation should combine high particle size and low amount of grain hull. Most cultivars revealed a significant correlation between the test weight of the grain and a mass of 1000 grains (r=0.95). The filminess of oat variety samples is a genetically determined trait with an indirect contribution of environmental conditions. The content of hull in the Pg 17 cultivar is low (V=0.5%) and the lack of correlation with hydrothermal conditions indicates intravarietal uniformity.

Conclusions

The formation of qualitative indicators of oat grain, along with genotypic features, is significantly influenced by climatic conditions of the environment. The characters of correlation on the formation of quality in the grain of the analyzed cultivars of different ecotypes with the weather conditions of the vegetation period and the phases of development with the aim of improving the varietal potential of oats are described. The varietal specificity of the dependence of the protein content in the grain on the hydrothermal conditions of the growing season was revealed. Most cultivars revealed a significant correlation between the test weight of the grain and a mass of 1000 grains. The hull of oat cultivar samples is a genetically determined trait with an indirect contribution of environmental conditions.

Abstract

Genotype × Environment interactions for cotton fiber traits are of great importance affecting quality. The purpose of this study was to evaluate fiber quality traits across four diverse environments by Advanced Fiber Information System (AFIS) instrument. The five most cultivated commercial upland cotton cultivars were used and each cultivar was sown in 16 fields (80 fields in total for all cultivars). Four samples from each field were collected for analysis of nine fiber traits. Many fiber traits exhibited statistically significant differences for both factors environments and cultivars (genotypes), indicating differences in environmental conditions and cultivar behavior. Genotype × Environment interactions were not present except for two traits that were very close to 0.05 significance level. Finess showed the greatest mean squares, while in most cases, mean squares of the factor environment were greater than for genotypes (except for IFC and Finess, where genotypes contributed the most in total variability). Thrace followed by Macedonia, proved to be the best regions in Greece to cultivate cotton for all fiber traits, except for trait SFC (percent of short fibers by weight). Cultivar CELIA showed the best measurements for almost all fiber traits across all Greek regions.

Key words: *AFIS, quality, Greek regions*

Introduction

Genotype × Environment interactions are of major concern to plant breeders for ensuring heritability during the process of developing improved cultivars (Cheng and Cheng, 2002; Kang, 2004; Campbell *et al.*, 2012). Upland cotton (*Gossypium hirsutum* L.), is one of the main cultivations in Greece, in four main regions with special environmental characteristics (Baxevanos *et al.*, 2013; Greveniotis and Sioki, 2017). Improvement in fiber quality is the primary objective, based on reliable methods that measure fiber traits. Cotton industry needs suggest breeders to adopt market expectations. More accurate measurements are now available to handle quality data (Hequet *et al.*, 2007). Now, Advanced Fiber Information System (AFIS, Uster Technologies, Inc.), is used by textile mills for extensive cotton fiber quality control (Hardin et al., 2018). Fiber quality is depended on various traits (Poehlman and Sleper, 2006) that depend on both genetic (cultivars) and environmental factors (Bradow and Davidonis, 2000). Ghosh et al. proposed at least three specimens for better assensing quality parameters (1992). McAlister *et al.* (2003) used AFIS for assessing fiber qulity. They stated that that the high micronaire cottons exhibited more convolutions and longer fibers exhibited higher frictional. Kelly and Hequet (2018), implemented a novel statistical model for better describing quality data retrieved by AFIS measurements. They also used comparisons to HVI measurements. The purpose of this study was to evaluate fiber quality traits across diverse environments by AFIS instrument which is used for more accurate quality estimations. This could lead to both an environment selection for cotton cultivations and also best cotton cultivars for a specific environment.

Materials and methods

Four main cotton-production Greek regions were selected because of their different environments, i.e. Thessaly, Sterea Ellas, Macedonia and Thrace. The five most cultivated commercial upland cotton (*Gossypium hirsutum* L.) cultivars were used, i.e. DP332 and DP377 (Monsanto Co), ST402 (Pioneer Hi-Bred), CELIA and ELSA (Bayer Crop Science). These cultivars varied in origin and maturity class. Four fields in each of four regions were chosen for sowing each cultivar separately, in order to evaluate different soil types and environmental conditions. During experimental years' environmental data were monitored and showed significant differences. Each cultivar was sown in 16 fields and 80 fields in total were used for all cultivars. Rows spaced 96 cm apart and plant density was on average 15 plants per m^2. Crop management practices for each location were consistent with typical agronomic practices. Four samples from each field were collected in random to analyze fiber quality traits at the accredited laboratory of National Center of Cotton, in Karditsa, Greece. Before testing cotton samples were conditioned for at least 24 hours at 65 ±2% RH and 21 ±1 ºC (ASTM, 2015).

The cotton traits were measured by AFIS instrument (Advanced Fiber Information System – AFIS by Uster Technologies AG, Uster, Switzerland) as follows: L-w: Average fiber length by weight of all the cotton fibers in the sample. L-n: Average fiber length by number of all cotton fibers in the sample. UQL-w: Upper Quartile Length by weight: length exceeded by 25% of the fibers. SFC-w: Percent of all fibers in a cotton sample that are shorter than 12.7 mm (0.5 in.) by weight. SFC-n: Percent of all fibers in a cotton sample that are shorter than 12.7 mm (0.5 in.) by number. L(n) 5%: 5%-Fiber Length by number IFC: Immature Fiber Content (%), Percentage of immature fibers. FINE (MTex): Fineness (MTex= in mg/m), fiber weight per length, estimated from fiber shape and form. MAT: Maturity Ratio, Ratio (%) based on degree of fiber wall thickness. Factor analyses (ANOVA) for each fiber trait across environments were performed according to Steel and Torrie (1981). Factors were both environments (the Greek regions) and genotypes (the five cultivars). Experimental Coefficient of Variation (CV%) was also computed. Separations of means were based on Duncan's test.

Results and discussion

As shown in Table 1, many fiber traits exhibited statistically very significant differences for both factors environments and cultivars (genotypes), indicating differences in environmental conditions and cultivar behavior (Bradow and Davidonis, 2000; Greveniotis and Sioki, 2017; Greveniotis *et al.*, 2017). Only fiber traits IFC and MAT showed small differences, statistically significant for cultivars but not for environments. Genotype × Environment interactions were not present except for traits UQL-w and Finess, which were found close to 0.05 level. Finess showed the greatest mean squares (up to 770.45), while in general, mean squares of the factor environment were greater than for genotypes (except for IFC and Finess, where genotypes contributed the most in total variability). Experimental CV(%) was high for IFC and SFC, indicating a rather unstable behavior of these fiber traits (Greveniotis *et al*,. 2018).

In Table 2, Thrace followed by Macedonia, proved to be the best regions in Greece to cultivate cotton for all fiber traits, except for SFC which is in diverse expression to other fiber traits by definition (Jin et al., 2016), favored by Thessaly and Sterea Ellas regions. This was in agreement with the findings of Greveniotis *et al.* (2018) for other measurements of fiber traits. Table 3 presents measurements and comparisons between cultivars. Cultivar CELIA showed the best measurements for almost all fiber traits across Greek regions, followed by ELSA and ST402. This was also in agreement with the findings of Greveniotis *et al.* (2018) for other measurements of fiber traits.

Table 1. Factor analyses (ANOVA) for each fiber trait (L-w, L-n, UQL-w, SFC-w, SFC-n, L(n) 5%, IFC, MTex, MAT) mean squares and degrees of freedom, as well as experimental CV(%) are presented

Abstract

The purpose of the present research was to analyze yields of 24 different genetic materials (cultivars) of winter cereals under extreme conditions for years (2011 and 2012). For this to be done, seven breadwheat cultivars (Yecora E, Acheloos, Centauro, Nestos, Vergina, Irnerio, Yenerozo E.), five durum wheat cultivars **(**Fenix, Simeto, Bob, Mexicali 81, Athos), five barley cultivars **(**Cannon, Plaisant, Sonora, Zotis, Konstantinos) five triticale cultivars **(**Catria, Ariti, Niobi, Vrodi, Vrito) and two oat cultivars (Pallini, Flega) were used. The experimental design was a Randomized Complete Block (RCBD) with four replications. Bread wheat cultivars exhibited the greater mean values 4.3 Mg/Ha, exceeding the mean value of the Greek bread wheat cultivars. The best cultivar was Yenerozo E. Reversely to this, durum wheat cultivars exhibited low yields about 2.7 Mg/Ha, compared to 3 Mg/Ha of the Greek mean. The best cultivars were Finix, Mexicali 81 and Simeto. The yields for barley were also low, about 3.8 Mg/Ha, compared to 4 Mg/Ha of the Greek mean. The best barley cultivars were Zotis and Cannon. Triticale cultivars showed unexpectedly very low yields. Oat had also very low yields. A Genotype x Year interaction was found statistically significant, indicating different response of the cultivars in relation to the environmental conditions.

Key words: *Wheat, barley, oat, triticale*

Introduction

Commercial cultivars in order to be useful to farmers must incorporate high yield potential and stability across environments (Stratilakis and Goulas, 2003). Inbred cultivars like wheat or barley are easily maintained by farmers in Florina, by keeping part of the harvest seed for the next season but this may result in off-types and reduced field yield (Khan *et al.* 2007; El-Kalla *et al.* 2010). Josephides (1993) analyzed various cultivars of bread and durum wheat together with barley and triticale, concluding that barley is a more suitable cereal for low yielding environments. Bread wheat and durum wheat are better performers in medium to high yielding environments respectively. Lopez-Castaneda and Richards (1994) compared bread and durum wheat together with barley, oat and triticale for grain yield and biomass. They concluded that barley was the best yielding cereal among all species. Geveniotis *et al.* (2009) compared and analyzed yield components between barley cultivars, in order to reveal the genetic basis of yield factors.

Florina (Greece) has extreme environmental conditions from October until April especially during winter, resulting in low yields for many cereals as reported by farmers and local authorities. That was the reason for the present research, in order to analyse yields of 24 different genetic materials (cultivars) of winter cereals under extreme conditions.

Material and methods

The 24 different genetic materials of winter cereals were sown in November in years 2010 and 2011 in the farm of the Technological Educational Institute (TEI) of Western Macedonia in Florina ($40^o46'$ N, $21^o22'$ E; 705 m a.s.l.); the soil was sandy loam: 61.2% sand, 27.6% silt, 11.2% clay, and pH 6.25. Environmental data are presented in Figure 1. For the purpose of the study, seven bread wheat (*Triticum aestivum* L.) **(**Yecora E, Acheloos, Centauro, Nestos, Vergina, Irnerio, Yenerozo E.), five durum wheat (*Triticum durum* L.) **(**Fenix, Simeto, Bob, Mexicali 81, Athos), five barley (*Hordeum vulgare* L.) **(**Cannon, Plaisant, Sonora, Zotis, Konstantinos), five triticale (x *Triticosecale* Wittmack) **(**Catria, Ariti, Niobi, Vrodi, Vrito) and two oat (*Avena sativa* L.) cultivars (Pallini, Flega) were used.

A Randomized Complete Block (RCBD) experimental design with four replications was established. Each plot was 1.5x5 m. Plant rows were 6 in each plot with conventional plant spacing. All the proper field activities were applied.

Measurements were based on mean grain yield (in Mg/Ha) fixed for moisture, after weighing by an electronic balance. Factor analysis (ANOVA) was performed according to Steel and Torrie (1981). Factors were both years (the local environment) and genotypes (five species – 24 cultivars). Experimental Coefficient of Variation (CV%) was also computed. Ranking of means were based on Duncan's test.

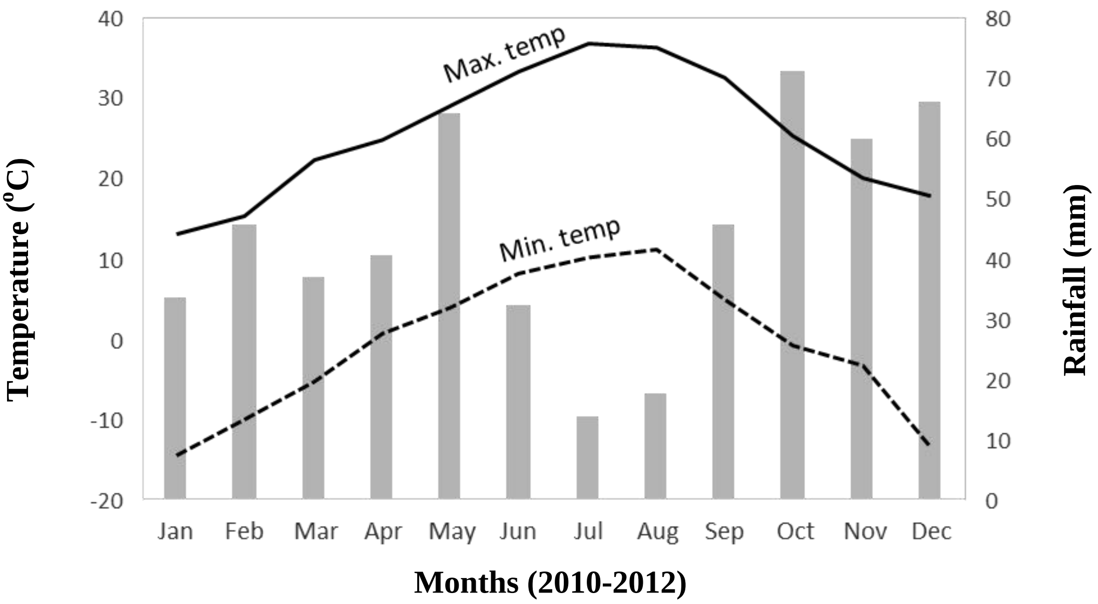

Fig. 1. Environmental conditions in Florina, Greece (temperatures and rainfall)

Results and discussion

The different genetic materials showed statistically significant differences within years and over years (Table 1). Bread wheat cultivars exhibited the greater mean value, that exceeded the corresponding Greek mean of (4.3 Mg/Ha and 4.0 Mg/Ha respectively, Tavoularis, 2012). The best cultivar was Yenerozo E with 4.8 Mg/Ha, followed by Irnerio and Centauro. In the opposite side, durum wheat cultivars exhibited lower yields compared the the Greek mean (2.7 Mg/Ha and 3 Mg/Ha respectively, Tavoularis, 2012). The best cultivars were Finix, Mexicali 81 and Simeto. A similar view was noticed in barley (3.8 Mg/Ha, compared to the 4 Mg/Ha of the Greek mean, Tavoularis, 2012). The best cultivars were Zotis and Cannon (over the Greek mean), while Konstantinos had very low yield and that was one of the reasons for the low barley mean yields. Triticale cultivars showed unexpectedly very low yields, about 3.9 Mg/Ha, compared to the 5 Mg/Ha of the Greek mean (Tavoularis, 2012) with Catria and

Niobi to performe better. In oat the view was similar with the mean yield to be lower than the corresponding Greek mean (2 Mg/Ha, and 4 Mg/Ha respectively Tavoularis, 2012). Cultivar Flega performed better than Pallini.

(***) Significant at p<0.001, (ns) non-significant
Letters determine the statistical differences between means

It is obvious that the extreme conditions in Florina decreased yields except in bread wheat mean yield. Zotis and Cannon barley cultivars are fully recommended for the area of Florina, since they produced very satisfactory yields. Oat and triticale are not recommended for the specific environmental conditions. Factor genotypes found significant indicating differences between species and cultivars. Genotype x Year interaction was also significant, indicating different response of the cultivars in relation to the environmental conditions (Greveniotis et al., 2009). These findings are not in fully agreement with Lopez-Castaneda and Richards (1994) reports, but they are similar in some cases to Josephides (1993) reports. Mediterranean conditions are not the same everywhere and, in case of Florina the extreme environmental conditions favoured two barley cultivars and bread wheat cultivars.

Conclusions

Bread wheat cultivars exhibited the greater mean values among all cereals. The mean is above the Greek mean for bread wheat. The best cultivar was Yenerozo E. Reversely to this, durum wheat cultivars exhibited lower yields, about 2.7 Mg/Ha, compared to the 3 Mg/Ha of the Greek mean. The best cultivars were Finix, Mexicali 81 and Simeto. Barley also performed lower than the Greek mean (3.8 Mg/Ha, compared to the 4 Mg/Ha of the Greek mean). Zotis and Cannon barley cultivars are fully recommended for environment of Florina, since they exhibited very satisfactory yields. Oat and Triticale are not recommended for the specific environmental conditions. Extensive research in many diverse environments will enrich our conclusions**.**

Abstract

Two forage pea varieties (Saša and NS Junior) and three grain varieties (NS Javor, Baccara and NS Dukat) of field pea were cultivated in 2016 and 2017. The research was conducted at the experimental field of the Agricultural Institute of Republic of Srpska in Banja Luka and in the experimental field of the Agricultural Faculty in East Sarajevo to determine the influence of agro-ecological conditions on the protein content, fat content and ash content of pea grains. The grain quality of the pea was significantly influenced by the locality, while the interaction of the variety/location and the year/location significantly influenced the ash content and the fat content and had a significant effect on the protein content of the pea grain. In the experiment conducted in Banja Luka, there was significantly higher content of protein (26.89%) , fat (2.468%) and ash (3.504%) in the pea grain, compared to the quality of the pea grain produced in East Sarajevo, where the content of protein was (24.88%), fats (2.312%) and ash (3.10%). The largest amount of protein and ash was found in the variety Saša, in the area of Banja Luka. These results can influence the improvement of breeding work at the Agricultural Institute of Republic of Srpska, stimulating the production of peas and increasing the area on which this crop will be grown. Special attention should be paid to hilly and mountainous areas where field peas can be important in providing sufficient quantities of plant proteins to feed domestic animals.

Keywords: *pea, locality, proteins, fats, ashes.*

Introduction

Grain pea is an economically important agricultural plant species that is primarily cultivated due to the high content of protein in the grain. Favorable biological features, including short vegetation, modest requirements for production conditions, variety of use, high and stable yield, as well as the quality of biomass and grains, make the field pea significant in resolving the deficit of plant proteins (Čupić et al., 2010; Čupić et al., 2013). In the organized production of forage, pea provides rational use of land with relatively small investments (Ćupina et al., 2000; Ćupina *et al*., 2005). Despite the great importance of field pea in the production of fodder and grain, production in our country is very small and official statistics do not cover the area of forage pea production and seed yield production. Peas is primarily grown as a spring plant for grain and for green mass (Ćota & Čamdžija, 2010).

For the production of green forage production, most commonly used are winter peas varieties, but there is a need for a new assortment of pea's grain, which can have a dual purpose: the use of grain, but also the whole plant (Gantner et al., 2014). Spring field pea is usually produced for the usage of grains and represents a highly concentrated protein feed of high-quality nutritive values. In comparison to other raw materials, such as soybean, soybean meal, fish meal, it is a significant source of "cheaper" proteins.

Therefore, the biological value of peas as a forage crop is very similar to other protein crops (Mihailović et al., 2004; Marohnić, 2006). The protein content of pea seed types depends on the variety, the year and the region in which it is grown. The content of starch, fat, proteins

and constituent elements in pea grain vary, and are significantly influenced by variety and ecological conditions (Santalla et al., 2001; Wang & Daun, 2004).
The aim of this research was to determine the influence of agro ecological conditions and varieties on the quality of spring field pea. Since the Agricultural Institute of the Republic of Srpska has an acknowledged variety of common peas (Saša) it is included in this research.

Materials and methods

The field experiments were cultivated in 2016 and 2017 at two localities: locality 1- in the vicinity of Banja Luka (experimental field of the Agricultural Institute of the Republic of Srpska), altitude of 163 m (17°49'19 " latitude and 44°48'13" longitude), and locality 2 - in the vicinity of East Sarajevo (experimental field of the Faculty of Agriculture in East Sarajevo), altitude 550 m (43°49'01" latitude and 18°20'57" longitude). The basic soil treatment was carried out in the autumn, at a depth of 25 cm, and the pre-sowing preparation at a depth of 10 cm. Basic fertilization with 350 kg of ha^{-1} $N_8P_{24}K_{24}$ was done together with the basic cultivation of soil. The sowing was done at 12.5 cm spacing and a interspace of 8 cm in the main plot of 5 m^2. For sowing, inoculated seed of five spring fodder pea varieties were used: NS Javor (G1), Baccara (G2), NS Dukat (G3), NS Junior (G4) and Sasa (G5). Three varieties were cultivated at the Institute for Field and Vegetable Crops in Novi Sad - Republic of Serbia (NS Dukat, NS Junior and NS Javor), Baccara is a variety cultivated in France while Sasa is a homemade variety cultivated at the Agricultural Institute of Republic of Srpska in Banja Luka. In the group of genotypes for combined production (biomass and grain) we included: NS Junior and Sasa, while NS Javor, Baccara and NS Dukat were used for grain production. In 2016, the sowing was done on 15 April and harvest on 15 July, while in 2017 the sowing was on 23 March, and harvest on 6 July. In 2016, sowing was late because of bad weather conditions. Long rainy period did not allow pre-season preparation and the mechanization to enter the field.
The parameters of the pea's grain quality (chemistry composition) were determined by the following methods: the crude proteins were determined by the micro-Kjeldahl method, or the crude protein multiplied by a factor of 6.25; crude fats in plant material, using the Soxhlet method, and crude ash content in the plant material by annealing at 550°C to a constant weight. The analyzes were done inat the laboratory of the Faculty of Agriculture in East Sarajevo. The obtained data were processed by the variance analysis method (MANOVA) and tested by the LSD test (STATISTICA 7.1 for Windows) (Stat Soft 2005).
The distribution of total monthly rainfall and average monthly air temperature for research years and the perennial average for Banja Luka and East Sarajevo are shown in Table 1. Average monthly air temperatures for the locality Banja Luka in both years were higher than the perennial average, and only in May 2016 the average monthly temperature was slightly lower than the perennial average. In the period of vegetation, the precipitation varied from year to year and from month to month. In 2016, the extreme month was April whith only 0.5 mm of precipitation, while in 2017 dry months were June and July. The uneven distribution of the precipitation affected the yield and the quality of the fodder pea. There were higher average monthly temperatures, compared to perennial average at the locality East Sarajevo in 2016. The exception was May when the average monthly temperature was lower for 0.9 °C. The amount of rainfall was lower than the perennial average in April and May. In April and May 2017, the temperatures were lower than the averages for the given months, while in June and July they were significantly above the perennial average. The amount of rainfall was significantly lower than the perennial average for January, March, April, May, June and July. Analyzing the years, 2017 was evidently more unfavorable. Analyzing the meteorological conditions during the performance of the experiments in Banja Luka and East Sarajevo, we

found significantly more favorable meteorological conditions in Banja Luka, especially when it came to the quantity and distribution of precipitation.

Soil in Banja Luka where the experiments were set has good physical characteristics with a depth of 35 cm. According to agrochemical analysis done at the Agricultural Faculty in East Sarajevo, it contains 0.13% nitrogen, 2.05% humus, 40 mg/100 g phosphorus and 38.48 mg/100g potassium. The soil reaction is neutral, pH in nKCl is 6.97. According to the agrochemical analyzes conducted at the Agricultural Faculty in East Sarajevo, the soil at the experimental field of the Faculty of Agriculture (Eastern Sarajevo) contains 0.27% nitrogen, 4.12% humus, 40.40 mg/100g phosphorus and 36.41mg/100g potassium. The soil reaction is moderately acidic, pH in nKCl is 6.39.

Results and Discussion

The locality significantly influenced pea grain quality (Table 2). In the experiments in Banja Luka, there was significantly higher protein content (26.89%) , fat (2.468%) and ash (3.504%) in pea grain, compared to the quality of pea grain produced in East Sarajevo, where the pea grain had a protein content of (24.88%), fats content of (2.312%) and ash content of (3.10%).
Protein content of the pea seed depends on the genotype and the environmental factors during the filling of the seed (Lhuillier-Soundélé et al., 1999). Research by Santalla et al. (2001) have shown that there is a significant interaction between the variety and environment that influenced the protein content. Wang&Daun (2004) determined the protein content varied depending on the ecological conditions and the variety, the protein content ranged from 20.2% to 26.7%. In extensive researches by Mihailović (1994), the protein content of the grains of the pea varieties varied from 23.0% to 26.4%. The protein content, depending on the locality, varied from 24.26% to 27.90%. The domestic variety Saša had the highest protein content in the Banja Luka area, while the lowest varieties of proteins at the locality of East Sarajevo were found in the French variety Baccara. In all varieties, significantly lower protein content in pea grains grown in East Sarajevo was determined, compared with the content of protein in pea grain in all varieties grown in Banja Luka. In both years of research, the protein content was significantly higher in pea grain grown in Banja Luka.

Table 2. Quality of grain varieties of peas depending on cultivation location

		% of protein	% of fat	% of ash

L		**	**	**
LxS		*	**	**
LxG		*	**	**
LxSxG		ns	ns	ns

Values marked by different lowercase letters per column are significantly different at the level P 0.05 according to LSD¬test; * F test significant at P 0.05; ** F test significant at P P0.01; The ns¬F test is not significant.

The lowest fat content in pea grains had the variety NS Dukat at the locality of Banja Luka, and the highest content the variety Baccara at the locality of East Sarajevo (interaction of variety/locality), which is in agreement with the results of Wanga&Dauna (2004), which found significant influence of varieties and environmental conditions on the content of starch, ADF, NDF and fats. The highest variations in fat content, depending on the locality, were found in the variety NS Junior, and the least in the variety NS Javor. A highly significant year/locality interaction was also established. The highest fat content had the grain pea produced in Banja Luka in 2016, while the pea produced at the same location in 2017, had the smallest fat content.

The location had a significant influence on the ash content of pea grains in all the varieties studied (interaction of variety/locality), since all varieties grown in Banja Luka had more ash content in pea grain, in comparison withcompared to East Sarajevo. For the NS Junior varieties, these differences were significant, but minor compared to other varieties.

Compared to other varieties, this variety had the highest ash content in pea grains (Banja Luka), but at the site in East Sarajevo, the lowest content of ash was found in this variety, when compared to other varieties. Significant differences in ash content of the pea grain during the interaction of years / locality were also found. The pea grain produced in 2016 at the locality of Banja Luka had significantly higher ash content than grain pea produced in Eastern Sarajevo in both 2016 and 2017. The season did not have an impact on the ash content of pea grains produced at the location in East Sarajevo, which is in agreement with the results of Wang & Daun (2004).

Conclusion

In two years of quality research of five varieties of peas in the vicinity Banja Luka and East Sarajevo, we can conclude:

- The locality in the vicinity of Banja Luka has significantly more favorable agro-ecological conditions compared the locality in the vicinity to East Sarajevo, which has significantly influenced the better quality of field pea grain;
- Meteorological conditions (temperatures and precipitation schedule) were more favorable in 2016 compared to 2017, which is why pea grains produced in 2016 had higher protein, fat and ash content compared to 2017;
- The domestic variety Saša had the highest protein and ash content at the Banja Luka locality, while the Baccara variety at the East Sarajevo locality had the highest fat content;
- Production of field peas, should be stimulated, due to its characteristics, as well as the work on pea varieties breeding, at the Agricultural Institute of Republika Srpska, in order to obtain new varieties that can be grown in different agro-ecological conditions of Republika Srpska (Bosnia and Herzegovina).

EFFECT OF THE 1BL.1RS WHEAT-RYE CHROMOSOMAL TRANSLOCATION IN BREAD WHEAT CULTIVARS ON PHYSIOLOGICAL TRAITS

Fokion PAPATHANASIOU[1]*, Ioannis TASIOS[1], Dimitrios TRAKOSIARHS[1], Fani KOYTSOYRA[1], Athanasios G. MAVROMATIS[2], Chryssanthi I. PANKOU[2], Ioannis N. XYNIAS[1]

Abstract

In order to study the effect of the 1BL.1RS wheat-rye chromosome translocation on yield and physiological traits, three Hellenic spring wheat varieties with (cvs. Acheron, Elissavet and Orfeas), six cultivars without the translocation (cvrs. Apollonia, Acheloos, Vergina, Doirani, Nestos and Strymonas) and the Russian cultivar KVZ/Cgn as a check, were evaluated for three successive years under low input conditions. Total chlorophyll content, chlorophyll fluorescence, CO2 assimilation rate, stomatal conductance, intercellular CO_2 concentration and transpiration rate were measured. Significant differences were recorded in yield and in two traits, i.e. total chlorophyll content and transpiration rate. Regarding yield, despite the existing variability between cultivars with and without the translocation, no effect of the translocation was noticed. The two cultivars with (Elissavet and Acheron) carrying the translocation performed almost equally with two of the top yielding varieties without the translocation (Apollonia, and Achellos). Also, the same two wheat cultivars without the translocation showed high total chlorophyll content but they did not differ significantly from cv. Elissavet one of the translocation carriers. No positive effect of the translocation was observed on transpiration rate with the top yielding cultivar Apollonia without the translocation differing significantly from the top yielding cultivar Elissavet with the translocation. When the studied physiological traits were compared to the yield of the corresponding cultivars it was concluded that the 1BL.1RS chromosome translocation did not give any significant advantage on the yield potential of the genotypes. Further research is needed under different environments to confirm the results of the present study.

Keywords: *Yield potential, Drought resistance, Chlorophyll content, Transpiration rate.*

Introduction

One of the main problems in releasing new cultivars is that this new germplasm will probably be grown on marginal environments due to the irrational waste of territorial resources noticed in previous years. The drought conditions prevailing in spring especially in the last decades, is the main obstacle of agricultural production in the southern regions of Europe (Yau and Saxena, 1997) complicating the problem of food sufficiency. Thus, one of the most decisive factors in all breeding programs is the identification and integration of genes into cultivated varieties that confer resistance or tolerance to drought (Blum, 1988) and avoid mistakes of the past (Acevedo and Fereres, 1994). This led breeders and especially those working on wheat, to look for new gene pools to face the problem (Fehr, 1987). According to various reports bread wheat *(Triticum aestivum* L. em Thell) cultivars carrying the 1BL.1RS wheat-rye chromosome translocation are characterized among other by high yield potential (Kim *et al.*, 2004; Xynias *et al.,* 2007) and resistance to drought (Hoffmann, 2008). The 1BL.RS translocation is originated from cv. Kavkaz/Cgn (Schlegel and Meinel, 1994) and it's unique traits are attributed to genes located on the short arm of the first chromosome of rye (Schlegel and Meinel, 1994; Xynias *et al*., 2007). According to Acevedo and Fereres (1994) one crucial mistake in developing new germplasm was the non-sufficient exploitation of certain physiological traits, rendering cultivated plants more competitive to weeds. Common physiological traits used to recognize increased stress tolerance are gas exchange parameters such as assimilation rate (A), stomatal conductance (g_s), transpiration rate (E) and intercellular CO_2 concentration (c_i), chlorophyll content and chlorophyll fluorescence (Hura *et al.,* 2007; Živčák *et al.,* 2008). The above physiological traits have exhibited a good correlation with tolerance to stresses and yield parameters with a high heritability and repeatability (Fotovat *et al.*, 2007; Sayar *et al.*, 2008). In a preliminary report Pankou et al. (2017) stated that no evidence was obtained to confirm the positive effect of the translocation on relevant physiological traits.

The aim of the present study was to further investigate the effect of the 1BL.1RS wheat-rye chromosomal translocation on certain physiological traits and elucidate how they affect yield and drought resistance.

Materials and Methods

Plant material

For the purpose of the study, nine Hellenic bread wheat cultivars (eg. Acheron, Elissavet, Orfeas, Apolonia, Acheloos, Vergina, Doirani, Nestos and Strymonas) that were developed at the Cereal Institute of Thessaloniki (Anonymous, 1985) were used. The Russian cultivar Kavkaz/Cgn, one of the donors of the 1BL.1RS wheat-rye chromosome translocation (Xynias *et al.,* 2006; Weng, 2007) was used as check. Three of the Hellenic cultivars were found to carry the 1BL.1RS wheat-rye chromosome translocation (cvs. Acheron, Elissavet and Orfeas) whereas the other six cultivars, were lacking the specific translocation (Xynias *et al*., 2006; Peros *et al.,* 2015).

Methods

The experimentation applied for three growing seasons. The examined cultivars and the control were sown in early November 2015 and at the same time in November 2016 and November 2017, in a field of the University of W. Macedonia Farm in Florina Greece (40°46′ N, 21°22′E, 707 m asl), in a sandy loam soil with pH 6.3, organic matter content 14.0 g kg^{-1}, N-NO_3 100 mg kg^{-1}, P (Olsen) 50.3 mg kg^{-1} and K 308 mg kg^{-1} and water holding capacity 21.8% (0 to 30 cm depth). Seedbed preparation included mouldboard plough, disc harrow and cultivator. Nitrogen and P_20_5 at 80 and 40 kg ha^{-1}, respectively, were incorporated into the soil as diammonium phosphate (20-10-0) before sowing. The crop was kept free of weeds by hand hoeing when necessary. The Randomized Complete Blocks (RCB) experimental design (fixed model) was applied, with four replications. The plots were consisted of five rows (plot area 3 m^2) of which the three inner were threshed (harvest area 1.8 m^2).

The mechanically harvested grain was weighed and a sample of grain was dried in an oven at 105° C for 24 h to determine grain moisture content. Grain yield was referred to 12% grain moisture. Chlorophyll content readings were taken with a hand-held dual-wavelength meter (SPAD 502, Chlorophyll meter, Minolta Camera Co., Ltd., Japan). For each plot six fully expanded flag leaves per plot were used when the plants were at physiological maturity with six measurements per leaf, a total of 36 readings per plot. A portable photosynthesis system (LI-6400 XT, Li-Cor, Lincoln, Nebraska, USA) equipped with a 2X6 (12 cm^2) open top narrow leaf chamber was used for determinations of CO_2 assimilation rate (A), transpiration rate (E), stomatal conductance to water vapour (g_s), and intercellular CO_2 concentration (C_i) during grain filling period. Leaf gas exchange was measured on the fully expanded flag leaf during the grain-filling period on six plants from each plot from 09:00-12:00 in the morning to avoid high vapor-pressure deficit and photoinhibition at midday. The quantum

photosynthetic yield of photosystem (PS) II or Y was measured with the portable OS5p Chlorophyll Fluorometer (Opti-Sciences Inc. Hudson, NH, USA).
The means were compared according to the L.S.D. method. The data obtained were analyzed statistically with Mstat-C (Freed and Eisensmith, 1986).

Results and Discussion

Significant differences were recorded between the examined cultivars in yield (significant differences at p=1%, Table 1). Regarding of the physiological traits studied significant differences were revealed in total chlorophyll content, CO_2 assimilation rate and transpiration rate (in the last at p=5%). No differences were observed in the other physiological traits between the examined cultivars regardless of the presence of the translocation (Table 1).

Table 1. Analysis of variance of bread wheat with and without the 1BL.1RS wheat-rye chromosomal translocation regarding yield and six physiological traits.

Source	df	Yield (g/plot)	Total chlorophyll content	Chlorophyll fluorescence	CO_2 assimilation rate	Stomatal conductance	Intercellular CO_2 concentration	Transpiration rate
Years (Y)	2	ns	**	**	ns	**	ns	**
Cultivars (A)	9	**	**	ns	**	ns	ns	*
(Y) x (A)	18	**	* *	ns	**	ns	ns	ns
Error	81							
CV		17.35	10.71	45,73	15,06	74,17	6,01	19,00

Table 2. Ranking of the bread wheat cultivars according to chlorophyll content.

Cultivar	Yield (g/plot)	Total chlorophyll content	CO_2 assimilation rate	Transpiration rate
Acherontas*	A	BC	AB	AB
Elissavet*	A	AB	CD	CD
KVZ/Cgn*	A	CD	BC	AB
Orfeas*	E	CD	AB	BCD
Apollonia	AB	AB	A	A
Acheloos	A	A	AB	ABC
Yecora E	DE	D	D	D
Doerani	BC	A	AB	AB
Nestos	CD	BC	BC	ABCD
Strymonas	BC	AB	A	ABC
LSD	79.56	3.327	1.503	0.6056

*Cultivars carrying the 1BL.1RS wheat-rye chromosomal translocation

The cultivars were classified according to their yield performance (Table 2). Three cultivars with the translocation (Acheron* Elissavet*, KVZ/Cgn*) and one without (Acheloos) were ranked in top yielding places, (marked with A). They were followed by three cultivars without the translocation (Apollonia, Doerani, and Strymonas (marked with AB, and BC) and the last group was consisted of the cultivars Nestos, Yecora E, and Orfeas* (marked with CD, DE and E respectively). It is obvious from the above results that there was no particular yield advantage of the presence of the translocation on the varieties studied. This is in disagreement with the conclusion of Kim *et al*. (2004), who reported a positive effect of the translocation on yield performance. Sufficient yield can be produced by elite cultivars despite the effect of the translocation. This yield performance supports the view that it is possible that the presence of the translocation gives some advantage to the host cultivar. However, this advantage is not so crucial because two other cultivars without the translocation performed equally well. The results presented in this study are in agreement with the respective stated by various authors

that in order the translocation to express its valuable genes, the genetic background of the host cultivar is important (Lazaridou *et al.*, 2017; Xynias *et al.*, 2018).
The insufficient yield performance of cv. Yecora E could be attributed to the very low temperatures prevailing in Florina during winter. However, there is no explanation for the inferior performance of cvrs. Orfeas* and Nestos, which are supposed to be resistant to low-temperatures.
Similar results were recorded and in the ranking of the physiological traits (Table 2). The cultivars were classified in four groups according to total chlorophyll content and transpiration rate and in five groups in CO_2 assimilation rate. For total chlorophyll content, four cultivars without (cvs. Aheloos and Doerani, Appolonia, Strymonas) and one with the translocation (Elissavet*) were ranked in the first places. A similar view was found in assimilation and transpiration rates, where Apollonia was ranked first. Thus, it could be stated that there is no obvious effect of the translocation on the traits studied. The aforementioned results support the view of Acevedo and Fereres (1994) who stated that exploitation of certain physiological traits could be beneficial in producing high yield varieties. Cvs. Apollonia and Acheloos which were ranked in first places not only in yield but also in all physiological traits studied are good examples of the former statement.

Conclusions

The results obtained in the present study, supported previous statements that the 1BL.1RS chromosome translocation does not give any significant advantage regarding the physiological traits of the host cultivar. The presence of the translocation seems to be beneficial in the cold area of Florina. However, further research is needed to confirm the results of the present study.

Abstract

Agroforestry systems combine two close areas of land use, namely agriculture and forestry. Agroforestry can provide certain ecological benefits, such as increased biodiversity, reduced soil erosion, increased land use efficiency and production, and increased carbon sequestration. The aim of this contribution is the evaluation of species composition of vascular plants in two woody strips on a field under organic farming. The experiment was established on two fields near to Starnberg (Germany) in 2014. In May 2019, the evaluation of the vegetation was carried out using phytosociological plots of size 4 m^2. The percent coverage was estimated in each plot. A total of 36 plant species belonging to 17 plant families occurred in the monitored area. Woody strips can provide shelter and food for animals, but they can also be a potential source for weeds spreading to the surrounding land. Our results show whether plants are able to spread to the surrounding land and whether they are able to affect the vegetation in agricultural lands.

Keywords: *short rotation coppice, agriculture, energy crops, phytosociological methods*

Introduction

Humans have altered earth's landscape more than any other species, with agriculture representing the largest anthropogenic use of land area (Foley *et al*., 2005; Ramankutty *et al*., 2008). Only in Europe is about one half of land is farmed (Kanianska, 2016). Agriculture is a multifunctional system. It provides economic (private) production and ecosystem services for public goods. Agriculture characterized appearance of agriculture landscape (Wiggering *et al*., 2006). Information on the effects of management on ecosystem processes is consequently necessary to the development of predictive management models for major land-use change (Forup *et al*., 2008). Climate change induced warming is expected to impact plant diversity and distribution at all levels starting from single species to biomes (Parmesan, 2006). It will also result in alterations in population dynamics of native species that may enhance climate mediated biological invasion, alter community interactions and structure, and ecosystems functions (Walther *et al*., 2002). Biologically-diversified farming can contribute to ecological intensification of agriculture by providing multiple ecosystem services, such as the promotion of biocontrol services (e.g., a decrease in pest abundance and an increase in the abundance of natural enemies of pests) (Harvey *et al*., 2014). The widening focus from the traditional tree-based land use practice to more advanced landscape scale agroforestry approach creates a stronger link between agroforestry and biodiversity conservation (Sanchez, 1995). Agroforestry practices are often part of strategies to improve natural resource management (Ong and Kho, 2015). Short Rotation Coppice (SRC) is a technique for the cultivation of biomass, which lies midway between agriculture and forestry. Fast-growing species of trees (such as poplar and willow) are densely planted in rows and then harvested at certain intervals. They are planted at a distance of 0.5 - 1 m and are harvested at intervals of 2 to 8 years (Vanbeveren and Ceulemans, 2019). Changes in species composition resulting from the transition from arable land to increased cultivation of SRC may have a wider impact on ecosystem processes and ecosystem services (Rowe *et al*., 2013). The objective of the present contribution is evaluation of species composition of vascular plants in two woody strips on a field under organic farming.

Material and Methods

The experiment was established on two fields near to Starnberg (Germany) in 2014. Trees (willows, poplars) were planted on the edge of the plot in four double rows. Rows of trees were spaced 3 meters and trees were planted with a spacing 50 cm. In the first plot, the planting of willow and poplar alternated every 50 m. In the second plot, the planting of willow and poplar alternated every 60 m. In May 2019, the evaluation of the vegetation was carried out using phytosociological plots of size 4 m^2. The percent coverage was estimated in each plot. Three phytosociological relevés were recorded in the woody strips (willows, poplars) with 10 meter spacing. In addition, four phytosociological relevés were recorded in the field with a distance of 4 m from each tree species (see Figure 1.). Phytosociological relevés or also vegetation plots serve to describe the species composition and diversity of the vegetation of a given site. It is a list with information about certain habitat species and other relevant data (for example density, frequency, cover, exposure of the given site…). Another four phytosociological relevés were placed on the opposite edge of the field without tree rows. The obtained data were processed by multivariate analysis of ecological data segment analysis DCA (Detrended Correspondence Analysis) and canonical correspondence analysis CCA. A total number of 999 permutations were calculated in Monte-Carlo test. Collected data were processed by a computer program called Canoco 5.0 (Ter Braak and Šmilauer, 2012).

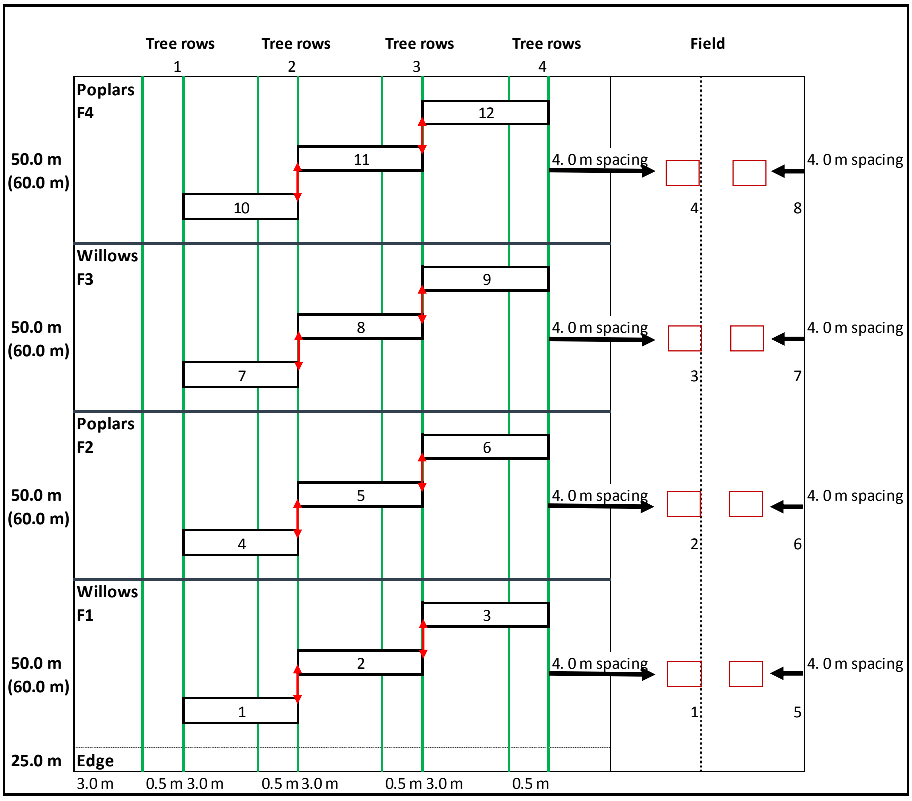

Figure 1 Schema of tooking phytosociological relevés

Results and Discussion

A total of 36 plant species belonging to 17 plant families occurred in the monitored area (see Table 1). Among the poplars 18 species have grown, among the willows 20. Of these, four species were also found on the areas at a distance of 4m from the stripes. In comparison, 13 species were found on the opposite side of the field. Only four of them grown on the areas with poplars and willows.

Table 1 Number of found species according to their family

	Willows	Poplars	Distance of 4 m	Opposite edge of the field
Family	Number of found species			
Amaranthaceae	0	1	0	1
Asteraceae	1	2	2	3
Boraginaceae	1	1	1	1
Brassicaceae	0	0	2	2
Caryophyllaceae	1	0	1	2
Convolvulaceae	0	1	0	1
Euphorbiaceae	0	0	1	1
Fabaceae	1	1	0	0
Geraniaceae	1	0	1	0
Lamiaceae	1	2	1	2
Papaveraceae	0	0	0	1
Plantaginaceae	2	2	1	1
Poaceae	6	5	0	0
Polygonaceae	2	1	1	1
Rosaceae	2	2	0	0
Rubiaceae	1	1	1	1
Violaceae	0	0	1	1

The obtained data about evaluation of species composition were initially processed by the DCA analysis which determined the length of the gradient, and it was 7.0. Based on this calculation for further processing was selected canonical correspondence analysis CCA. Analysis CCA defines the spatial arrangement of plant species and selected environmental factors. This is subsequently graphically expressed by the ordination diagram (see Fig. 2) Species and monitored factors are shown by points of different shape and colour. The species found can be divided into five groups: species that only occurred in willows, occurrence only in poplars, occurrence in poplars and willow, species that only occurred in the field and species that occurred at all sites. The only species found in willow were *Poa annua, Cerastium arvense, Fragaria viridis* and *Medicago sativa*. To species found only in poplars belong: *Convolvulus arvensis*, *Rubus idaeus* and *Vicia angustifolia*. The ordination diagram shows that the species from the family *Poaceae* were found only in poplars and willows. These species also had the highest coverage in the stripes of trees. The ordination diagram also shows that the number of found species was higher in the field, at different distances from woody strips. For example in willow and poplar plantations grown in southern and central Sweden, species numbers decreased with distance from the edges (Gustafsson, 1987; Weih *et al.*, 2003). Only four species were found at all sites, namely: *Cirsium arvense*, *Chenopodium album*, *Galium aparine* and *Polygonum aviculare*. These species can be considered as common weeds and results show that sites not influence occurrence of these species. These species belong to species with C, R and CR strategists and according to the Ellenberg indicator values for nutrients (value 7 and 8 for these species) belongs to species occurring at nutrient-rich sites.The found species *Chenopodium album* is listed as the world′s 10th most serious weed and is found in Asia, Europe and North America; as it is adapted to grow vigorously in many different climates and soils (Holm *et al.*, 1977). This species could be problematic for the future weed infestation; however, its occurrence is mainly dependent on the seeds in the soil seed bank.

There are many factors influencing species cover, species richness and the type of species occurring in SRC plantations (e.g. light climate and the tree age) (Baum *et al*., 2009).
Changes in species composition resulting from the transition from arable land to increased cultivation of SRC may have a wider impact on ecosystem processes and ecosystem services (Rowe *et al*., 2013). Depending on the location, SRC plantations can have positive as well as negative effects on biodiversity (Weih *et al*., 2003).
According to Baum *et al*. (2012) is species richness highest in SRC than in agricultural land and species composition correlated to SRC tree cover, SRC age and coppicing. There are a several studies assessed influence of a SRC. For example, Vanbeveren and Ceulemans (2019) conducted overview of the publications. They found out, that more than half relevant studies (33) assessed biodiversity of a willow SRC, while poplar was the second most studied SRC genus (20) other SRC genera were only occasionally reported on. The largest number of studies was performed on SRCs in, and equally spread between, the UK (22), the US (22) and Sweden (20). The remaining SRCs were mainly situated in Germany, Belgium and Italy.

Conclusions

During botanical monitoring altogether 36 plant species belonging to 17 plant families occurred in the monitored area were found. Most representatives of the *Poaceae* family were found in woody strips. Only four species found at all sites, namely: *Cirsium arvense*, *Chenopodium album*, *Galium aparine* and *Polygonum aviculare*. These species can be considered as common weeds and results show that sites not influence occurrence of these species. Some of the found plant species are able to enrich the soil seed bank (*Chenopodium album*, *Capsella bursa-pastoris*). Other plant species can spread by anemochoria (*Cirsium arvense*). These four species can cause a weed infestation of the area in the coming years. The results also indicate that areas with fast growing trees (willows, poplars) increase the diversity of vascular plants and can thus support the diversity of agricultural landscapes. However, SRC is a relatively new way of management and its influence on vegetation are not yet well known. Therefore, this topic offers an interesting area for research.

Abstract

Due to climate change, today, many agricultural areas are affected by drought. It is known that drought has many effects on plants, morphologically, physiologically and phenologically. In the study, the effects of drought stress on the fruit and seed color of the pumpkin genotypes were investigated. For this purpose, in 2017 and 2018, 48 pumpkin genotypes, consisting of 44 inbred lines and 4 commercial varieties, were grown in irrigation and non-irrigation conditions. The study was conducted by using a randomized block design with three replicates. Each parcel has an area of 20 m^2 and consists of 40 pumpkin plant. In this study, drip irrigation system was used and irrigation was applied ten times with seven days interval. We recorded fruits and seed color values (L *, a *, b *) with Chroma Meter CR-400, every two years. As a result of the study, it was determined that drought did not effect on fruit color values of L * and b *, but it had a significant effect on fruit color value of a* in pumpkin genotypes. Therefore, as the drought increases, the fruit colors shifted from green to red. Moreover, pumpkin seed color, which has economic value, was not affected by drought. When examined on the basis of genotypes, drought has important effects on fruit and seed colors.

Keywords: *drought, pumpkin, fruit color, seed color.*

Introduction

In the world, a total of 26 486 616 tons of pumpkin is produced in an area of 1 992 003 ha. China (7 838 809 tons) takes the first place in this production, while India (5 073 678 tons), America (3 315 909 tons), Russia (1 224 711 tons) and Indonesia (663 325 tons) make up the top five countries. Turkey is in area 764 458 da, 489 999 tons with production accounted for 1.84% of world production, it ranks 8th among the world countries (FAO, 2016). Confectionary pumpkin production in Turkey is approximately 737 891 in the area of 55 043 tons. The production of pumpkin is widespread in the inner regions of Turkey and Kayseri (16 751 tons), Nevşehir (16 403 tons), Konya (8 982 tons), Eskişehir (3 196 tons) and Karaman (1 205 tons) are the five provinces that produce the most (TÜİK, 2018).

Pumpkin seeds, in addition to being consumed as an appetizer in human nutrition, are used as additives for bread, salami, sausage, mayonnaise and many food products because of their high protein content (Rangahau, 2002). Some researchers have reported that pumpkin seeds improve the immune system (Chew and Park, 2004), and reduce the risk of stomach, breast, lung and colon cancer due to they have significant amount of antioxidants (Lelley *et al.*, 2009). It is also reported that phytosterols in pumpkin seeds play an important role in lowering cholesterol levels and in the treatment of advanced prostate (Fruhwirth and Hermetter, 2007).

Pumpkin seeds are among the oilseeds with a protein content of 28-40% (Kırnak *et al.*, 2019) as well as 35-50% fat content (Seymen *et al.*, 2016). In addition, it is rich in minerals such as potassium, phosphorus, calcium, magnesium, iron, which are important in human nutrition

(Erdinç *et al.*, 2018) and it is known as a good source of vitamin A, C and E (Eleiwa *et al.*, 2014; Kırnak *et al.*, 2019).

Climate change, rapid population growth, indiscriminate and excessive consumption and a shortage of fresh and clean water resources have led to irrigation problems (Rijsberman, 2006). Drought is currently one of the most common environmental factor limiting crop production in the world. Therefore, it is a necessity to make development of species and varieties which are tolerant to drought or where economic efficiency is achieved with less water.

With the increase of arid and semi-arid areas in the world, there is an increasing tendency to grow species such as confectionary pumpkin that can use water efficiently and economically. Its production has recently increased, due to the reasons such as less water requirement compared to other agricultural crops, lack of irrigation in some areas with sufficient precipitation, growing in rotation with field crops, ease of harvesting, the existence of mechanized cultural processes, the ability to be relatively resistant to diseases and pests, and the available for storage. Despite the increasing production, reaching commercial varieties in the market is an important constraint. Due to these reasons, a lot of research is being carried out, especially on drought studies in confectionary pumpkin, in Turkey (Yavuz et al., 2015a; Yavuz et al., 2015b; Ünlükara and Bakır, 2018; Seymen et al., 2019; Kırnak et al., 2019). Confectionary pumpkin often exhibits a higher economic yield in arid and semi-arid regions compared to other agricultural crops such as wheat, barley and chickpeas (Seymen et al., 2019).

It is well-known drought is cause many morphological and physiological changes in plants.

The objective of the present study was to determine the fruit and seed color through an experimentation conducted for two years in irrigated as well as non-irrigated conditions with 44 inbred pumpkin lines (G), 2 commercial hybrid cultivars (G1: Mert Bey F1 and G2: Sena Hanım F1), and 2 local cultivars (G3: Hatun Tırnağı and G4: Çerçevelik).

Materials and Methods

The present study was conducted during the May and Sept. in 2017 and 2018, at the Faculty of Agriculture, Selcuk University, Konya, located at 38°05'N, 32°36'E at an altitude of 1006 m, in central Anatolia, Turkey. Konya, which accounts for approximately 8% of the total agricultural area in Turkey and covers an area of 1.9 million hectares of arable land. Konya Plain has an arid and semi-arid climate, according to long-term climate data. In this region, the vegetation period (May-September) occurs only 90-100 mm of rainfall, and total annual precipitation is 320 mm. The soil of the study area has a silty–clayey–loamy texture. The organic matter content present in 0–90 cm of the soil profile, pH, and the bulk density values of the soil in the study area ranged from 1.43% to 2.16%, 7.44 to 7.50, 1.28 to 1.32 g/cm^3, respectively.

In this study used plant materials were collected from different regions of Turkey. The 44 confectionary pumpkin genotypes which were purified to the S7 stage by self-pollinated were used. In addition, two-hybrid (G1: Mertbey F1 and G2: Senahanim F1) and two local cultivars (G3: Hatuntırnağı and G4: Cercevelik) with high commercial value in the market were used to serve as a control group.

The present study was conducted by using a randomized block design with three replicates, in full-irrigated and complete-stress (drought) conditions. Each parcel has an area of 20 m^2 and consists of 4 rows of plants. A total of 40 pumpkin seeds were sown by hand with 1 m row spacing and 0.5 m inter-row spacing within each parcel. In this study, drip irrigation system was used and irrigation was applied ten times with seven days interval.

On the basis of soil analyses, 10, 10, and 12 kg ha^{-1} of N, P_2O_5, and K_2O were applied before sowing the seeds, respectively. Throughout the developmental period of the plants, cultural

practices such as cultivation, weed control, pest and disease management were conducted regularly. Twenty days prior to the harvest time, irrigation was discontinued in the fully-watered plots. Post complete drying of the plants, fruits were harvested and mature seeds were extracted from these fruits.
In both years, 4 fruits obtained from 20 other plants, except edge effects in the plots, were harvested at harvest maturity stage and L, a *, b * were recorded by chroma Meter CR-400. In addition, L, a *, b * values from each genotype were determined from a total of 5 seeds.The fruit and seed color parameters were subjected to analysis of variance, and the results were considered statistically significant at 5% significance level according to Duncan's test (Düzgüneş *et al.,* 1987). The analysis of variance and correlation tests were performed by using the SPSS 22.0 packaged software.

Results and Discussion

Fruit color ''L*''

The L * value ranges from 0 to 100 and describes the coloration between black (0) and white (100). In the study, it was found that irrigation and drought conditions had a statistically significant on the average L * value in different genotypes in 2017 and 2018 at 5 % significance level (Table 1).In respect to the average L* values of 2017-2018, it was determined that the drought conditions caused a change in L * values by % according to the irrigation conditions (Table 1). When the changes were examined, L* values increased in some genotypes in drought conditions but caused decreases in some genotypes. The average L* values of the genotypes were found to increase by 1.8 % under drought conditions. Genotypes 3 (%8.58), 6 (%4.87), 12 (%4.52), 20 (%4.37), 28 (%4.73), 29 (%5.16), 38 (%4.74), 39 (%6.79) and 40 (%4.17) were the highest L* values under drought conditions. On the other hand, genotypes 11 (5.75%) and 31 (3.31%) had lower L * values under drought conditions than irrigation conditions.

Fruit color ''a*''

Positive values of ''a*'' refer red-purple colors while negative values define blue-green colors. In the study, it was found that full irrigation and full drought conditions had a statistically significant effect on average "a*'' value of 2017, 2018 and average of the years according to 5% significance level in different genotypes (Table 1). Considering of the average ''a*'' values of the different pumpkin genotypes in 2017-2018, it was determined that the stress conditions caused % change in the ''a*'' values according to the irrigation conditions (Table 2). When the changes were examined, '' a*'' values increased in some genotypes in drought conditions. ''a*'' value decreased by 14% under drought conditions. 9 (31%), 13 (88%), 39 (18%), 42 (62%) and 45 (25%) genotypes gave higher fruit color ''a*'' values under stress conditions. On the other hand, 5 (48%), 6 (72%), 21 (66%), 31 (50%) and 41 (48%) genotypes gave lower''a*'' values under drought conditions compared to irrigation conditions.

Fruit color ''b*''

In b *, positive values are yellow and negative values are blue. In the study, it was found that the full irrigation and full drought conditions had a statistically significant effect on the average ''b*'' values of 2017, 2018 and average of the years in different genotypes at 5% significance level (Table 1). It has been determined that the drought conditions cause a variation in ''b*'' values according to the irrigation conditions (Table 1). ''b*'' values increased in some genotypes and decreased in some genotypes under drought conditions. ''b*'' values of genotypes were found to increase by 2.64 % under drought conditions. When genotypes were examined, 3 (10.86%), 4 (10.56%), 10 (11.28%), 25 (11.40%), 29 (14.89%), 37 (11.04%) and 43 (17.14%) had higher ''b*'' values under drought conditions. On the other hand, genotype 28 (7.93%), 31 (10.17%), 35 (6.39%) and 39 (5.10%) gave lower ''b*'' values under drought conditions than irrigated plots.

Table 1. Fruit color ''L*, a*, b*'' under irrigation and drought conditions in 2017 and 2018.

In many studies, ''L *, a *, b *'' values of harvested fruits were determined by using Chroma meter. In our study, vide range of variations in ''L *, a *, b *'' color values were observed on the basis of genotypes. The drought did not have much effect on the ''L*'' and ''b*'' color values, but caused a significant change ~~on~~ in the color ''a*''. As drought increased, fruit colors turned from green to red. In other words, the drought caused the fruit color to become red. Ermiş (2010) determined the fruit colors in different pumpkin genotypes and different locations. He obtained from ''L*'' values between 63-74, ''a*'' values between 3.42-19.17 and ''b*'' values between 35-62. As a result of the study, it was reported that fruit colors are not affected by locations but there are significant differences between genotypes. Different researchers have reported that genotype, growing conditions, ripening period and cultural practices have an effect on fruit colors (Itle and Kabelka, 2009; Gajewski *et al.*, 2008). The values we obtained were similar to the previous studies, and it was observed that drought had a significant effect especially on the ''a*'' value.

Seed color ''L*''

In the study, it was found that the full irrigation and full drought conditions had a statistically significant effect on the average seed color ''L*'' value of the 2017, 2018 and years average according to 5% significance level in different genotypes (Table 2). Pumpkin genotypes give an ''L*'' value average of 78.88 in 2017 and 2018 under irrigation conditions. Under stress conditions, the average ''L*'' value was 78.88 in 2017 and 2018. It was determined that the drought conditions caused the seed color ''L*'' values change according to the irrigation conditions ''L*'' values of different pumpkin genotypes in 2017-2018 (Table 2). When the changes were examined, seed color ''L*'' values increased in some genotypes in drought conditions but caused some genotypes to decrease. When the average color ''L*'' values of the genotypes were examined, no difference was found. Genotypes 7 (8%), 11 (4%) and 40 (4%) gave higher seed color ''L*'' values under drought conditions. On the other hand, genotypes 2 (4%), 4 (4%), 18 (5%), 31 (5%), 43 (4%) and 45 (4%) had lower seed color ''L*'' values under drought conditions.

Seed color ''a*''

In the study, it was found that the full irrigation and full drought conditions had a statistically significant effect on the average seed color ''a*'' value of the 2017, 2018 and years average according to 5% significance level in different genotypes (Table 2). It has been determined that the drought conditions caused by the seed color ''a*'' values of different pumpkin genotypes in the 2017-2018 year caused a change in % of seed color ''a*'' values according to the irrigation conditions (Table 2). When the average color ''a*'' values of genotypes were examined, it was found that it decreased by about 3.92% under drought conditions. Genotypes 2 (77%), 5 (90%), 6 (103%), 10 (105%), 26 (98%), 28 (82%) and 43 (114%) had higher seed color ''a*'' values under stress conditions. On the other hand, 7 (52%), 16 (39%), 25 (42%), 29 (44%), 34 (54%), 39 (58%), 40 (57%) and 48 (53%) genotypes gave lower seed color ''a*'' values under stress conditions.

Seed color ''b*''

In the study, it was found that the full irrigation and full drought conditions had a statistically significant effect on the average seed color ''b*'' value of the 2017, 2018 and years average according to 5% significance level in different genotypes (Table 2). It has been determined that the drought conditions caused by the seed color ''b*'' values of different pumpkin genotypes in the 2017-2018 year caused a change in % of seed color ''b*'' values according to the irrigation conditions (Table 6). When the seed color ''b*'' values of the genotypes were examined, it was found that it increased by 2.91% under drought conditions. Genotypes 4 (11%), 6 (14%), 17 (12%), 23 (15%), 25 (12%), 31 (30%), 35 (11%) and 46 (11%) gave higher seed color ''b*'' values under drought conditions. On the other hand, genotypes 7 (14%), 15 (10%), 40 (10%) and 48 (15%) gave lower seed color ''b*'' values under drought conditions.

Using Chroma Meter to determine the color of the seeds, ''L*, a*, b*'' values give important information. In this study, although drought did not have much effect on ''L*, a* and b*'' values, significant changes in ''a* and b*'' values occurred on the basis of genotypes. It is preferred to have cream-colored and bright seeds in appetizer pumpkin. Turgut (2015), obtained from different pumpkin genotypes ''L*'' value between 73-82, ''a*'' value between

-0.84-1.1 and ‘’b*’’ values between 10-17. Our results are consistent with the study. Ermiş (2010), reported that ecology has no significant effect on seed color. In the study, it was observed that drought did not show differences in seed color in general.

Table 2. Seed color ‘’L*, a*, b*’’ under irrigation and drought conditions in 2017 and 2018.

Conclusion

In this study, the effect of drought on fruit and seed color of different pumpkin genotypes was determined. According to the results, important fruit and seed colors were found among genotypes. In addition, it was observed that drought did not have any effect on seed color, while fruit color had a significant effect on ’’a* ’’ value. It was thought that fruit color became redder in drought conditions and color substances were secreted more in drought conditions. This is explained as a physiological response of the plant to drought.

Abstract

As the result of national breeding programmes, three sweet cherry cultivars have been named and released so far in the Republic of Serbia – 'Asenova Rana' and 'Čarna', developed by planned hybridization at Fruit Research Institute (FRI), Čačak, and 'Canetova', selected from natural cherry population at Faculty of Agriculture, University of Belgrade. In addition to the inadequate assortment structure, lacking in well-adapted domestic and introduced cultivars, sweet cherry production in Balkan region is generally accompanied by insufficient knowledge on gametophytic self-incompatibility, the fertilization relationship among the cultivars belonging to certain incompatibility groups, as well as phenological characteristics and synchronization during the flowering phenophase of the main cultivars and pollenizers. The assessment of an adequate pollenizer composition for 'Asenova Rana', 'Čarna' and 'Canetova' in this research is based on determined *S*-allele constitution, parameters of pollen tube growth *in vivo* in the pistils of these cultivars, and their perennial average flowering characteristics in relation to the introduced cultivars – potential pollenizers. The research was conducted in the main sweet cherry growing regions in the Republic of Serbia (West Serbia/Šumadija and region of Belgrade). It resulted in the development of a pollination scheme for in total 28 national and introduced cultivars, its application in the plant material production, and dissemination of quality national sweet cherry cultivars with adequate pollenizers. The results could also influence sweet cherry breeding work on development of genotypes with improved biological and productive characteristics, and application of modern molecular and reproductive biology methods in this research area.

Keywords: *sweet cherry, cultivars, S-allele constitution, flowering, pollination scheme*

Introduction

Sweet cherry (*Prunus avium* L.) flowers express a self-incompatibility system which is controlled by the polymorphic *S*-locus with gametophytic action. The interaction between the components in the style (*S*-allele specific ribonuclease – product of the *S-RNases* gene) (Bošković and Tobbut, 1996) and in the pollen (*S* specific F-box protein, product of the *SFB* gene) (Yamane *et al.*, 2003), determines the outcome of fertilization. Furthermore, fertilization will be prevented if a pollen expresses the same *S*-allele as one of the two *S*-alleles present in the style (Marchese *et al.*, 2007). The other aspects of the reproductive process, which also affect optimal fruit set and yield are characteristics of flowering and stable overlap in the full bloom between the main cultivars and pollenizers from year to year, pollen quality and its transfer, stigma receptivity, ovule longevity etc.

In recent decades, at FRI, Čačak, many research in this area have been done – determination of *S*-allele constitution of introduced sweet cherry cultivars (Radičević *et al.*, 2013, 2015; Marić and Radičević, 2014; Marić *et al.*, 2015); evaluation of sweet cherry flowering characteristics in the Republic of Serbia (Radičević *et al.*, 2012, 2015); investigation of

climate change effect on flowering characteristics, in sense of earlier flowering onset, the shortening of the phenophase duration (Wenden *et al.*, 2016; Drkenda *et al.*, 2018), and ovule longevity (Radičević *et al.*, 2018); evaluation of pollen viability *in vitro* in domestic and introduced sweet cherry genotypes (Cerović *et al.*, 2005; Radičević *et al.*, 2012). The previous research has also revealed the importance of ensuring full-flowering overlap of at least five days (Cerović *et al.*, 2005) accompanied by a short range of the flowering beginning, up to 2–3 days (Radičević *et al.*, 2015), as well as the advantage of one or two days earlier flowering pollenizer, which is better than later-flowering (Radičević *et al.*, 2016).
Up to now, three sweet cherry cultivars have been released in the Republic of Serbia – 'Asenova Rana' and 'Čarna', developed by planned hybridization at FRI, Čačak, and 'Canetova', selected from natural cherry population at Faculty of Agriculture, University of Belgrade. The aim of this paper is to determine the best pollenizers for these national cultivars, which are recommended for commercial growing in the Republic of Serbia, due to their good pomological and productive characteristics (Radičević *et al.*, 2017).

Material and Methods

Twenty-eight national and introduced sweet cherry cultivars were used in this study viz. , 'Asenova Rana', 'Bigarreau de Schrecken', 'Bigarreau Jaboulay', 'Burlat', 'Napoleon', 'Bing', 'Canetova', 'Colney', 'Čarna', 'Ferrovia', 'Drogans Gelbe Knorpelkirshe', 'Emperor Francis', 'Germersdorfer', 'Hedelfinger', 'Junska Rana', 'Karina', 'Kordia', 'Lambert', 'Lapins', 'Merchant', 'Regina', 'Souvenir', 'Stark Hardy Giant', 'Stella', 'Summer Sun', 'Summit', 'Sunburst' and 'Van'. The trial was performed at two sites – West Serbia/Šumadija region (sweet cherry collection orchard of FRI, Čačak, Ljubić facility; 43°54' N, 20°21' E, 224 m above the sea), and region of Belgrade (orchard of an individual grower, Grocka; 44°40' N, 20°43' E, 116 m above the sea), which are typical areas for fruit growing.
Young leaves of 'Asenova Rana', 'Čarna' and 'Canetova' were frozen in liquid nitrogen and stored at –80°C until use for the extraction. Genomic DNA was isolated using the CTAB method (Doyle and Doyle, 1987), with addition of 1% ß-mercaptoethanol and 2% polyvinylpyrrolidone (PVP 40) in the buffer. To identify the *S-RNase* alleles, polymerase chain reactions (PCR) were performed with the consensus primers specific for the first and the second intron (PaConsI-F + -R and PaConsII-F + -R, respectively) and primers specific for alleles S_3 to S_6, as well as for S_1 and S_9 alleles (Sonneveld *et al.*, 2003). PCR products were separated by electrophoresis in a 1.5% agarose gel (70 V for 3–4 h), visualised by ethidium bromide staining and sized by comparison with a 1 Kb plus DNA ladder (Invitrogen).
Flowering phenophase was investigated according to Wertheim (1996), in the period of 2000–2014 (Ljubić), i.e. 2004–2015 (Grocka).
Pollination experiment was carried out according to the method described by Radičević *et al*. (2016). Aniline blue staining was used (Kho and Baër, 1968; Preil, 1970), and pollen tube growth *in vivo* of the following pollenizers: 'Asenova Rana', 'Burlat', 'Čarna', 'Stella' and 'Van' (in the pistils of 'Asenova Rana' and 'Čarna'), i.e. 'Bing', 'Burlat', 'Bigarreau Jaboulay', 'Emperor Francis' and 'Van' (in the pistils of 'Canetova') was monitored under UV light on the Olympus BX61 microscope, and analysed by AnalySIS software, using Multiple Image Analysis. A total of 30 pistils of each treatment (15 combinations) was observed.

Results and Discussion

The results of investigation include: 1) developing of pollenizer composition schemes, in the main sweet cherry regions in the Republic of Serbia – West Serbia/Šumadija, and region of Belgrade; 2) defining the general rules for their aplication; 3) creating the list of pollenizers by priority (the categories of mandatory pollenizers, pollenizers of the second priority, pollenizers of the last choice, and unsuitable pollenizers), for each national cultivar.

Graph. 2. The scheme of pollenizer composition for sweet cherry cultivar 'Canetova' in agroecological conditions of Belgrade region

The research indicates the following:
- For 'Asenova Rana' (S_3S_9), the mandatory pollenizers are 'Lapins', 'Bigarreau Jaboulay', 'Merchant', respectively; pollenizers of the second priority – 'Emperor Francis', 'Napoleon', 'Van', 'Stella', 'Čarna', respectively; pollenizers of the last choice – 'Stark Hardy Giant' and 'Summit', respectively; the unsuitable pollenizers are: 'Souvenir', 'Burlat' and 'Junska Rana', as well as the cultivars from category 'insufficient overlap', regardless of incompatibility group (Graph. 1);
- For 'Čarna' (S_1S_4), the mandatory pollenizers are 'Stella', 'Van', 'Napoleon', 'Emperor Francis', 'Stark Hardy Giant', 'Summit', 'Sunburst', 'Kordia', 'Summer Sun', 'Germersdorfer I', respectively; pollenizers of the second priority – 'Merchant', 'Junska Rana', 'Asenova Rana', 'Burlat', 'Lapins', 'Souvenir', 'Bigarreau Jaboulay', respectively; pollenizers of the last choice are 'Bing', 'Hedelfinger', 'Karina', 'Germersdorfer II', 'Colney', 'Ferrovia', respectively; the unsuitable pollenizers are cultivars from category 'insufficient overlap', regardless of incompatibility group (Graph. 1);
- For 'Canetova' (S_5S_6), the mandatory pollenizers are 'Burlat', 'Lapins', 'Souvenir', 'Bigarreau Jaboulay', 'Emperor Francis', 'Napoleon', respectively; pollenizers of the second priority are 'Van' and 'Stella', respectively; the unsuitable pollenizers are cultivars from category 'insufficient overlap', regardless of incompatibility group (Graph. 2).

Conclusions

Determination of pollenizers for sweet cherry cultivars released in the Republic of Serbia – 'Asenova Rana', 'Čarna' and 'Canetova', and developing pollination scheme for in total 28 national and introduced sweet cherry cultivars, are directly applicable in dissemination of quality national and introduced cherry cultivars, with adequate pollenizers. The results are also important for developing new sweet cherry cultivars, as well as for further application of molecular and reproductive biology methods in fruit trees breeding work.

Abstract
Despite the huge diversity of maize germplasm, modern maize breeding programme and agricultural practices decrease the diversity of modern hybrids. Genetic characterization of maize hybrids allows knowledge of the genetic relationship among them, thus preventing the risk of increasing uniformity. Because of their high reproducibility, informativeness and easey application of microsatelites are the most frequently used molecular markers in maize genetic diversity studies. The aim of our work was to evaluate genetic diversity of maize hybrids by SSR markers and compare results with their pedigre information. Sixteen polymorphic SSR (*Simple Sequence Repeats*) markers were used to characterize 14 maize (*Zea mays* L.) hybrids belonging to different breeding programs and FAO groups (from 300 to 800). A total of 53 alleles were found, ranging from two to four alleles. Genetic similarities were calculated in NTSYSpc2 program package using Jaccard's coefficient based on binary data (presence or absence of alleles). The highest value of genetic similarity was 0.80 between H1 and H2, while the lowest value (0.26) was found between H12 and H13. Cluster analysis was done by unweighted pair group method (UPGMA) on the basis of genetic similarity matrix. Dendrogram analysis grouped maize hybrids in one cluster (most of the analyzed genotypes), one smaller cluster and one branch. The results revealed genetic heterogeneity between analyzed maize hybrids.

Keywords: *maize hybrids, genetic similarity, SSR markers, Zea mays L.*

Introduction
Maize, wheat and rice are the most important cereal crops grown in the world. Maize is used mainly for food, feed, as feedstock for food processing and in chemical industry. Due to huge genetic and phenotypic variability maize is adapted to different agroecological environments, edaphic and climatic conditions.

Maize has an important role in the field of scientific research such as the application of molecular genetic techniques and identifying genes and their functions. Maize is biological model system for genetics, evolution and domestication of cereals of the highest public interest (Wei et al., 2007). The main characteristic of maize is based on its variability in morphological traits and the high polymorphism of the DNA sequence (Matsuoka et al., 2002). During the breeding programs, maize hybrids have narrowed the genetic basis, leding to a significant reduction in diversity, so maize in commercial use contribute around 5% of the available germplasm (Carena et al., 2009).

In order to prevent genetic erosion, i.e. loss of individual genes and their combinations, as well as further narrowing of maize diversity, it is necessary to characterize existing elite lines, modern varieties and hybrids. Many methodologies are used for the assessment of genetic diversity in maize such as pedigree data, morphological traits and molecular markers. Compared with morphological variation, molecular polymorphism is generally considered to be independent of the environment and they are able to detect differences on DNA level on different individuals. (Ghebru et al., 2002; O'Neill et al., 2003).

Molecular diversity analyses can be performed using various kinds of methods including fragment length polymorphisms (RFLPs), amplified fragment length polymorphisms

(AFLPs), randomly amplified polymorphic DNA markers (RAPD), simple sequence repeats (SSRs) or single nucleotide polymorphisms (SNPs). SSR markers have been the marker of choice for assessing maize genetic diversity due to the high level of polymorphism, multi-allelic nature, random distribution throughout the genome and cost effectivness (Barcaccia et al., 2006; Mason, 2015). In plant genomes they show an extensive variation in different individuals and genotypes (Cömertpay et al., 2012). Single nucleotide polymorphism (SNP) are new marker technologies that could also be used for estimating genetic diversity, but they are still to be adjusted for studies of genetic relatedness in maize (Yang et al.,2011).
In the present work SSR fingerprinting of 14 maize hybrids was done for molecular identification and assessment of genetic diversity, as well as to compare their clasification with their pedigre information.

Materials and Methods

A set of fortheen maize hybrids from the Maize Research Institute „Zemun Polje" that belong to different breeding programs were analyzed with molecular markers to evaluate genetic diversity. These 14 hybrids are covering different FAO groups, in the range from 300 to 800 (Table 1).

Table 1. List of the analyzed maize hybrids and their FAO groups

Hybrid	FAO group	Hybrid	FAO group
H1	300	H8	500
H2	300	H9	600
H3	600	H10	700
H4	300	H11	800
H5	500	H12	600
H6	500	H13	400
H7	500	H14	400

Genomic DNA was isolated from kernel using the CTAB (cetyl trimethylammonium bromide) procedure according to Doyle and Doyle (1987). Simple sequence repeat (SSR) characterization was done with 18 markers from the maize germplasm bank (www.maizegdb.org) (Table 1). Polymerase chain reaction (PCR) was carried out in 25µL reaction volume containing: 50ng of DNA sample, 1xBuffer, 0.8mM dNTP, 0.5µM of each primer pair and 1U Taq polymerase. The PCRs were performed using the following touch-down program: an initial denaturation at 95ºC/5min. by 15 cycles each of denaturation at 95ºC/30 s, annealing at 63.5/1min (-0.5ºC/cycle) and extension at 72 ºC /1min; and another 22 cycles of 95 ºC /30 s, 56ºC/1min and 72ºC/1min. Final elongation was at 72°C for 4min. Using vertical electrophoresis (Mini Protean Tetra-Cell BioRad) the amplified PCR fragments were separated on 8% polyacrylamide gel, with 20 bp ladder as a marker. Gels were photographed under UV light on BioDocAnalyse Biometra after staining with 0.5µg/µL ethidium bromide. Data were assembled into a binary matrix after SSR profiles were scored as presence or absence (1/0) of fragments in each sample. Genetic similarities (GS) between maize hybrids were calculated in accordance to Jaccard (1908): $GSij = a/(a+b+c)$; where *a* is number of fragment shared by both individuals; *b* is number of fragments present in *i* but not in *j*; *c* is number of fragments present in *j* but not in *i*. For marker data analyses statistical NTSYSpc2 program package (Rohlf FJ, 2000) was applied.

Results and Discussion

The loss of maize diversity is considered one of today's most serious problem in maize production. Genetic biodiversity of maize is crucial for future breeding programmes in continuing advances in yield, grain quality improvement, disease and pest resistance.

In order to determine genetic diversity between 14 maize hybrids, molecular characterization was done using 18 SSR markers (Table 2). Two SSRs were not included in data analyses since they were monomorphic. Total of 53 alleles among the analysed 14 maize hybrids were identified. The number of alleles obtained with different primers varied from two (nc133) to four (bnlg1083, phi083, umc1448, umc1109, bnlg2235, umc1492 and umc1152) with the average value of 3.31 per locus. Similar number of alleles 3.33 was found in work with 38 Iranian maize hybrids (Shiri et al., 2015). Bantte and Prasanna (2003) reported slightly lower number of alleles (3.25) with 36 SSR loci. Some other works have shown considerably higher number of alleles. Nikkhoy and Shiri (2017) obtained 4.2 alleles per locus with 20 SSRmarkers on maize hybrids, while Lu and Bernardo (2001) found 4.9 alleles with 83 SSR loci, same as Warburton et al. (2002) with 85 SSR loci.

Table 2. List of 16 informative primers, with their chromosome position, repeat motif, number of alleles and allele range within analyzed maize hybrids

	Probe	Bin	Repeat motif	Number of alleles
1.	umc1282	1.00	(AT)6	3
2.	phi109275	1.03	AGCT	2
3.	bnlg1083	1.02	AG(29)	4
4.	umc1122	1.06	(CGT)7	3
5.	umc2047	1.09	(GACT)4	3
6.	phi083	2.04	AGCT	4
7.	umc1448	2.04	(GCT)5	4
8.	nc133	2.05	GTGTC	2
9.	umc1109	4.10	(ACG)4	4
10.	umc1153	5.09	(TCA)4	3
11.	phi452693	6.04	AGCC	3
12.	bnlg2235	8.02	AG(23)	4
13.	phi080	8.08	AGGAG	3
14.	umc1492	9.04	(GCT)4	4
15.	umc1152	10.01	(ATAG)6	4
16.	bnlg1526	10.04	AG(15)	3

Based on presense or absense of alleles in each sample coefficient of similarity was calculated by Jaccard. The genetic similarities were in range from 0.26 for H12 and H13 to 0.80 for two pairs of hybrids H1 and H2. Hybrids H12 nad H13 belong to specific types of maize, popcorne and sweet corn hybrids, respectively. On the other hand, single crosses hybrids H1 and H2 showed the higest similarity, because they have one same parental component and the other one are highly related inbred lines.

The cluster analysis using UPGMA method, based on Jaccard similarities distributed genotypes into two clusters (A and B) and one branch (c) showing good separation of hybrids and agrement with their pedigre data. Hybrids with very similar parental lines were grouped together within dendrogram. Cluster A contained most of the analyzed genotypes (11), dividing into subclusters A1 and A2. Subclaster A1 grouped hybrids with same genetic basis; hybrids H5 and H7 have one same parental component, and H4 and H6 are three way crosses and they have one parental line in common. This subclaster contained all hybrids from 300

FAO group, two from 500 FAO group and one from 600 FAO group. In subcluster A2 were grouped hybrids from 500 to 800 FAO groups, which have also same genetic basis. H9 and H10 have very similar parental lines, from te same source. Sweet corn hybrids (H13 and H14) formed cluster B, while branch c was formed of popcorn hybrid H12.

The average similarity of 0.54 among 14 maize hybrids showed satisfying variability between hybrids. The lower variability was reported in Bauer et al. (2005) with RAPD markers on maize hybrids, where Jaccard's coefficient of similarity ranged from 0.69 to 0.93. Also, Chen et al. (2008) reported higer genetic similarities with average value of 0.77 among 186 maize hybrids in China.

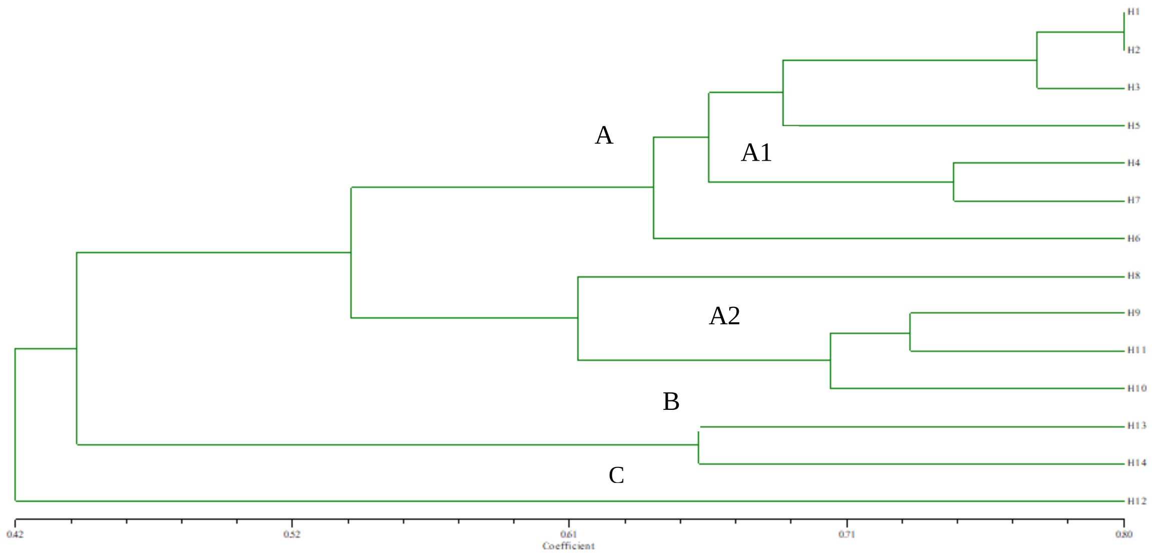

Figure 1. Dendrogram of 14 maize hybrids constructed using UPGMA cluster analysis of genetic similarity values (Jaccard, 1908) obtained from SSR data.

In his study SSR analysis determined variability among maize hybrids, as well as their grouping by genetic background. The dendrogram constructed from UPGMA method distinguishing hybrids to clusters according to their parental lines.

Conclusions

SSR markers is powerful tool for genetic characterization of maize hybrids and their clasification comparing with pedigree data. In this work 16 polymorphic SSR markers classified 14 maize hybrids into different groups in accordance to their pedigree data. Molecular marker could be successful and significant in evaluation of maize diversity assigned the most of the maize hybrids to their genetic background.

Abstract

Testing of maize inbred lines distinctness, uniformity and stability was done according to the UPOV (Union Internationale pour la Protection des Obtentions Végétales) markers. In this study, three-year field experiment was conducted according to Complete Randomized Block Design (RCBD), in two densities and sowing data, in two replications. Eleven visual (VG) assessed traits, eight measured (MS) morphological traits and eight yield components, as well as grain yield, were evaluated. For this purpose, previously applied Ultra Thin Isoelectric Focusing marked five inbred lines (L1 – L5) differing in genetic purity, to be evaluated in field experiment for uniformity and stability. According to visual assessment, all inbred lines observed exhibited maximum uniformity in anthocyanin coloration of glumes of cob. Poor uniformity was achieved by all inbreds evaluated for anthocyanin coloration of glume excluding base and color of dorsal side of grain. L1 inbred expressed the highest uniformity and stability for most of the traits. Both inbreds with low genetic purity (i.e. L4 and L5) showed trend of segregation for almost all the traits. Three-way Analyses of Variance (ANOVA) was used for agro-morphological data analyzing. The best performing line was L3, as the most stable and uniform. Compared to pure inbreds, results of ANOVA showed more pronounced variations in morphological traits within lines with low genetic purity. Testing of inbreds differing in genetic purity by UPOV descriptors confirmed, to a certain extent, the results considering genetic purity obtained by IEF testing.

Keywords: *Genetic purity, Isoelectric Focusing, UPOV descriptors, Zea mays* L.

Introduction

Uniformity and stability of maize hybrids depend upon high and stable inbred lines performance. For both attaining good agronomic performances and encouraging investment and innovation in plant breeding, a high level of genetic purity in crop varieties have to be achieved and maintained *(Ipsilandis et al.*, 2005). The ability of a genotype to specify a phenotype consistently (i.e. the phenotype uniformity) is a key target for selective breeding in crops (Makumburage and Stapleton, 2011). Distinctness, uniformity and stability (DUS) testing is one of the important criteria to test inbred lines and it is essential to comprehend different modes of the traits expression. DUS testing of cultivars is one of the requirements for granting Plant Breeders Rights (PBR) and it is conducted according to national guidelines prepared on the basis of UPOV (Union Internationale pour la Protection des Obtentions Végétales) guidelines (Yadav and Singh, 2010). According to the environmental changes and low level of polymorphism, low heritability, late expression, limited discriminative power, and lower potential to measure relatedness and genetic similarity, morphological characterization has its own disadvantages, it is time-consuming and varies (Babic *et al.*, 2016). However, morphological traits are still very important in determination of the agronomic value and in taxonomic classification of plant species, including maize (Ortiz *et al.*, 2008). Traditionally, morphological comparisons have formed the basis for genetic purity evaluations. Biochemical assays, including isozymes, can distinguish varieties within species. Isozymes have been routinely used in checking seed-lot purity in maize. Ultra Thin Isoelectric

Focusing (UTLIEF) analysis is a standard reference method for testing the genetic purity of lines and hybrids (Dou *et al*., 2012). This method consists of extracting seed storage proteins (aqueous soluble – albumins and alcoholic soluble - zeins) from individual grains and their separation on a polyacrylamide gel. However, this method is limited due to many factors affecting isozyme expression, including development of plant tissue and the environment. Less loci and restricted polymorphism may also affect the utility of these markers. Because isozymes and genes affecting morphological traits are most usually coded by different and unlinked loci, a "clean" isozyme profile will not necessarily correlate with morphological homogeneity. For this reason, the aim of this study was to estimate the efficiency of morphologycal markers towards genetic purity determination.

Material and Methods

Based on previously conducted UTLIEF method (ISTA, 2005) regarding determination of electrophoretic patterns for storage proteins (albumines and zeins), five maize inbred lines (L1 – L5) differing in genetic purity were tested. Further on, the inbreds were subjected to distinctness, uniformity and stability evaluation according to the UPOV markers in three-year field experiment (from 2016 to 2018), carried out in Zemun Polje, Serbia (44°52´N, 20°19´E, 81 m asl). The experiment was set up according to Complete Randomised Block Design (RCBD), in two densities (i.e. D-30cm and D-40cm) and two sowing dates (in ten-day interval), in two replications. Inbreds of different maturity group L1 – L2 (maturity of FAO 300), L3 – L4 (maturity of FAO 400), and L5 (maturity of FAO 600), were sown in the four-rowed plot, with 10 hills per row and spaced 0.75 m apart. Four seeds per hill were sown and thinned to two plants per hill. Both visualy scored (VG) and measured (MS) morphological traits were observed on plants from two central rows, in a particular developmental stage. Eleven VG traits included eight quantitative (QN) traits (e.g. anthocyanin coloration of sheath, at base of glume, of glumes excluding base, of anthers, silks, of brace roots and of glumes of cob, as well as the angle between blade and steam), two pseudo-qualitative (PQ) traits (e.g. color of top and dorsal side of grain) and one qualitative (QL) trait – type of grain. In both replications, measuring of morphological traits – plant height (PH), plant hight to upper most *node (PHN)*, number of leaves above upper most ear (NLAE), leaf length (LL), leaf width (LW), ear height (EH), length of main axis above the lowest lateral (LALB) and the highest lateral (LAHB) branch, were conducted on ten representative plants per maize inbred. After manual harvesting and drying to 14% of moisture content, grain yield (GY) was calculated per plant basis. For each inbred line, yield components – ear length (EL), ear diameter (ED), cob diameter (CD), kernel length (KL), width (KW) and thickness (KT), number of kernels per row (NKR) and number of rows per ear (NRE), were recorded on ten randomly chosen ears per replication. Three-way analyses of variance (ANOVA) was used for agro-morphological data analyzing.

Results and Discussion

Genetic homogeneity refers to the presence of identical genotypes, whereas genetic stability refers to phenotypic uniformity (homeostasis) in different environments *(Živanović et al*., 2004). When a variety has been shown to be uniform, it can also be considered to be stable by UPOV. It has been shown that the uniformity threshold was never surpassed within a single trial, but discrepancy was observed between three annual scores (Gunjaca *et al*., 2008). In our study, all five observed inbreds exhibited maximum uniformity and stability for anthocyanin coloration of glumes of cob (ACGC). In all inbreds, poor uniformity was evidenced for anthocyanin coloration at base of glume (ACBG) and color of dorsal side of grain (CDG), respectively. According to VG traits, L1 expressed the highest uniformity and stability (Table 1). This line showed maximum uniformity (100%) in three observed traits: ACSh, ACBG and

GT, and close to this rating was ACBR. Lines L2 and L3 also were highly uniform and stabile. Similar trend in VG traits expression is observed between 2016 and 2017 in L1 and L2, and between 2017 and 2018 in L3. In L4 and L5, however, segregation was recorded for most of the observed traits, as well as their higher variation per year basis. Thus, results of visual assessment by UPOV descriptors confirmed, to a certain extent, the results obtained by UTLIEF.

Table 1. Segregation in VG traits according to particular UPOV descriptors scale level (given in brackets) for five (L1 – L5) maize inbred lines evaluated

VG trait	L1	L2	L3	L4	L5
	Quantitative traits (QN)				
ACSh	1:0 - (1)	5:1 - (3,5)	5:1 - (1,3)	4:1 - (1,3)	1:7:2:2 - (1,3,5,7)

ACS	1:5 - (1,3)	1:3 - (3,5)	3:1 - (3,5)	1:4:1 - (3,5,7)	2:9:1 - (5,7,9)
ACBR	1:11 - (1,3)	1:3 - (7,9)	5:1 - (5,7)	1:1 - (1,3)	1:1 - (5,7)
ACGC	1:5 - (3,5)	1:0 - (5)	11:1 - (5,7)	2:1 - (5,7)	1:0 - (1)
ABS	5:7 - (3,5)	1:3 - (1,3)	1:11 - (3,5)	6:5:1 - (1,3,5)	7:5 - (1,3)
	Pseudo-qualitative traits (PQ)				
CTG	1:3 - (4,5)	11:1 - (5,6)	1:3 - (3,4)	1:1 - (3,4)	5:7 - (3,4)
CDG	1:3 - (3,4)	3:1 - (3,4)	7:5 - (5,6)	5:3:4 - (2,3,4)	6:2:3:1 - (1,3,4,5)
	Qualitative traits (QL)				
GT	1:0 - (1)	2:1 - (1,2)	1:5 - (3,4)	5:7 - (3,4)	3:1 - (2,3)

ACSh ─ anthocyanin coloration of sheath; ACBG ─ anthocyanin coloration at base of glume; ACGB ─ anthocyanin coloration of glumes excluding base; ACA ─ anthocyanin coloration of anthers; ACS – anthocyanin coloration of silks; ACBR ─ anthocyanin coloration of brace roots; ACGC ─ anthocyanin coloration of glumes of cob; ABS ─ angle between blade and steam; CTG ─ color of top side of grain; CDG ─ color of dorsal side of grain; GT ─ type of grain.

The plant morphology depends largely upon environmental conditions, as well as upon plants traits with their genetic variability (Tardieu, 2013). Since the experiment was conducted in three year, highly varying in environmental conditions, factor A had the most significant influence on observed morphological traits for all analyzed genotypes (Table 2). Moreover, higher plant density impose a variety of stresses on plants, including competition for light, water, and nutrients (Sher *et al.*, 2017). Factor B showed significant effect on two traits (NLAE and LW) only in inbred L5. Interaction A x B influenced L4 for PH, PHN and LL, while L5 varied for PHN. Although pure L1 inbred varied in five out of eight traits observed, inbreds L2 and L3 exhibited high stability. Inbred L4 was affected the most by factor C for LL, LW, EH, LALB and LAHB. Considering observed interactions, under A x C, L1 performed the best, however, pure L3 line varied in LW, LALB, and LAHB (the last two are the most variable traits). Genetically poor inbred L4 varied in NLAE, LW and LAHB, while L3 varied in PHN and EH. Our findings were in line with the study on four maize inbred lines under two-year experiment, that LALB and LAHB were considered relatively less stable traits as compared to other measurable characteristics (Akande and Lamidi, 2006; Olaoye, 2009). For all inbred lines tested, interactions B x C and A x B x C were insignificant. Similarly, in study on forage maize, Moosavi *et al.* (2012) reported insignificant effect of sowing date and plant density on morphological traits.

Table 2. Sagnificance for observed morphological traits according to ANOVA for inbred lines

P – plant height; *PHN* – plant hight to upper most *node;* NLAE – number of leaves above upper most ear; LL – leaf length; LW – leaf width; EH – ear height; LALB – lowest lateral; LAHB – length of main axis above the highest lateral branch; *,**,*** – significant at $p \leq 0.05$, 0.01 and 0.001 probability level, respectively; ns – non-significant.

In comparison with morphological traits, the results of ANOVA for yield components showed a slightly pronounced effect of observed factors and their interactions (data not presented). Effect of year (A) had the biggest impact on the observed parameters, similarly as observed for morphological traits. Factor B had the highest influence on pure L1 and L2 inbreds for most of the traits. Our results are in agreement with Testa *et al.* (2016), that plant density decreased cob diameter (-10.8%) and the number of kernels per row (-10%). Pure L2 inbred was highly affected by A x B interaction for KW, KT, NKR and CD as the most variable trait, except for L5. Effect of sowing date (factor C) was observed only for CD in L4 line, opposite to reported significant effects on yield components (Beiragi *et al.*, 2011). Interactions A x C and A x B x C affected pure L1 line for EL, ED, CD, KL and NRE. Compared to morphological traits, more pronounced effect of A x B x C interaction was observed for yield components. In all lines evaluated, interaction B x C was insignificant for all the traits observed, similar to morphological traits.

Grain yield and yield stability across multiple years (i.e. weather conditions) are some of the most important selection targets for plant breeding (Moose and Mumm, 2008). In our study, the results of ANOVA for grain yield, showed that factor A (year) had highly significant ($p \leq 0.001$) effect on all observed inbreds, being the highest in optimal 2018 and the lowest in dry 2017 (Table 3). Opposite trend for plant density (factor B) effect on grain yield was observed between pure inbreds (L1, L2 and L3) (i.e. $p \leq 0.001$, 0.001 and 0.01, respectively) and low genetic purity inbreds (L4 and L5) (insignificant). Sowing date (factor C) was highly significant for all the inbreds ($p \leq 0.001$), except for L4 ($p \leq 0.05$). For both L4 and L5 (low genetic purity inbreds), effect of all interactions on grain yield was insignificant, which was opposite to pure inbreds (L1, L2 and L3). This could be explain by the presence of genomic heterozygosity, which plays a significant role in stability level (Ertiro *et al.*, 2015).

Table 3. Three-way analyses of variance (ANOVA) for grain yield achieved by inbred lines evaluated

Inbred line	Source of variation	Repl.	Factor A	Factor B	Factor C	A x B	A x C	B x C	A x B x C
	df	1	2	1	1	2	2	1	2

	CV (%)	16.03							

df ‒ degrees of freedom; MS ‒ mean square; CV ‒ coefficient of variation; Factor A ‒ year; Factor B ‒ plant density; Factor C ‒ sowing date; *,**,*** ‒ significant at $p \leq 0.05$, 0.01 and 0.001 probability level, respectively; ns ‒ non-significant.

Conclusions

Uniformity and stability largely differed among observed plant traits. High stability of visualy scored morphological traits was confirmed by estimated good performances of pure L1 inbred, as well as segregation trend for almost all VG traits in low genetic purity L4 and L5 inbreds. A certain level of variability observed in pure L1 inbred performances, followed by more pronounced variations in morphological traits within lines with low genetic purity, confirmed the low stability of MS agro-morphological traits. Opposite to pure inbreds, the presence of genomic heterozygosity contributed to higher level of yield stability in low genetic purity inbreds.

Abstract

The paper compares agrochemical and microbiological parameters of arable land (for more than 50 years involved in agricultural activity) and natural ecosystem never exposed to anthropogenic impact. The study was conducted during the growing season of 2018 on meadow brown soil of experimental field of Far Eastern Agricultural Research Institute, Russia (48°31'05.9"N 135°16'25.6"E). Indicators of soil fertility and biological activity were determined. Hydrolytic acidity and pH values were measured potentiometrically; aluminium content was measured colorimetrically with xylenol orange; organic matter (humus), humic and fulvic acids – according to the methodology of M.M. Kononova and N.P. Belchikova. The total number of CFU was determined by method of serial dilutions with consequent spread plating on agar media (nutrient agar, starch-ammonia agar). A rise in exchange acidity provided an increase in the aluminium content (Al^{3+}) in arable horizon. Intensive pressure on the soil of experimental plots led to a decrease in humus content compared to the soil of natural ecosystem by 2.69-1.68 times and to an increase in the acidity of the arable horizon by 1.4-1.1. Anthropogenic pressure had a negative effect on the number of microorganisms inhabiting the soil of agrocenoses: the content of nitrifiers was 50.2 million units / 1 g abs. dry soil in the meadow versus 11.66 million units / 1 g abs. dry soil of agrocosystem; the content of ammonifiers - 21.2 million units / 1 g abs. dry soil versus 3.14 million units / 1 g abs. dry soil respectively.

Keywords: *Agrocenosis, Nitrifiers, Ammonifiers, Anthropogenic transformation, Soil fertility.*

Introduction

All the most important soil processes take place with the direct or indirect participation of organic matter. Nearly all soil organic matter is transformed by microorganisms. The final products of this activity are minerals. However, in the process of transformation of organic matter, intermediate complex and diverse organic compounds are formed, which are united by one common concept - humus. Fulvic and humic acids play a special role in soil formation. The quality of humus depends on the ratio of humic acids carbon to fulvic acids carbon. All soils with humate-fulvate (1.0-0.5) and especially with fulvate (<0.5) humus are characterized as acidic, they urgently need liming.

After the involvement of virgin soils in agricultural activity, the humus content in them noticeably decrease due to the strengthening of its decomposition processes. The loss of humus is greatest in the first years after involvement, and then a lower equilibrium content of humus is established in the soil.

Soil organic matter is a source of nutrition for both plants and microorganisms. Under their influence it is transformed with the formation of biologically active substances and releasing the large amounts of carbon dioxide, which is essential for activating photosynthesis in plants. (Basistiy, 2008)

The content and forms of nutrient compounds in the soil reflect the nature of the soil-forming process and serve as a diagnostic indicator of the fertility of soil (Sedykh et al., 2014). However, in modern conditions, natural factors affecting the soil, are combined with anthropogenic, affecting, as a rule, the level of soil fertility. Therefore, both natural and anthropogenic impacts are almost always the cause of changes in soil fertility. The anthropogenic factors may include (but not limited to) the application of chemicals (fertilizers, pesticides), soil and plants treatments using agricultural machinery (ploughing, cultivation, planting, harvesting etc.) with consequent fuel pollution, depletion of nutrients in soil as a result of continuous agricultural activities.

The anthropogenic pressure also has a significant effect on the soil microbial community, transforming important ecological functions in the biosphere associated with the cycling of nutrients, regulation of the atmospheric gas composition and the formation of the soil structure (Griffiths, 1965; Glazovskaya, 1984; Zvyagintsev, 1992; Conrad, 1996).

Soil microorganisms perform system-forming functions in such processes as soil formation, decomposition of soil organic matter, growth stimulation for plants and performing protection from pathogenic microflora (Morris et al., 1998; Raubuch, Beese, 1995).

The purpose of this study was to determine the effect of long-term anthropogenic stress on the transformation of physicochemical and microbiological properties of soils involved in agricultural activities.

Materials and Methods

The study was conducted in the fields of the long-term stationary experiments of the Far Eastern Agricultural Research Institute, Russia (48°31'05.9"N 135°16'25.6"E), which had been cultivated since 1963. The ecosystem that has never been exposed to anthropogenic pressure (the meadow) was chosen as a control. The region is characterized by meadow-brown, heavy loamy soils with an acidic soil pH. The sum of surface layer air temperatures >10℃ for the growing season (from sowing to harvesting) was 1793.5 ℃; the amount of precipitation for the period was 297.6 mm. The crop rotation system on experimental field includes the alternation of oats, soybean and wheat with perennial grasses. Soil treatment system is conventional for the region and includes ploughing, spring pre-sowing disking and harrowing in 2 tracks.

The studies were conducted in two directions: 1 – the comparison of the amount of exchangeable bases (calcium, magnesium), aluminium, hydrolytic acidity and pH values in soils of agroecosystem (with the application of different doses of mineral fertilizers) and the natural ecosystem never involved in agricultural activity (meadow); 2 – the comparison of the content of humus, humic and fulvic acids, their ratio, pH and number of nitrifying and ammonifying bacteria in soils of agroecosystem (with mineral fertilizers and with the aftereffect of organic fertilizers and liming) and natural ecosystem (meadow). Samples for microbiological analyses were taken from plots without any fertilizers.

Soil samples were taken before sowing crops, in the middle of the growing season and before harvesting. For microbiological analyses, samples were taken with observance of asepsis.

Hydrolytic acidity and pH values were measured potentiometrically; aluminium content was measured colorimetrically with xylenol orange; organic matter (humus), humic and fulvic acids - according to the methodology of M.M. Kononova and N.P. Belchikova.

The method of serial dilutions with consequent spread plating on agar media (nutrient agar, starch-ammonia agar) was used to determine the total number of colony-forming units per 1 gram of absolutely dry soil and quantitative characteristics of two main groups of microorganisms: nitrifying and ammonifying bacteria. Nutrient agar (NA) was used to count the ammonifying microorganisms that decompose the nitrogen-containing organic matter in the soil. Starch-ammonia agar (SAA) - to count the amylolytic microflora, capable of carrying out the destruction of oligo-, polysaccharides and immobilization of nitrogen.

Also, the coefficient of mineralization was determined as a ratio of the number of ammonifying microorganisms to the number of microorganisms that assimilate mineral nitrogen.
Based on the data on the quantitative composition of microorganisms on different nutrient media, the conclusion about the level of enrichment of soil with microorganisms was made.
The species composition of soil microorganisms was determined by molecular genetic methods: DNA was extracted from the most typical microorganisms, the part of 16S ribosomal RNA gene was amplified using PCR, and the obtained products were sequenced by Sanger.

Results and Discussion

Long-term use of meadow-brown soils in field crop rotation has led to levelling of zonal properties, as well as to their unidirectional degradation (Table 1), especially with increasing anthropogenic pressure. The rise of metabolic acidity provided an increase in the content of aluminum (Al^{3+}) in arable horizon, especially in the variants with high doses of nitrogen fertilizers. The acidity of the soil solution is an important factor in determining the availability of nutrients for plants.

Table 1. Transformation of soil properties in agricultural lands.

Variants	pH	Hydrolytic acidity	Ca^{2+}	Mg^{2+}	Ca^{2+}+ Mg^{2+}	Al^{3+}, mg / 100 g soil
		mEq. / 100 g soil				
1. Natural ecosystem (meadow)	5.6	7.1	8.4	11.4	19.8	0.06
2. Without fertilizers	4.9	3.7	5.4	11.4	16.9	0.09
3. $N_{16}P_{16}K_8$	4.8	5.5	6.1	11.8	17.9	0.10
4. $N_{32}P_{16}K_{16}$	4.7	6.8	8.1	10.7	18.8	0.29
5. $N_{48}P_{16}K_{24}$	4.8	6.0	9.2	10.0	19.2	0.62
6. $N_{16}P_{16}K_8$	4.8	3.4	8.4	10.2	18.6	0.10
7. $N_{16}P_{32}K_{16}$	4.8	3.0	6.8	12.8	19.6	0.33
8. $N_{16}P_{48}K_{24}$	4.7	5.0	7.3	10.3	17.6	0.94
9. $N_{56}P_{56}K_{28}$	4.7	5.1	6.1	11.0	17.0	0.94

On acidic soils, plants lack nitrates. The soil pH has a particularly strong influence on the phosphate regime of the soil, since as a result of the inhibition of the nitrification capacity, the binding of phosphates to trivalent forms of iron and aluminium inaccessible to plants occurs. On acidic soils, the negative effect of aluminium increases. In addition, aluminium forms insoluble phosphates with phosphorus that are poorly used by plants in an acidic environment (Sychev et al., 2010). In this case, an excess of aluminium and manganese has a toxic effect on plants. In addition, the alienation of the overwhelming majority of biomass with harvested crops violated the biogeochemical circulation, as a result of which the soil supply with biophilic nutrients decreased.

The total activity of humus in relation to the mineral part of the soil depends on the ratio and content of humic and fulvic acids. Due to the strongly acidic reaction (control variant) and good solubility in water, fulvic acids actively destroy the mineral part of the soil and reduce humus accumulation. In the variants with mineral fertilizers and with the aftereffect of organic fertilizers and liming, the ratio of humic acids carbon to fulvic acids carbon C_H/ C_F). grows, which has a favourable effect on the accumulation of humus in the arable horizon of the soil, and at a ratio of C_H/ C_F. more than 1, active humus accumulation occurs and the mineral part remains almost unchanged (Table 2).

Table 2 - Changes in the content of humus and humus acids with continuous anthropogenic impact.

Variants	Mass fraction of organic matter (humus), %	Humic acids, %	Fulvic acids, %	C_H/ C_F	pH
Natural ecosystem (meadow)	**5.48**	**1.17**	**1.85**	**0.63**	**5.6**
1. Control (without fertilizers)	2.79	0.24	0.74	0.32	4.2
2. Peat compost 100 t / ha (aftereffect)	3.15	0.45	0.78	0.58	4.3
3. $N_{32}P_{32}K_{16}$	3.80	0.71	0.72	0.99	4.5
4. Ca 2.25 GK (aftereffect)	3.70	1.07	0.76	1.41	4.5

Microflora of areas exposed and not exposed to anthropogenic influence, differed significantly in the number of microorganisms that decompose mineral nitrogen: an average of $50.2 \cdot 10^6$ in the meadow versus $4.01 \cdot 10^6$ in agrocenosis; as well as by the number of organic nitrogen destructors: $21.2 \cdot 10^6$ versus $3.14 \cdot 10^6$ (Table 3).

Table 3. The average number of microorganisms in soils affected and not affected by anthropogenic factor

Soil type	Number of soil microorganisms, million units / 1 g of absolutely dry soil	
	NA	SAA
Natural ecosystem (meadow)	21,20	50,20
anthropogenically modified soil	3.14	11.66

The number of microorganisms had been increasing during the growing season, but it was smaller than before the crop was planted. On average, there is a noticeable predominance of nitrifiers over ammonifiers in areas both influenced and not influenced by agricultural activity ($50.2 \cdot 10^6$ vs. 21.2 10^6 in the meadow; 11.66 10^6 against 3.14 10^6 under oats), the numbers of these groups of microorganisms differ by 2-3 times.
According to the scale of assessment of the level of soil enrichment with microorganisms (Table 4), meadow soils not involved in agricultural activity were very rich, while long-term

anthropogenic impact negatively affected the soil microflora in the experimental plots, thus transferring these soils into medium enriched group.

Table 4. Scale of assessment of the degree of soil enrichment with microorganisms (according to Zvyagintsev, 1980)

Level of soil enrichment with microflora		number of soil microorganisms determined by cultivation on various nutrient media, $\times 10^6$ units / 1 g absolutely dry soil.	
		NA	SAA
I	Very poor	<1	<2
II	Poor	1-2	2-4
III	Moderately enriched	3-5	5-10
IV	Rich	6-10	11-20
V	Very rich	> 11	> 21

The coefficient of mineralization shows the intensity of transformation of organic matter of plant and animal residues, as well as applied various organic fertilizers in the soil (Milashchenko, 1990). It is determined by the ratio of the number of microorganisms that characterize the process of conversion of ammonia nitrogen, to the number of microbes that characterize the transformation of protein substances in the soil. This coefficient represents the degree of development of the amylolytic part of the soil microflora and, accordingly, its activity in the transformation of soil carbohydrates and the binding of free nitrogen. The higher it is (> 1), the more immobilization processes take place, which indicates either very high ammonia nitrogen availability in soil (this may be due to the high amounts of ammonifiers), or the appearance of organic matter in the soil (straw, bark, etc.). The latter phenomenon, in turn, can activate the development of oligotrophic and autochthonous groups of microorganisms, which ultimately leads to an increase in the number of amylolytic microflora, since a certain amount of ammonia is released into the soil solution as a result of the activity of oligotrophs. In agrocenosis, an excessively large value of this coefficient (> 3-5) may indirectly indicate an increase in the rate of decomposition of the specific organic matter of the soil — humus (Schulz et al., 2013).

Calculated this coefficient for our soils, we obtained the following data: 2.34 for meadow and 3.56 for agrocenosis in average (Fig. 1).

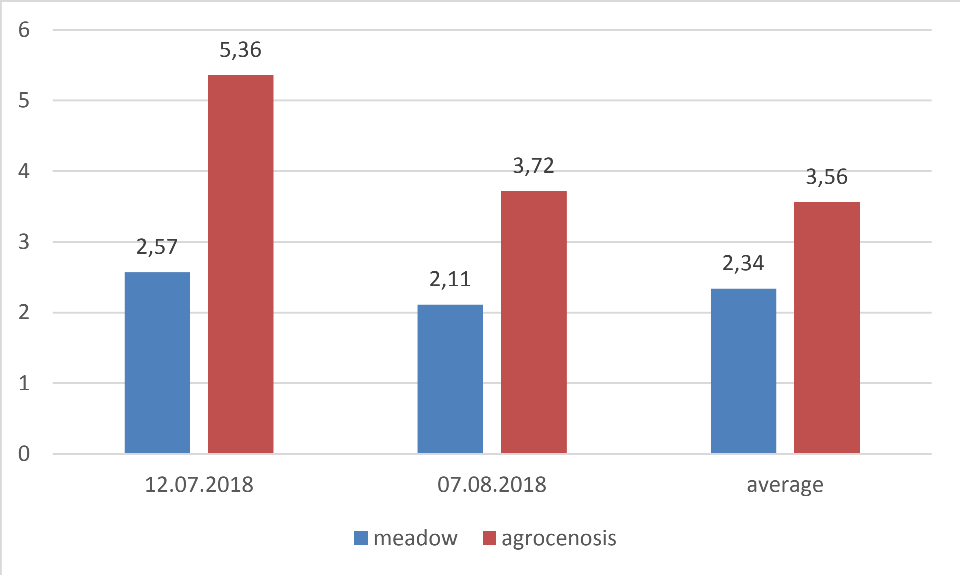

Figure 1. Dynamics of the mineralization coefficient

According to the sequencing data, the microorganisms most typical for the soils of the region were identified. The most common microorganisms were representatives of the genera *Flavobacterium, Pedobacter, Bacillus, Enterobacter, Arthrobacter, Streptomyces, Acinetobacter, Leifsonia, Luteibacter, Burkholderia, Stenotrophomonas, Massilia, Microbacterium, Aneurinibacillus.*

Conclusions

Long-term use of meadow-brown soils in field crop rotation has led to leveling of zonal properties, as well as to their unidirectional degradation. A rise in the exchange acidity provided an increase in the content of aluminium (Al^{3+}) in the arable horizon.

The involvement of the soil in agricultural activities led to a decrease in the percentage of humus in the upper arable layer, and it is necessary to consider not only the natural loss of humus, but also an increase of the treated arable layer with a general decrease in the humus content due the involvement of the low humus below lying horizons. Extensive pressure on the soil of experimental plots led to a decrease in the humus content compared to soil of natural ecosystem by 2.69-1.68 times and to an increase in the acidity of the arable horizon by 1.4-1.1.

In addition to decrease in soil fertility, active involvement in agricultural practices also significantly reduces the biological activity of the soil. Anthropogenic pressure had a negative effect on the number of microorganisms inhabiting the soil of agrocenosis: the content of nitrifiers was 50.2 million units / 1 g abs. dry soil in the meadow versus 11.66 million units / 1 g abs. dry soil of agroecosystem; the content of ammonifiers - 21.2 million units / 1 g abs. dry soil versus 3.14 million units / 1 g abs. dry soil respectively.

The value of the mineralization coefficient indicates that the rate of transformation of organic nitrogen in the soils affected by agricultural activity is about one and a half times higher than in meadow soils. The reason for this can also be the long-term waterlogging of the soil during the growing season (prolonged flooding contributed to the accumulation of large amounts of ammonia nitrogen).

Abstract

Soybean production contributes to the wide range of industries and is one of the main grain and oilseed crops in global agriculture. The task of increasing its production in Russia is of great importance. The paper analyzes the results of study of the productivity of soybean cultivar Batya plants, grown from seeds obtained from different nodes of the parent plant in Khabarovsk Kray (Russia's Far East). The yield of offspring, productivity of one plant, mass of 1000 seeds were considered. The following phenotypic characteristics were determined: plant height, number of nodes, number of productive nodes, number of pods, bottom pod attachment point. Parent plants of soybean cultivar "Batya" were characterized by high productive qualities. The average seed weight per plant was 11.7 grams, and the yield with the density of 50 plants m^{-2} was 4.67 tons ha^{-1}. With an average 1000 seeds mass of 163.8 grams, the largest mass of 1000 seeds was on 7-16 nodes, and the highest productivity was on 8-15 nodes. Studies have shown that soybean plants grown from the seeds of the lower layer of parent plants possessed the highest productive qualities. The average number of productive nodes on plants grown from lower layer seeds was 12.0, and the number of pods was 26.9. And, as a result, the average yield of plants grown from seeds of the lower layers was 4.86 tons per hectare, which is 0.67-0.7 tons per hectare higher than yield of plants grown from seeds of the middle and upper layers.

Keywords: *Soybean, Parent plants, Productivity, Plant node, Yield structure.*

Introduction

Soybean occupies the main areas in the agrocenoses of the Russian Far East. The prevalence and rapid growth of soybean production is mainly due to the unique biochemical composition of its grain, which determines its multifunctional (food, feed and technical) use, and the high profitability of its production (Benkin and Tomilina, 1985; Pavlovskaya, 2004). High and stable yield is the result of high cultivar adaptability to the conditions of cultivation that vary in a wide range. For stable maintenance of a sort, it is necessary to have a precise characteristic of the developmental rhythm due to specific environmental and climatic factors, and to identify the number of major and related biotypes in it, as well as those that give the full range of features of this sorting population during reproduction. In order to properly conduct seed production, it is necessary to know and consider the structure and genetic features of a particular cultivar, its degree of ecological stability. It should be noted that the potential achievable productivity of all soybean cultivars, including the most precocious, is realized only by 30-70% (Ozyakova and Polzukhina, 2014). However, it cannot be denied that the mechanisms for maintaining high productivity of the cultivated varieties, their adaptation to growing conditions, and resistance to abiotic and biotic factors remain insufficiently studied (Belyaeva, 2007). The most important attributes that determine the yield of soybean varieties include, for example, the number of seeds per pod, the number of pods per plant, plant height, branching, seed weight per plant, height of attachment of the lower pod (Vashchenko *et al.*, 2014). A promising, highly productive soybean cultivar "Batya" - middle-ripe, belongs to the Manchurian type. The vegetation period is 108-118 days, indeterminate type, the degree of lateral shoots formation is average, the plant is compact. The height of the plants is 80-110 cm. The mass of 1000 seeds is 193-270 g. Due to the rapid growth in the period of germination - flowering and wide leaf plate this cultivar competes well with weeds. Seed yield is up to 5.4 t / ha. The purpose of this study was to compare the productivity of soybean plants of the "Batya" cultivar, grown from the seeds of different nodes of the parent plants.

Materials and Methods

The studies were conducted on the fields of the Far Eastern Agricultural Research Institute in 2017 and 2018. The soil of experimental plot is meadow-brown, heavy loamy, humus content – 4.1%, pH <4.5, hydrolytic acidity – 10-12 mEq/100 g of soil, the sum of exchangeable bases – 15-17 mEq/100 g of soil, the availability of mobile phosphorus is low, and availability of exchangeable potassium is high to very high. The object of the study was the soybean cultivar "Batya". Sowing seeds, treating crops and harvesting experimental plots were conducted manually. Soybean seeds for the research were taken from soybean plants, harvested in 2017. The experiment was laid on the ridges with a base of 70 cm. Seeds were sown in 2 lines, the distance between the lines was 8 cm, the density of standing of the stems is 50 pieces / m^2. The analysis of the yield structure of soybean plants grown from parent plants' seeds was performed according to the following parameters: plant height, seed weight from 1 plant, mass of 1000 seeds, number of productive nodes, number of pods per plant, the height of attachment point of the lower pod. The protein content in seeds of the plants grown in 2018 was also considered.

Results and Discussion

Parental plants of soybean cultivar "Batya" possessed high productive qualities. The average seed mass per plant was 11.7 g, and the yield with a density of 50 plants per 1 m^2 was 4.67 t / ha. With an average weight of 1000 soybean seeds of 163.8 g, the largest mass of 1000 seeds was at 7-16 nodes, and their highest productivity was in nodes 8-15 (table 1, figure 1).

20	-	-	-

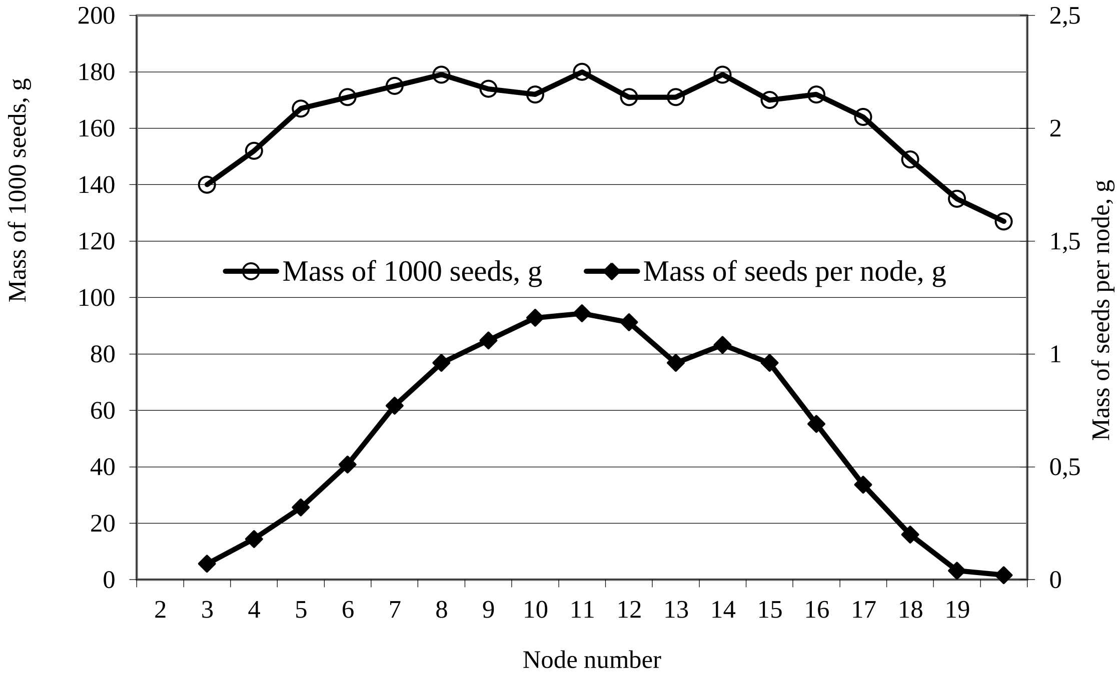

Figure 1 - Productive qualities of parent plants.

The number of productive nodes on the plant was the most stable feature. The average number of productive nodes on soybean plants grown from the seeds of the lower level was 12.0, and from the top - 10.4.

The number of pods on a plant is a varying characteristic and one of the most important elements of productivity, and depends on the biological parameters of the cultivar, soil, climatic and agrotechnical conditions of cultivation. On average, about 25 pods were formed on the plants during the study period. At the same time, the highest value of this indicator was observed in seeds grown from the lower layer – 26.9 pcs., and the lowest value - 23.7 pcs. - from the top layer. The average yield of plants grown from the upper layers is lower by 0.67-0.70 tons / ha compared to the yield of plants on the lower layer.

One of the main features in the structure of the plant, which determines the productivity, is the mass of seeds per plant. Analysis of the productivity indicators of soybean plants (Table 2), grown from seeds of various nodes of parent plants, showed that from the second to the nineteenth node, the productivity of soybean plants of the cultivar Batya decreased by 2 g, which is indicated by the trend line, obtained as a result of approximation and smoothing the graph and has a polynomial appearance (Fig. 2).

Elements of the yield structure of plants are important indicators. The height of the stem of soybean plant is genetically determined. Under the same growing conditions, the variability of this trait in different soybean cultivar samples is on 80–90% determined by the genotype. The height of plants grown from the lower layers of the parent plant reached 101-109 cm, and the average height of plants from seeds of the upper layers was 93 cm.

Table 2 - The productive qualities of soybean plants grown from the seeds of various nodes of the parent plants

Node / layer 2-7 / lower layer 8-13 / middle layer 14-19 / upper layer	Average productivity of soybean plants grown from seeds of various nodes of parent plants of soybean

The height of the bottom pod attachment point is a technologically important attribute. The variability of this trait is only by 28% determined by hereditary factors, 72% fall on the conditions of cultivation of crop (Babich and Kokhanyuk, 2014). In our experiment, the attachment point of the lower pod was on the 3 and 4 nodes of the soybean plant.

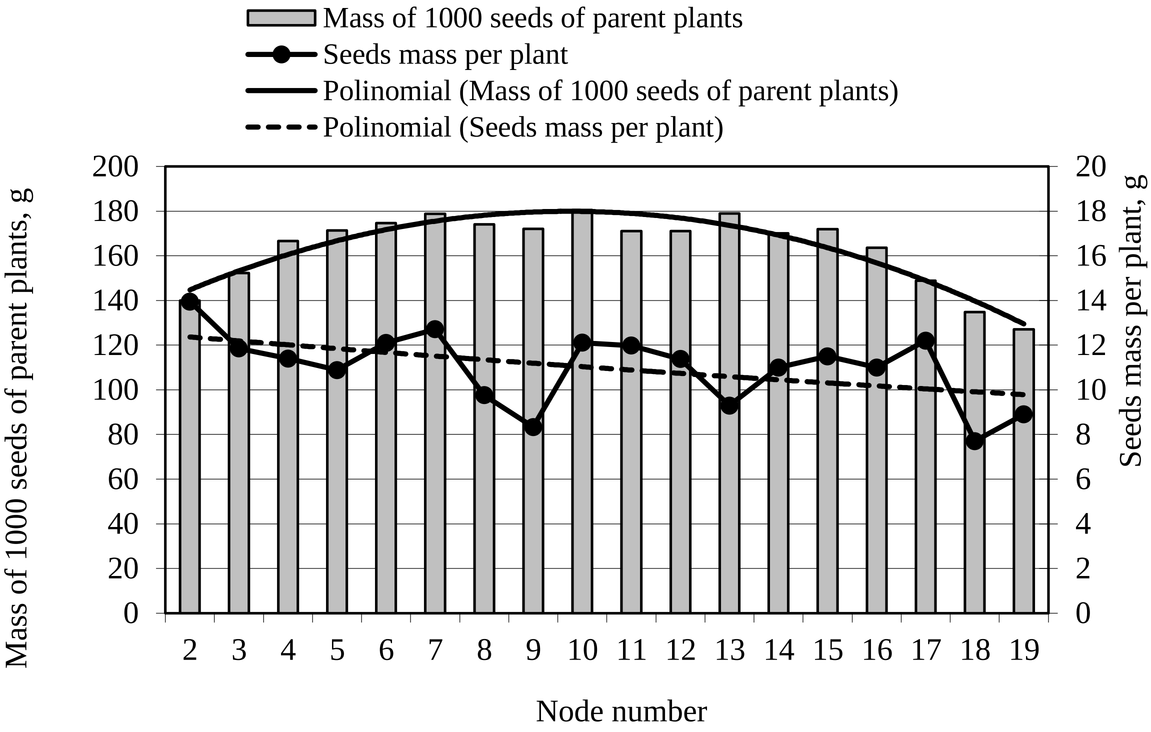

Fig. 2. The productivity of soybean plants grown from seeds of various nodes of parent plants.

The correlation coefficient between the mass of 1000 seeds of parent plants and the productivity of plants grown from these seeds is 0.19, which indicates a small association of indicators. A more significant connection (r = –0.5) occurs between the node numbers of the parent plants and the productivity of the offspring. This indicates that the seeds of the lower nodes of the parent plants are more productive and provide a higher yield than the seeds from higher layers (Table 2, Fig. 2).

A medium positive correlation was established (r = 0.37) between the mass of 1000 seeds of parent plants and the mass of 1000 seeds of offspring. There is no reliable connection between the numbers of the nodes of the parent plants and the mass of 1000 seeds of the offspring; the mass of 1000 seeds of offspring practically does not depend on which node of the parent plants the seeds are taken from. A very insignificant association (r = 0.19) was observed between the mass of 1000 seeds of soybean parent plants and the productivity of the offspring grown from these seeds. Comparison of the quantity and quality of the crop by the layers of parent plants showed a significant superiority of the productive qualities of soybean plants grown from the seeds of the lower layer. Plants grown from the seeds of other layers of parent plants had slightly different productive qualities, except for a mass of 1000 seeds and plants height. The mass of 1000 seeds of the upper layer, compared to the mass of 1000 seeds grown from seeds of the middle layer, decreased by 6 g.

The protein content is a quantitative trait characterized by polygenic inheritance and high sensitivity to changes in environmental conditions, which often exceed the influence of the genotype (Petibskaya, 2001). Under favorable conditions of humidity, soybean cultivars completely support themselves with biologically fixed atmospheric nitrogen, and therefore can realize their genetic potential - the protein content in the seeds rises to 48% (Posypanov *et al.,* 2006).

In the experiments, the protein content in the seeds of plants grown from the seeds of the lower and middle layers was almost the same (35 and 34.9%), and in the seeds of plants grown from the seeds of the parent plants of the upper layer was 32.0% (3% lower) . The correlation coefficient between the numbers of the parent plant nodes and the protein content in the seeds of the soybean offspring of the "Batya" cultivar was (- 0.87). This convincingly demonstrates the advantage in protein content of plants grown from seeds of the lower layers of parent plants.

Conclusion

Studies have shown that soybean plants grown from the seeds of the lower layer of parent plants possessed the highest productive qualities. The average number of productive nodes on plants grown from lower layer seeds was 12.0, and the number of pods was 26.9. And, as a result, the average yield of plants grown from seeds of the lower layers was 4.86 tons per hectare, which is 0.67-0.7 tons per hectare higher than yield of plants grown from seeds of the middle and upper layers. In this regard, during the primary seed production of the soybean cultivar "Batya" in nurseries of individual selection of initial plants, selection should be carried out and seeds from 2-7 nodes of the lower layer should be used for sowing.

Abstract

The island of Cyprus - a centre of endemism and a biodiversity "hotspot" - is located in the Eastern part of the Mediterranean Basin, which comprises one of the largest groups of islands in the world. This island system has been early and widely colonized by the black rat *Rattus rattus* since their spread from the Indian Peninsula. This species is considered one of the most damaging alien invasive predator to have been introduced on more than 80% of the world's major islands and known to negatively affect island biota and agriculture. Although across the Mediterranean Sea the brown rat *R. norvegicus* is present along with the black rat, on the island of Cyprus there were only *R. rattus.* This study reports the first documented record of *R. norvegicus* on the island of Cyprus from two localities, the city of Geri and Neo Chorio near Kythrea. The species identification was first carried out by morphological analysis, and then confirmed by molecular evidences inferred by the analysis of mitochondrial DNA sequences. The implications of the discovery of this new alien invasive species on agriculture and the local biota of Cyprus are examined.

Keywords: *Rattus norvegicus, brown rat, agricultural damages, alien invasive species.*

Introduction

According to CABI Invasive Species Compendium, (https://cabi.org.isc/datasheet/46829), the brown or Norwegian rat (*Rattus norvegicus*) is globally widespread and costs primary industry hundreds of millions of dollars per year. It has caused or contributed to the extinction or range reduction of native mammals, birds, reptiles and invertebrates through predation and competition. It restricted the regeneration of many plant species by eating seeds and seedlings, eats food crops and spoils food stores by urinating and defecating in them (ISSG, 2011; Donahoe, 2016; CABI, 2019). *R. norvegicus* is found on 36% of the world's island groups (Atkinson, 1985) and there is ongoing risk of invasion of new islands. Once an island group is colonised *R. norvegicus* is able to widespread throughout the archipelago rapidly through further hitch-hiking and natural dispersals, including swimming. It is capable of swimming 2.5 km (CABI, 2019). Cyprus is the third largest island in the Mediterranean Basin, however, until now there is no documented record of *R. norvegicus* on this island (Kryštufek and Vohralík, 2009; Nicolaou *et al.*, 2016; Hadjisterkotis, 2017). In January 2019 in the City of Geri (Nicosia district) we observed a female *R. norvegicus* feeding in a bird feeder, with all the external characteristics of brown rats described by Qumsiyeh (1996), Yiğit (1999), Nagorsen (2002), Kryštufek and Vohralík (2009). Several other rats were seen also in two other localities on the island. *Rattus* genus includes 66 species (Musser and Carleton, 2005), its taxonomy is complex and is further complicated by many synonyms for different species (Robins *et al.*, 2007). Identification of individuals, even by experts, is often difficult (Taylor *et al.*, 1982). The analysis of morphological traits combined with the genetic characterization of molecular markers is the most efficient system for identifying individuals at the species level (Musser and Carleton, 2005).

The primary aim of this report is to examine for the first time new molecular and morphological evidences to establish or reject the presence of *R. norvegicus* on the island of Cyprus. In addition, to examine the possible effects which this alien invasive species might have on agriculture, livestock and the local biota, and to recommend management measures for the protection of biodiversity, livestock and agriculture.

Materials and Methods

Examination of live specimens and carcasses

In January 2019 a female rat bred in a rock garden next to a bird feeder in the city of Geri in Nicosia district (Figure 1).

Figure 1. Female *Rattus norvegicus* in the city of Geri, Cyprus. Photo: E. Hadjisterkotis

Two of the younger animals were captured using snap traps in order to take body measurements and hairs for DNA analysis. A roadkilled rat with the external characteristics of *R. norvegicus* was found at Neo Chorio village near Kythrea, on the 5th of April 2019, and a hair sample was collected for DNA analysis. In addition, visual observations at the Mia Milia sewage treatment ponds indicated the presence of rats having the characteristics of *R. norvegicus*, i.e. compared with *R. rattus*, smaller ears, smaller eye, blunt nose, thick heavy body, tail shorter than head and body (Qumsiyeh, 1996; Nagorsen, 2002; Kryštufek and Vohralík, 2009). On the skull of *R. rattus* supraorbital ridges diverged posteriorly along parietals; close to occipital region they are slightly bent or curved. In *R. norvegicus* supraorbital ridges ran mainly parallel along parietals (Qumsiyeh, 1996; Kryštufek and Vohralík, 2009; Nagorsen, 2002). In older individuals, the skull ridges are characteristic in shape, well-defined, relatively straight and situated close to one another, which gives the impression of a relatively narrow braincase (Pimsai *et al.*, 2014).

DNA extraction, amplification and sequencing

Genomic DNA was extracted from hair by means of the InstaGene™ Matrix (Bio-Rad) according to the manufacturer's protocol. Sample quality and DNA concentration were determined via spectrophotometry using a ND-8000 (NanoDrop Technologies, Thermo Fisher Scientific Inc., Wilmington, DE). Two pairs of primers were designed by means of the "Web Primer: DNA and Purpose Entry" bioinformatic tool available at http://www.candidagenome.org/cgi-bin/compute/web-primer (Skrzypek *et al.*, 2017) and used to amplify two regions of the *R. norvegicus* mitogenome encompassing the first 434 bp of the D-loop region (HVS-I domain) and the first 534 bp of the cytochrome c oxidase subunit I (CO I) gene, respectively. PCR products were purified and then sequenced on an ABI 3130 sequencer. Sequences were compared to GenBank sequence database using BLAST in order to estimate the statistical significance of matches. Sequences were also aligned with the homologous sequences of *R. rattus* (NC_012374) and *R. norvegicus* (KM114608) using Clustal X 2 (Larkin *et al.*, 2007). Further experimental details can be found in the Hadjisterkotis et al., 2019 (BioInvasion Records - submitted on 9 July 2019).

Results and Discussion

Observations on dead specimens

The preliminary body measurements and the shape of the skulls of the two juvenile rats collected in the city of Geri, and the rat found dead on the road in the village Neo Chorio indicated that all three specimens were *R. norvegicus* (Table 2). The tail length is less than head and body in both types wild (Geri) and laboratory (Neo Chorio).

Examining the cranial characteristics, it was observed that the braincase is narrow and elongated. The parietals and interparietal are bordered by well-defined ridges which are straight and almost parallel, a diagnostic characteristic of *R. norvegicus*. In the juvenile specimen from Geri the skull ridges were not so well-defined as in the older specimens.

For the Mia Milia sewage treatment ponds only visual observations were available, with the diagnostic characteristic of *R. norvegicus*, i.e. blunt nose, shorter ear, shorter tail than head and body, heavy thick body and smaller eyes.

Table 2. Body measurements (mm) of *R. norvegicus* from Geri, and one adult male from Neo Chorio, Kythrea.

	Geri 1	**Geri 2 (juvenile)**	**Neo Chorio Kythrea**
Head and Body	195	149	230
Tail	160	130	205
Hind foot	43.4	32.0	43.0
Ear	20.3	12.31	20.00
Ear bend forward	Just reaching the eye	Just reaching the eye	Not reaching the eye

DNA analysis

The sequences analysis of the D-loop region and the COI gene from two rat specimens allowed to assess that both samples were *R. norvegicus*, although belonging to two different genetic strain. Discrimination was possible due to the variability detected in the D-loop region which showed a 1.66% divergence between the two sequences. No differences were found at the level of the COI gene.

Competition with black rats

A problem that this new alien invasive species might face in its dispersal in Cyprus, is competition with the previously introduced black rat, which occupy just about every rural habitat (Kryštufek and Vohralík, 2009; Hadjisterkotis, 2017). For such a widespread and damaging pest, with the exception of its damage on carob trees, surprisingly little is known about its ecology and its impact on Cypriot ecosystems. This makes it even more difficult to predict and highlight the potential for impacts of *R. norvegicus* on humans, livestock, agriculture and wildlife in Cyprus. The black rat eats the eggs of ground nesting birds and the eggs of woodpigeons nesting on trees (Hadjisterkotis, 2000, 2017). They are a menace for carob trees (*Ceratonia siliqua*) plantations, almonds (*Prunus amygdalus*), pomegranate (*Punica granatum*), and other fruits and crops. They feed on carob pods and on the bark, eventually killing the trees (Hadjisterkotis, 2017). However, brown rats being larger in size, on other Mediterranean countries are described as more adaptable and much more aggressive than black rats (Canale, 2019). Black rats are well adapted to small islands, whereas Norway rats are mostly observed on the largest islands where humans also occur (Amori *et al.*, 2008; Canale, 2019). Considering that Cyprus is the third largest island in the Mediterranean, Norway rats are expected to adapt and to compete well with black rats and to exert a stronger impact on native species.

Destruction to agriculture, livestock and spreading of zoonoses

Rats are destructive pests particularly in and around farm facilities. This can be especially true during the winter months, as they seek food and refuge indoors. Rats consume and contaminate feed, gnaw on structural, mechanical, and electrical components, weaken concrete slabs and walkways with their burrowing activities and spread diseases to livestock as well as to wild animals (Donahoe, 2016). Are reservoirs and vectors of pathogens that can infect livestock, wildlife species and humans. Such infectious zoonotic diseases are the plague agent *Yersinia pestis*, hantavirus, leishmania, leptospirosis, scrub typhus, toxoplasmosis viral haemorrhagic fevers (Herbreteau *et al.*, 2012) and many other. A costly disease that was found to infect farm animals and rats, is paratuberculosis. This is a chronic, contagious granulomatous enteritis of farm ruminants characterized by persistent diarrhea (mainly in cattle and less in sheep), progressive weight loss, debilitation and eventually death. The etiologic agent is *Mycobacterium avium* ssp *paratuberculosis* (MAP). MAP infection results in significant economic losses for the farm industry with annual estimates of millions of dollars around the world. In one study it was estimated that paratuberculosis costs the U.S. dairy industry alone 200 to 250 million dollars annually (Ott, 1999). Viable MAP has been isolated from Cypriot cattle, sheep and goat populations and dairy food (Liapi *et al.*, 2011, 2015; Botsaris *et al.*, 2013). Several studies revealed MAP isolations from non-ruminant free-ranging wildlife, such as from tissue samples from foxes (*Vulpes vulpes*), Norway rats (Florou *et al.*, 2007) and feral cats (*Felis familiaris*; Palmer *et al.*, 2005). Infected rats may have the greatest effect on the epidemiology of *MAP* infection on farms that have eliminated all infected livestock from the premises or on *MAP*-free farms in the same geographic area as infected farms. Two of the predators of rats on Cyprus are red fox (*Vulpes vulpes*) which can be infected by feeding on rats, as well as domestic cats which are kept on farms for the control of rats and mice. These species may live for several years with home ranges that cover areas large enough to include more than one farm, spreading the disease from farm to farm, and reinfecting farms which eliminated all infected livestock.

Conclusions

This study reports the first documented record of an alien invasive species *R. norvegicus* on the island of Cyprus and the first breeding record in the wild. On other islands this species has caused or contributed to the extinction or range reduction of native mammals, birds, reptiles and invertebrates through predation and competition, is causing millions from damages in agricultural crops and the spreading of diseases to humans, livestock and wildlife. For the protection of agriculture, livestock and biodiversity, an extensive study for the dispersal and habitat selection of *R. norvegicus*, competition (both within the species and with *R. rattus*), predation, zoonoses and effect on agriculture must commence as soon as possible. These studies should take place in combination with an eradication program, with emphasis on farm land and livestock premises.

INFLUENCE OF INTERCROPPING MAIZE WITH COWPEA AND FERTILIZATION WITH CLINOPTILOLITE ON FORAGE YIELD AND QUALITY

Abstract

Maize forage is poor in protein content which leads to low quality and nutritive value. Regarding the high feed costs of protein supplementations, legumes can be used in livestock nutrition for their high protein content, and thus, provide cost savings. In this study, maize (*Zea mays* L.) and cowpea (*Vigna unguiculata* L.) were intercropped in different sowing densities and fertilization with naturale zeolite clinoptilolite and their monocropping equivalents were tested to determine the best intercropping system on forage yield and quality. Maize was cultivated alone (75 000 plants ha^{-1}) and intercropped with cowpea as follows: 75 000 plants ha^{-1} of maize and 37 500 plants ha^{-1} of cowpea (MC$_1$), 75 000 plants ha^{-1} of maize and 50 000 plants ha^{-1} of cowpea (MC$_2$) and 75 000 plants ha^{-1} of maize and 75 000 plants ha^{-1} of cowpea (MC$_3$), in rows alternating with maize. The highest dry matter yield was produced by MC$_3$ (23.2 t ha^{-1}), and the lowest by maize monocrop (20.3 t ha^{-1}) in fertilization with clinoptilolite. All intercropped systems had higher crude protein contents, MC$_1$ (99 g kg^{-1} DM), MC$_2$ (106 g kg^{-1} DM) and MC$_3$ (114 g kg^{-1} DM), than the maize monocrop (82 g kg^{-1} DM) in fertilization with clinoptilolite. Intercropping of maize with cowpea and fertilization with clinoptilolite reduced neutral detergent fiber, resulting in increased forage digestibility. Therefore, maize intercropping with cowpea and fertilization with clinoptilolite could substantially increase forage quantity and quality, and decrease requirements for protein supplements as compared with maize monocrop.

Keywords: *Intercropping, Natural Zeolite Clinoptilolite, Maize, Cowpea, Yield, Quality.*

Introduction

In many regions of Europe, whole-plant maize silage is the basic feed used in feeding cows and fattening cattle. Despite its high energy content, the protein content is low (88 g kg^{-1}) compared with legumes silage (Anil et al., 2000) and needs to be supplemented with proteins for better feed quality (Stoltz et al., 2013). Intercropping maize with legumes for silage is a feasible strategy to improving the level of crude protein (Contreras-Govea et al., 2009). Javanmard et al (2009), worked on intercropping of maize with different legumes, and showed that dry matter yield and crude protein yield of forage were increased by all intercropping compositions compared with the maize monocrop. Dahmardeh et al. (2009) concluded that intercropping of maize and cowpea resulted in more digestible dry matter and also crude protein content than maize mono-cropping. Physiological and morphological differences between intercrop constituents influence their ability to use resources; especially cereals with legumes, have several advantages such as higher overall yields, better soil utilization (Dhima et al., 2007), yield stability of the cropping system (Lithourgidis et al., 2006), better use of light, water and nutrients (Javanmard et al., 2009), improved soil conservation (Anil et al., 1998), soil fertility through biological nitrogen fixation, increases soil conservation through greater soil coverage as compared to sole cropping, and ensures better soil-susceptible crop in monoculture (Lithourgidis et al., 2006), and better control of pests and weeds (Vasilakoglou et al., 2008). Atmospheric nitrogen fixation using legumes plants can reduce nitrogen competition in the reciprocal intercropping system of legumes and

cereals enabling the cereals to use more nitrogen in the soil (Eskandari et al., 2009). This can affect the quality of the fodder intercrop components because the protein content is directly related to the content of nitrogen in the forage plants (Putnam et al., 1985). Nutrients use efficiency can also be achieved through theuse of clinoptilolite zeolite because of the unique physical and chemical properties of clinoptilolite zeolite coupled with their abundance in sedimentary deposits and in rocks derived from volcanic parent materials have made them useful in many agricultural applications (Ramesh et al., 2010). Clinoptilolite zeolite is widely used in cultivating different crops such as cereals, forage, vegetables, vine, and fruit crops due to their exceptionally high ion-exchange capacity (Butorac et al., 2002).
This study was designed to determine the influence of different patterns of maize-cowpea intercropping and fertilization with natural zeolite clinoptilolite on the yield and quality of forage.

Material and Methods

A field experiment was carried out during the 2018 growing season at experimental fields in Oborovo (45°40'54"N 16°15'12.5"E), Croatia. Meteorological data of the experimental site are presented in Table 1.

Table 1. Mean monthly air temperature and rainfall during the 2018 growing season

Meteorological data	Month					
	April	May	June	July	August	September
Air temperature (°C)	15.7	19.2	20.9	22.4	23.0	17.2
Rainfall (mm)	51.6	50.5	144.4	94.4	66.1	36.4

The experiment was set up as a randomized complete block design with three replicates. Maize hybrid seed (KWS Kolumbaris) was obtained from Seed Company "KWS". Seed of the cowpea cultivar "Dolga vigna" was obtained from Company "Sjemenarna". The treatment comprising the individual plot size was 50 m × 2,8 m. The maize population 75 000 plants ha^{-1} (SM) were spaced at 70 cm × 19 cm and cowpea population 37 500 (MC_1), 50 000 (MC_2) and 75 000 plants ha^{-1} (MC_3) were spaced at 70 cm × 38.1 cm, 70 cm x 28.6 cm and 70 x 19 cm, respectively, in rows alternating with maize. Basic tillage was carried out by ploughing to 30 cm depth. Presowing preparation was done using a tractor-mounted rototiller. All plots were fertilized with the same amount of fertilizer before sowing, containing 200 kg of N ha^{-1}, 100 kg P_2O_5 ha^{-1} and 200 kg of K_2O ha^{-1} in variant of control and additionally in the vegetation of crops (stage six maize leaves) introduced supplementation 300 kg natural zeolite clinoptilolite ha^{-1}. Clinoptilolite used in this work originated from Slovakia, and the particles size of zeolite ranged in size from 0.5 to 2.0 mm. Maize and cowpea were sown to a depth of approximately 5 cm by maize drill in May 8, 2018. Herbicide Wing P (active substance 212.5 g/l dimethenamide-p and 250 g/l pendimethalin) was applied pre emergence in intercropping maize with cowpea at a dose of 4 l ha^{-1}. The soil of the research area has an acid pH 4.2 reaction (M-KCl), good humus (3.2%), poorly supplied with physiologically active phosphorous (4.6 mg P_2O_5/100 g soil), medium supplied with physiologically active potassium (20.0 mg K_2O/100 g soil) and richly supplied with total nitrogen amounting to 0.17%. The fresh fodders were manually harvested when the maize reached soft dough stage and cowpea at R8 stage and then chopped into 20 mm size pieces with a chaff cutter. The dry matter content was determined by drying in an oven at a temperature of 65°C to a constant mass. Crude protein was measured according to Kjeldah, phosphorus was analysed by colorimetry (AOAC, 2000) and neutral detergent fibre according to (Van Soest et al., 1991).

Analyses of variance were made for fresh fodder and dry matter yield and forage quality parameters ($P<0.05$), and the Tukey test was used for comparing means ($P<0.05$). Data were analyzed using SAS statistical software (SAS Inst., 2002).

Results and Discussion

The diferences in the yield of forage are statistically significantly and yield of dry matter are not statistically significantly ($P<0.05$). The yield of forage and dry matter ranged from 77.4 t ha^{-1} (MC_3) to 60.1 t ha^{-1} (SM) and 23.2 t ha^{-1} (MC_3) to 20.3 t ha^{-1} (SM) in fertilization with naturale zeolite clinoptilolite (Table 2). The diferences in the yield of forage and dry matter in fertilization with naturale zeolite clinoptilolite were better than in control of the variant are statistically significantly ($P<0.05$). The use of natural zeolite with urea increased silage corn dry matter production and provided the best use of nitrogen at the higher doses of fertilizer (Bernardi et al., 2011). According to the results, when cowpea seed number and fertilization with naturale zeolite clinoptilolite increased in intercrop, forage and dry matter yields on parcels increased. Cowpea can be intercropped with maize (Dahmardeh et al., 2009) and sorghum (Azraf et al., 2007). for a higher yield and quality compared with sole cropping. Legume contribution to maize in mixtures was significant and increased the total biomass yield of mixtures (Geren et al., 2008). One of the main reasons of intercropping maize and cowpea is the increase crude protein level in silage.

Table 2. Fresh forage yield and dry matter yield of maize and maize-cowpea intercropped

Treatments	Fresh forage yield t ha^{-1}			Dry matter yield t ha^{-1}		
	Control	Clinoptilolite	Mean	Control	Clinoptilolite	Mean
SM	53.5a	60.1c	56.8d	19.4a	20.3b	19.9a

Since crude proteins are very important in cattle fodder, silage containing more crude proteins is desirable. In this study it was found that the value of crude proteins of intercropped forage MC_1, MC_2 and MC_3 was statistically significantly ($P<0.05$) higher than SM during a two treatments of fertilization (Table 3). According to the results, when cowpea seeds number and fertilization with naturale zeolite clinoptilolite increased in intercrops, the content of crude protein in the mixture increased. Cowpea fodder is a rich source of crude protein, giving up to 184 g kg^{-1} (Khan et al., 2010).

Mean	**94b**	**100a**		**1.91b**	**2.23a**	

Results in the present study were in agreement with other studies where legumes also increased crude protein concentration when in a mixture with maize (Dawo et al., 2007). This could be due to higher nitrogen availability for maize in intercropping compared with the monoculture crop (Eskandari et al., 2009). In this study it was found that the yield of crude proteins of intercropped fodder MC_1, MC_2 and MC_3 was statistically significantly ($P<0.05$) higher than SM during a two fertilization treatments (Table 3). Treatment of MC_3 had the highest yield of crude protein 2.23 t ha^{-1} in control of the variant and 2.65 t ha^{-1} in variant fertilization with naturale zeolite clinoptilolite from other fodder mixtures (Table 3). From this point of view fodder produced in maize-cowpea intercrops is important not only to profit from the increase in the content of crude protein, but also from the reduction of the content of neutral detergent fibers. For this reason, the best option in maize-cowpea intercropping is the use of cowpea genotypes that provide forage with the greatest amount of pods at harvest. In addition, the level of neutral detergent fibers is associated with the stage of maturity of the fodder due to the level of the cell wall components, mainly cellulose, hemicellulose and lignin (Mugweni et al., 2000). The value of a neutral detergent fiber refers to the total cell wall and consists of an acid detecting fiber fraction plus hemicellulose. In this study it was found that the values of neutral detergent fibers of intercropped MC_2 and MC_3 were statistically significantly ($P<0.05$) lower than SM during two fertilization treatments (Table 4).

Table 4. Content of neutral detergent fiber and phosphorus of maize and maize-cowpea intercropped

Treatments	Content of neutral detergent fiber g kg^{-1} DM			Content of phosphorus g kg^{-1} DM		
	Control	Clinoptilolite	Mean	Control	Clinoptilolite	Mean
SM	367a	339a	353a	2.2c	2.4d	2.3d
MC_1	355a	326ab	341ab	2.3bc	2.5c	2.4c
MC_2	342b	319bc	330bc	2.4ab	2.6b	2.5b

Mean	**348a**	**322b**		**2.35b**	**2.55a**	

Different letters in the column mean significant difference ($P<0.05$).

According to the results, when cowpea seed number and fertilization with clinoptilolite increased in intercrop, the values of neutral detergent fibers in the mixture decrase. The content of neutral detergent fiber is important in ration formulation because it reflects the amount of animal forage that animals can consume (Lithourgidis et al., 2006). In general, the concentration of neutral detergent fibers is higher for grass than for legumes (Dahmardeh et al., 2009). Since smaller amounts of fiber components are used for better digestion, the cowpea intercropped plots to be superior to monocrop maize in terms of neutral detergent fiber. Result in the present study were in agreement with other studies where clinoptilolite decreased of neutral detergent fibers values in silage of maize (Bernardi et al., 2011). In this paper, the value of phosphorus of intercropped forage MC_1, MC_2 and MC_3 was statistically significantly ($P<0.05$) higher than SM during a two fertilization treatments (Table 4). According to the results, when the cowpea seed number and fertilization with naturale zeolite clinoptilolite increased in intercrop, the values of phosphorus in the mixture increased. Contribution of legumes with sweet sorghum in mixtures was significant increased phosphorus in fresh fodder (Basaran et al., 2017).

Conclusion

The conclusion of the present study is that intercropping of maize with cowpea at various planting densities and fertilization with natural zeolite clinoptilolite was shown to be an effective way to influence fresh biomass production, dry matter and crude protein yield to enhance nutrient quality of forage. Intercropping of maize with cowpea and fertilization with natural zeolite clinoptilolite increased values of crude protein, phosphorus and decreased values of neutral detergent fibre concentrations in forage. Finally, intercropping with 75 000 plants ha^{-1} of maize and 75 000 plants ha^{-1} of cowpea and fertilization with 300 kg natural zeolite clinoptilolite ha^{-1} was most suitable according to the nutrient composition in forage.

UPTAKE OF PHOSPHORUS AND POTASSIUM IN SORGHUM PLANTS IN DEPENDENCE ON NUTRITIONAL LEVEL

Ivan VELINOV

Department of Agrochemistry and Soil Science, Agricultural University of Plovdiv, Bulgaria
Corresponding author: van211@abv.bg

Abstract

A pot experiment was carried out to determine the uptake and distribution of phosphorus and potassium in sorghum plants depending on the level of mineral nutrition. The plants were grown on eight levels of nutrition – $N_0P_0K_0$, $N_0P_{200}K_{200}$, $N_{600}P_0K_0$, $N_{200}P_{200}K_{200}$, $N_{400}P_{200}K_{200}$, $N_{600}P_{200}K_{200}$, $N_{800}P_{200}K_{200}$, $N_{600}P_{400}K_{400}$. The different levels of nutrients were created by applying of NH_4NO_3, $Ca(H_2PO_4)_2$ and KCl dissolved in water. It was established that sorghum grown at N_{600} level in combination with elevated levels of phosphorus and potassium $P_{400}K_{400}$ had the highest concentration of phosphorus and potassium. Self-nitrogen fertilization $N_{600}P_0K_0$ lowered the concentration of the two elements in the grain to values close to the unfertilized control. The highest content of phosphorus 1.09 $g.pot^{-1}$ was obtained at $N_{600}P_{200}K_{200}$ level, which exceeded the control by 146.7%. Sorghum plants removed the most potassium in maturity at $N_{600}P_{200}K_{200}$ and $N_{600}P_{400}K_{400}$ levels. Self-nitrogen fertilization $N_{600}P_0K_0$ reduced the total phosphorus and potassium uptake of the above-ground parts compared to triple combinations $N_{600}P_{200}K_{200}$ and $N_{600}P_{400}K_{400}$. The phosphorus and potassium harvest indexes were higher in the control plants, at the lower levels of mineral nutrition ($N_{200}P_{200}K_{200}$ and $N_{400}P_{200}K_{200}$) and at the N_{600} level combined with higher $P_{400}K_{400}$ fertilization. Sorghum gown at $N_{600}P_0K_0$ had been shown to reduce the proportion of phosphorus and potassium absorbed in the sorghum grain. Compared to the control, the decrease was by 4.8% for phosphorus harvest index and by 10.0% for potassium harvest index. Sorghum plants grown at the higher $N_{800}P_{200}K_{200}$ level were characterized with the lowest phosphorous (65.2%) and potassium (17.0%) harvest index.

Keywords: *Phosphorus, Potassium, Uptake, Sorghum.*

Introduction

Sorghum (Sorghum bicolor L. Moench) is one of the five major crops in the world (Shehzad et al., 2009). It can be used as food (grain), feed (grain and biomass), fuel (ethanol production), fiber (paper), fermentation (methane production) and organic by-products (Fernandes et al., 2013). In Bulgaria the production of grain sorghum has increased in recent years and sorghum is one of the top ten grown crops in the country (Ivanov, 2006). Sorghum is a multipurpose crop belonging to the Poaceae family, which are C_4 carbon cycle plants with high photosynthetic efficiency and productivity (Tari et al., 2012). The modern varieties are hybrids with high productivity potential appropriate for application of intensive forage grain production technologies (Kertikov, 2007). Nitrogen, phosphorus, potassium and water are considered as the major limiting factors in crop growth, development and finally economic yield (Enchev and Kikindonov, 2015; Jones, 1983). Proper nitrogen nutrition is critical to meet crop needs and indicate considerable opportunities for improving nitrogen use efficiency (Murell, 2011). Many agricultural soils have a limited ability to supply available nitrogen for target yields and nitrogen is the most limiting nutrient for cereal crops, including sorghum production (Gerik et al., 2014). Nutrient uptake of sorghum precedes dry matter accumulation because nutrients are required for growth and dry matter accumulation (Soleymani et al, 2011). The level of mineral nutrition has greater effect on growth and yield of cereals plants (Raun and Johnson, 1999). The studies of sorghum genotypes in this connection are limited.

For better fertilizer management the study about the effects of different levels of nitrogen, phosphorus and potassium on the growth and nutrient uptake of sorghum is very crucial. The objective of this research was to investigate the effect of different nutritional levels on the accumulation and distribution of phosphorus and potassium in sorghum plants.

Material and Methods

The effect of different levels of mineral nutrition on the accumulation and distribution of dry mass and nitrogen of sorghum plants was studied in a pot experiment under conditions of growing installation. The experimental design consisted of eight levels of mineral nutrition and four replications of each variant. The studied treatments of soil nutritional levels were: $N_0P_0K_0$, $N_0P_{200}K_{200}$, $N_{200}P_{200}K_{200}$, $N_{400}P_{200}K_{200}$, $N_{600}P_{200}K_{200}$, $N_{800}P_{200}K_{200}$, $N_{600}P_0K_0$ and $N_{600}P_{400}K_{400}$. The levels of nitrogen (N), phosphorus (P_2O_5) and potassium (K_2O) in the soil were created by adding of NH_4NO_3, $Ca(H_2PO_4)_2$ and KCl dissolved in a water. Three plants per pot of hybrid EC Alize were grown under optimal water regime in plastic pots of 10 L. Each pot contained 15 kg air-dry soil. The main agrochemical characteristics of the soil before sowing of the sorghum were: pH_{H2O} = 7.80 (slightly alkaline reaction); content of mineral nitrogen 27.6 mg $Nmin.kg^{-1}$ soil; content of available phosphorus (Egner-Ream) 158 mg $P_2O_5.kg^{-1}$; and content of exchangeable potassium 210 mg $K_2O.kg^{-1}$. These results showed low supply of the soil with mineral nitrogen and good soil supply with available phosphorus and potassium. A good water regime was maintained in the pots during the vegetation of the sorghum plants. The aboveground biomass was collected from the plants under all the treatments in a full maturity phase. The harvested samples were separated in a grain and stover (stems + leaves + chaff). The dry weight of grain and stover was determined after drying for 48 hours at 60 °C. The sub-samples of 0.5 g ground and dry plant material were mineralized using a wet digestion by H_2SO_4 and H_2O_2 as a catalyst (Mineev, 2001). The concentration of phosphorus and potassium in plant samples were determined by colorimetric methods and potassium concentration was analyzed by the flame photometer model PFP-7 (Tomov et al, 2009). The content of accumulated phosphorus and potassium was obtained by multiplying the dry mass of sorghum grain and stover by the concentration of nitrogen in each plant part. The differences in the accumulation and distribution of dry mass and nitrogen into sorghum plants among all levels of mineral nutrition were calculated by using the overall analysis of variance (ANOVA). Duncan's Multiple Range Test (Duncan, 1955) at $p < 0.05$ was used in order to determine the difference among the means.

Results and Discussion

The level of mineral nutrition had a significant effect on the percentage of phosphorus and potassium in the grain and sorghum stover in maturity (Table 1). The average phosphorus content of the grain was 0.97% P_2O_5 and 0.25% P_2O_5 in the stover. The results indicated that the concentration of phosphorus in the sorghum grain was nearly three times higher than in the stover. The lowest phosphorus concentration in the grain was obtained in the self-nitrogen fertilized variant and the control. The highest concentration of phosphorus in the grain, of plants grown at the level of N_{600} in combination with elevated levels of phosphorus and potassium $P_{400}K_{400}$. Self-nitrogen fertilization $N_{600}P_0K_0$ had a negative effect on the percentage of phosphorus in the grain and led to values close to the control. Excluding nitrogen fertilization and only added phosphorus and potassium slightly affected the percentage of phosphorus in the grain. The value of 0.97% P_2O_5 in this variant of $N_0P_{200}K_{200}$ did not differ significantly from that of the controls. The elevated N_{800} level of nitrogen had been shown to lower the phosphorus concentration in the sorghum grain compared to the fertilized variants with lower nitrogen levels N_{200}, N_{400}, N_{600} in combination with $P_{200}K_{200}$. The concentration of phosphorus in sorghum changed to a relatively narrow range of 0.23% to

0.33% P_2O_5. The highest concentration of phosphorus in sorghum stover was obtained in the self-phosphorus-potassium fertilization variant and at the $N_{600}P_{200}K_{200}$. The negative effect of increasing the level of phosphorus-potassium fertilization and its exclusion ($N_{600}P_{400}K_{400}$, $N_{600}P_0K_0$) on the percentage of phosphorus in sorghum stover compared to variant $N_{600}P_{200}K_{200}$ had been proven.

Table 1. Concentration of phosphorus and potassium of sorghum plants depending on the nutritional level

Nutritional level	% P_2O_5		% K_2O

*Values in each column followed by the same letters are not significantly different at $p<0.05$ according to Duncan's multiple range test.

In contrast to grain phosphorus concentration and mature stover, sorghum was characterized by approximately three times higher potassium concentration in the stover (1.05% K_2O average) compared to grain (0.38% K_2O average). The highest concentration of potassium in the above-ground portions of sorghum was found in variant N_{600} in combination with elevated levels of phosphorus and potassium $P_{400}K_{400}$, and the lowest in the control and self-nitrogen fertilized variant. $N_{600}P_0K_0$ nitrogen fertilized plants are characterized by low potassium concentration in maturity and the percentage of potassium in the grain and their stover did not differ significantly from plants in the control plants. No proven differences in potassium concentration in grain of sorghum grown at elevated $N_{800}P_{200}K_{200}$ and lower levels of $N_{200}P_{200}K_{200}$ and $N_{400}P_{200}K_{200}$ had been identified. The results reported indicated a tendency to increase the concentration of potassium in the stover in nitrogen fertilized plants. Plants grown only with nitrogen fertilizer $N_{600}P_0K_0$ are an exception to this trend. They had the lowest potassium concentration in stover 0.85% K_2O. Differences in potassium content in sorghum stover between variants $N_{600}P_{400}K_{400}$ and $N_{600}P_{200}K_{200}$ were not mathematically proven. This indicated a slight effect of the elevated $P_{400}K_{400}$ level on the potassium content of sorghum stover.

Accumulated amounts of phosphorus in the above-ground portions of sorghum in maturity varied widely depending on the level of mineral nutrition (Table 2). The average export of phosphorus to the sorghum grain was 0.55 g $P_2O_5.pot^{-1}$ and in the stover 0.24 g P_2O_5. All nitrogen fertilized variants export more phosphorus to the above-ground portions of the Sorghum accumulated the largest amount of phosphorus in the grain at N_{400} and N_{600} combined with phosphorus-potassium fertilization $P_{200}K_{200}$ or $P_{400}K_{400}$. In these two variants, $N_{600}P_{200}K_{200}$ and $N_{600}P_{400}K_{400}$ the phosphorus exported to the grain were 0.72-0.73 g $P_2O_5.pot^{-1}$ which exceeds the neutral control by 132.6% and 135.1%, respectively. Self-nitrogen fertilization $N_{600}P_0K_0$ had been shown to reduce the absorbed phosphorus in the grain compared to the $N_{600}P_{200}K_{200}$ and $N_{600}P_{400}K_{400}$ combinations.

Table 2. Phosphorus uptake of sorghum plants depending on the nutritional level, $g.pot^{-1}$

Nutritional level	Grain	% to $N_0P_0K_0$	Stover	% to $N_0P_0K_0$	Grain+Stover	% to $N_0P_0K_0$

*Values in each column followed by the same letters are not significantly different at $p<0.05$ according to Duncan's multiple range test.

Differences in the amount of phosphorus accumulated in the grain of the $N_{600}P_0K_0$ variant and nitrogen intake variant of 400 mg $N.kg$ $soil^{-1}$ combined with phosphorus-potassium fertilization $P_{200}K_{200}$ had been demonstrated. The lowest concentration of phosphorus in the sorghum grain was accumulated in variant $N_0P_{200}K_{200}$ and the control. The mineral nitrogen deposited at N_{200}, N_{400} and N_{600} levels significantly increased the amount of phosphorus accumulated in sorghum stover and increased by 72.6-180.2% relative to the non-fertilized plants. Control plants accumulated the lowest amount of phosphorus in the stover, and the most was accumulated in the $N_{600}P_{200}K_{200}$ variant compared to the other variants. The accumulated phosphorus in the stover had close values (0.22-0.25 g $P_2O_5.pot^{-1}$) at levels $N_{200}P_{200}K_{200}$, $N_{800}P_{200}K_{200}$, $N_{600}P_0K_0$ and $N_{600}P_{400}K_{400}$. The concentration of phosphorus in sorghum stover increased in parallel with an increase in the amount of nitrogen intake by 200, 400 and 600 mg N.kg soil-1 combined with phosphorus-potassium fertilization $P_{200}K_{200}$.

The average export of potassium to the sorghum grain was 0.22 g of $K_2O.pot^{-1}$ and 0.89 g of $K_2O.pot^{-1}$ in the stover (Table 3). All fertilized variants exported more potassium to the grain and stover compared to the control. Sorghum accumulated the highest amount of potassium in the above-ground parts when grown at the N_{600} level combined with phosphorus-potassium fertilization $P_{200}K_{200}$ or $P_{400}K_{400}$. In these two variants $N_{600}P_{200}K_{200}$ and $N_{600}P_{400}K_{400}$, the export of potassium to the grain was 0.31 g K_2O pot^{-1} in the stover was 1.26-1.27 g $K_2O.pot^{-1}$ which exceeded the untreated control by 178.7% in the grain and 208.5% in the stover, respectively. Concentration of potassium in stover and grain of sorghum increased in parallel with an increase in the amount of nitrogen intake of 200, 400 and 600 mg N.kg soil^{-1} combined with phosphorus-potassium fertilization $P_{200}K_{200}$, including variant $N_0P_{200}K_{200}$. $N_{600}P_0K_0$ self-nitrogen fertilization had proven to reduce the absorbed potassium in the above-ground portions of sorghum compared to the $N_{600}P_{200}K_{200}$ and $N_{600}P_{400}K_{400}$ combinations. Differences in the amount of accumulated in the grain and stover potassium in variant $N_{600}P_0K_0$ and variant with nitrogen input 400 mg N.kg soil^{-1} combined with phosphorus-potassium fertilization $P_{200}K_{200}$ had been proven. The lowest content of potassium in the grain and sorghum stover accumulated in the control. The differences in the amount of potassium exported in the sorghum grain between variants $N_{800}P_{200}K_{200}$ and $N_{600}P_0K_0$ had not been proven. The mineral nitrogen deposited at N_{200}, N_{400} and N_{600} levels significantly increased the amount of accumulated potassium in the grain by 93.1 - 178.7%, and in the stover the increase was by 110.3 - 208.5%, compared to the control plants.

Table 4. Distribution of phosphorus and potassium into sorghum plants depending on nutritional level

Nutritional level	PHI, %	% to $N_0P_0K_0$	KHI, %	% to $N_0P_0K_0$

*Values in each column followed by the same letters are not significantly different at $p<0.05$ according to Duncan’s multiple range test.

The fraction of phosphorus and potassium absorbed in the grain at maturity represents 69.3% and 19.5% of the total accumulated phosphorus and potassium in the biomass at maturity (Table 4). The phosphorus harvest index for sorghum varied between 65.2 and 74.4%, and the potassium harvest index ranges from 17.0 to 21.1% depending on the level of mineral nutrition. The phosphorus and potassium harvest index were higher in the control, at the lower levels of mineral nutrition $N_{200}P_{200}K_{200}$ - $N_{400}P_{200}K_{200}$ as well as in the N_{600} in the background of increased $P_{400}K_{400}$ phosphorus-potassium fertilization. Sorghum gown at $N_{600}P_0K_0$ had been shown to reduce the proportion of phosphorus and potassium absorbed in the sorghum grain by 4.8% for PHI and by 10.0% for KHI compared to the control. No proven differences were found in the phosphorus harvest index for variants $N_0P_0K_0$, $N_0P_{200}K2_{00}$, $N_{200}P_{200}K_{200}$, $N_{400}P_{200}K_{200}$, $N_{600}P_0K_0$ and the obtained values were close 67.5 - 72.1%. The KHI values obtained for variants $N_0P_0K_0$, $N_0P_{200}K_{200}$, $N_{200}P_{200}K_{200}$, $N_{400}P_{200}K_{200}$ and $N_{600}P_{400}K_{400}$ were very close 19.6 - 21.1%. Cultivation of the sorghum at N_{800} nitrogen level resulted in plants with the lowest phosphorous (65.2%) and potassium (17.0%) harvest index.

Conclusions

The sorghum grain had an average phosphorus concentration of 0.97% P_2O_5, which was nearly three times higher than the average phosphorus concentration 0.29% P_2O_5 in the stover. The average potassium concentration in the stover was 1.05% K_2O or approximately three times higher than in the grain. Cultivation of sorghum at the N_{600} level in combination with elevated levels of phosphorus and potassium $P_{400}K_{400}$ resulted in the grain with the highest

concentration of phosphorus and potassium. Self-nitrogen fertilization $N_{600}P_0K_0$ lowered the concentration of the two elements in the grain to values close to the control. Total phosphorus accumulated in maturity was highest at fertilization level $N_{600}P_{200}K_{200}$, which exceeded the control by 146.7%. Sorghum took up the most potassium in maturity at levels $N_{600}P_{200}K_{200}$ and $N_{600}P_{400}K_{400}$. Self-nitrogen fertilization $N_{600}P_0K_0$ reduced the export of phosphorus and potassium to the above-ground parts of the sorghum in maturity.
The harvested phosphorus index for sorghum varied between 65.2 and 74.4%, and the harvesting index of potassium ranged from 17.0 to 21.1% depending on the level of mineral nutrition. Cultivation of the sorghum at the increased N_{800} nitrogen level resulted in plants with the lowest phosphorous (65.2%) and potassium (17.0%) harvest index.

Abstract

The research tracked the behavior of the grain weights in the main panicle to a collection of autumn oat genotype. The purpose of the study was to assess the stability of this character under the influence of the climate conditions from the Western Plain of Romania. The studied collection comprised of 73 genotypes of different origins. Experimental data has been collected over three years. In statistical processing several methods of stability assessment, determining: the regression coefficients and stability, (Finlay-Wilkinson model), the variance of linear regression analysis (Hardwick-Wood model) and the variance heterogeneity (Muir model) were applied. The weight of grains in the principal panicle was influenced by the climatic conditions, the values differing from one year to another depending on genotype response. In the case of this character, 52.24% of the genotype x environment interaction was due to imperfect correlations, so that in appreciating its stability to study genotypes the results of both components could be used. Between the different models of stability assessment for this character, the studied material had a close concordance (very significant value for $\chi 2$ = 133.75). The estimates of used models, based on the ranks sum, showed that the highest stability of grain weight in the principal panicle occurred at: Carie, 4458, ARK 0151-61, 4480, Thonson genotypes. The analysis of the genotype x environment interaction revealed a high stability due to reduced interaction (less than 0.75% of total value) to: 4458, 4480, ARK-0151-61, Gerald genotypes. The studied collection includes valuable genotypes for breeding programs.

Key words: *autumn oats, stability, grains weight form panicle*

Introduction

Oats are grown on small surfaces although it has a special biochemical composition. A very important role is played by biologically grown material. The main parameters of productivity are the weight of grains from panicle, the grain size and grains number of the panicle. Against this, the stability of genotypes is the most important element for cultivators, because the risks due to unfavorable conditions are minimal (Brunava *et al.*, 2015). Productivity of oats panicle, in particular the number and weight of the grains of panicle are influenced by nitrogen fertilization and the precursor plant (Mantai Rubia Silva *et al.,* 2016). Production of grains of panicle is favored by the direct effect of the harvest index and indirectly by the size of the grain (Mantai Rubia Diana *et al.,* 2016). The characters of productivity and quality are also influenced by ecological conditions. Under the influence of annual conditions, the weight and the number of the grains of panicle are fluctuating characters with lower stability (Dumlupinar Ziya *et al.,* 2011). The variation of grain weights of panile depends also on the type of oats. The weight of the grains of the panicle is higher in the autumn sown forms than in the spring sown. Differences can be up to 80%. Much of these differences are due of differentiated development of primary and secondary grains (Crampton *et al.,* 1997). Among the productivity and quality characters, the productivity characters have the highest variability and lower stability under the influence of climatic conditions (Iannucci Anna *et al.,* 2011). Genotypic

correlations provide information on the genetic association between characters and indicates the most useful characters to be followed in the selection programs to achieve a certain objective. Grain production on the plant showed significant positive correlation coefficients in interdependence with the paniclea size, the weight of 1000 (Mushtaq *et al.,* 2013). In the realization of the weight of the grains of panicle and the stability of this character may intervene the competition between plants. The response to competition differs according to the variety's plasticity, the influence of the environment on productivity can range from 9% to 71%. Not found a negative association between production and the variety response to competition. Forms with high values will remain stable under conditions of competition with other plants (Sadras *et al.*, 2018). The study of varieties is necessary for their recommendation in culture, for each area, having to be recommended the best adapted variety to the conditions of that area. (Siloriya *et al.*, 2014). Assessment of the adaptability and stability of varieties is best done through quantitative characters. The oats genotypes have significant variations in the production of grains at the surface unit and all the characters that contribute to its realization. There are very stable genotype for(the weight of the panicle grains as well as for those quality. Through such studies can be found the genotypes adapted to specific conditions, to be cultivated or to be used in breeding programs for obtain high productivity varieties (Zeki *et al.,* 2018)
The present study aimed to evaluate the grains weight from main panicle stability in a collection of autumn oat genotypes.

Material and Methods

The study was conducted in Timisoara, under field conditions. The study was conducted over three years (2015-2017). The experimental soil was moderately cambicated chernozem. During the experiments, the climatic conditions were close to normal. Temperatures were within normal range. In the second year, in the spring was drought. In the third year, the drought was also in summer. The biological material harvested 73 genotypes of autumn oats. As a control, was used the Romanian variety Florina. The experimental data was obtained by determining the grain weights in panicle. From each genotype, representative samples were constituted.
In the processing of exprimental data, was applied a method of assessing the stability of genotypes under different environmental conditions, based on the fact that the components of the genotype x environment interaction are linearly linked to the effects of environmental conditions. These linkages are expressed by the average of genotype performances for the studied character. The genotype relative adaptability to different environmental conditions is appreciated through three parameters: the average of its performance, the response of genotype to different environmental conditions (regression coefficient), the stability of performance (deviations from regression) (Bernardo, 2002). There are several types of stability. According to the "static" concept, type I stability is when the performance of a genotype is constant in averages (coefficient of regression bi = 0). "Dynamic" concept, or Type II stability occurs if the response to the media is parallel to the average response of all genotypes studied. Type III stability is present when deviation from the regression line is small (Annicchiarico, 2002; Bernardo, 2002). For processing o experiemntal datas, were used different models: Finlay-Wilkinson, Hardwick-Wood, Wrike (Ciulca, 2006).For analyzing the genotype x environment interaction, are separated two components: one due to heterogeneity of genetic variants and another due to imperfect correlations. The association between the results of the different methods of assessing the stability of the studied characters was achieved using the coefficient of concordance (Muir *et al.,* 1992).

Results and Discussion

Table 1 shows that the highest Type I stability of production of the main panic during the experimental period was observed to genotypes: Solva, Le Conte, PA 725-4787, Gospodarski 48, Suergrain, to which this character has presented close values in the climatic conditions of the three years of experimentation. Also, the genotypes PA 621-3274, S Dak 40, 4482, 3378, Marettos Anderson, have achieved different values of this character from one year to the next exhibiting a reduced static stability. The lowest significant values of ecological valence, which indicates a high stability of the grain weight of the principal panicle were recorded in genotypes: Thonson, 3378, 4444, 4458, 4472, 4480. High variance values for genotype x environment interaction related to panicle productivity were recorded at: 4478, PA 621-3274, S Dak 40, Gospodarski 48, 4475, 4482, which shows a reduced stability of this character. The values of regression coefficient close to unity which shows a high dynamic stability have genotypes: Carie, 4458, ARK 0151-61, Gerald, CI 1908, where the weight of the main panicle beans was proportional to the favorable environmental conditions of the three experimental years. High values of median x genotype interaction were observed at the lines: S Dak 40, 4482, PA 621-3274, 3378. Minimum values of deviations from the right of regression, respectively high type III stability of this character was observed in genotypes: Norline, Tripolis, 4451, 4458, 4472, ARK 0151-61. Also, at 4478, PA 522-7, 5029, 4475 and Marys Quest, which exhibit reduced type III stability, the grain weights of the principal panicle in the three experimental years, shows great deviations from the right of regression. To the genotypes 4478, PA 621-3274, 4478, 3378, 4482, is observed a very high variability, associated with values of paniculum production above the average of experience.Between the results of different models of appreciation of the stability for the grain weight of the principal panicle in the varieties and lines studied there is a very close match, taking into account the very significant value χ^2 =133.75***. Given the estimates of the four used models, based on the amount of rank it is noted that the highest stability of that character presented the varieties and lines: Carie, 4458, ARK 0151-61, 4480, Thonson. (table 1)

High influence of genotype x environment interaction on the phenotypic expression of this character, respectively high values of the sum of the ranks according to the statistical models used, was observed at: 4482, Marettos Anderson, Wodan, 4475, Cimarron. In the case of this character, 52.24% of the genotype x medium interaction is due to imperfect correlations so in appreciating the stability of the grain weights of the principal panicle to the different varieties and lines from collection can be used efficiently the results of both components. Thus, taking into account imperfect correlations it is noted that the most stable values of principal panicle production were recorded by genotypes: Norline, Earlygrain, 4451, Nuptiale, Cocker 41-51. High values of deviations between ranks for primary panic production values during the experimental period they presented: 4478, PA 522-7, Gospodarski 48, PA 725-4787, 4475.In the case of varieties and lines Nortex, Suergrain, Norline, Walken, 4451, stability due to the reduced variation coefficients from one year to the next is correlated with a higher panic production than the average of the experience. To the genotypes 4478, PA 621-3274, 4478, 3378, 4482, is observed a very high variability, associated with values of paniculum production above the average of experience (Table 2) Of the plant morphological characters, some have greater variability and a lower stability to the interaction with growth factors. According to the analysis of correlation coefficients, the production of berries on the plant is positively correlated with the number of fertile tillers and the weight of the grains in the principal panicle. These characters should be used in the selection to improve the production capacity (Premkumar *et* al., 2017)

Conclusions

The weight of grains from the main panic to oats is a character that depends on the climatic and technological conditions. Creation of genotypes with good stability of this character is a major breeding target. The greatest variability of this character we found to the genotypes studied in climatic conditions of the first year of experimentation. The genotypes S Dak 40, PA 621-3274, Wodan, Tripolis, show values of main panicules production superior to the average of experience, which are strongly influenced by the genotype x environment interaction. The estimates of used models, based on the ranks sum, showed that the highest stability of grain weight in the principal panicle occurred at: Carie, 4458, ARK 0151-61, 4480, Thonson genotypes. The analysis of the genotype x environment interaction revealed a high stability due to reduced interaction (less than 0.75% of total value) to: 4458, 4480, ARK-0151-61, Gerald genotypes. The studied collection includes valuable genotypes for breeding programs.In the collections studied, there are few genotypes with good stability of the grain weight of the main panicle. However, there are some varieties that can be recommended for the breediongs programs of autumn oats in Western Romania.

Abstract

The aim of this study is to develop a selection approach to improve the adaptability of barley (Hordeum vulgare L.) to unfavorable environmental conditions based on chlorophyll content. A semicomplete diallel cross, including four barley genotypes, was analyzed for estimating variance of genetic effects, combining ability and heritability. Diallel analysis was used to estimate the genetic action of chlorophyll content in barley and provided an opportunity to get a quick and comprehensive view of the genetic control of a set of parents in early generation.The results revealed that the highest values of "cis" and "trans" heterosis were recorded in hybrids of the Andrew x DH260/18 combination, followed by hybrids of the Andrew x Djerbel combination. The greatest potential for amelioration of chlorophyll content is represented by the Andrew x Adi,combination, which allows for the identification of approximately 7,93 % recombinant lines with a chlorophyll content of at least 40 SPAD units in downstream generations. Achieving this 95% selection threshold requires the choice of at least 36 lines and 84 lines for an accuracy of 99.9%. High values of erytability in the broad sense and low values of erytability in a narrow sense confirms that a considerable part of the variability of this indicator is due to the genotype, due to the involvement of major genes in the determinism of this character.

Key words: *barley, chlorophyll content, genetic analysis, diallèl cross*

Introduction

Barley (*Hordeum vulgare*), first domesticated in the Near East, is a well-studied crop in terms of genetics, genomics, and breeding and qualifies as a model plant for *Triticeae* research (Nese *et al.*, 2008). Among the cereal crops, barley is a species with the greatest adaptability to a wide range of environments. Barley is cultivated from arctic latitudes to tropical areas, grown at the highest altitudes and adapted to specific sets of agro-ecological areas (Alemayehu *et al.*, 1997). It is adapted to a broad range of agro-ecological environments and tolerant to soil salinity, drought and frost to a considerable level. The crop grows successfully in the arid climates. In terms of the area and production worldwide, barley is the fourth most important cereal after wheat, rice and maize (Abebe *et al.*, 2010). In a 2007 ranking of cereal crops in the world, barley was fourth both in terms of quantity produced (136 million tons) and in area of cultivation (566.000 km²).The choice of an efficient breeding program depends to a large extent on the knowledge of gene action involved in the expression of the character. Diallel analyses were used to estimate gene action of yield components in barley and provide an opportunity to obtain a rapid and overall picture of genetic control of a set of parents in the early generation. Besides genetic effects, breeders would also like to know how much of the variation in a crop is genetic and to what extent this variation is heritable, because the efficiency of selection mainly depends on additive genetic variance (Eshghi *et al.*, 2009).These authors reported additive genetic effects of tillers number and an over-dominance gene action for number of grains per spike. Drought tolerance is the ability of a plant to survive, grow, and produce yield with limited water supply. Great progress has been achieved in the last two decades in understanding the genetic control of drought tolerance

(Abou-Elwafa, 2016).Chlorophylls are associated with chlorophyll-binding proteins of the photosystem I (PSI) and II (PSII) complexes (Kim *et al.*,1994 , Croce *et al.*, 2012) and accumulate in tissues where PSI and PSII are produced. A number of studies have been reported on the genetic elements that control chlorophyll accumulation in photosynthetic tissues (Eckhardt *et al.*,, 2004, Croce *et al.*, 2012). The aim of this study is to develop a selection approach to improve the adaptability of barley (Hordeum vulgare L.) to unfavorable environmental conditions based on chlorophyll content. The method will be used during the growing season for field applications, or at any time during the year in laboratory applications. Our study emphasized the addition of some new explanations concerning the hydric stress on chlorophyll accumulation to sustain the applying that indirect method of testing in a quickly selection of tolerant shapes.

Material and methods

Four barley varieties with different genetic and ecologic origin, along with their 6 one-way crosses, were studied in the field of Breeding plant departamant, from Banat's University of Agricultural Sciences and Veterinary Medicine King Michael I from Romania Timisoara. The biological material was cultivated in drought conditions during 21 days. The measurement of the chlorophyll content was made in early stage of the plants using portable chlorophyll meter SPAD- 502 (Konica Minolta, Japan), which measures the absorbance at 650 nm, this being a non-destructive method. The evaluation of results from diallel was done based on the mathematical model described by Hayman (1954).

Results and discussion

According to the data presented in table 1, it is observed that most of the hybrids, cultivated under stress conditions, showed positive values of the heterosis index, respectively a higher chlorophyll content than the average of the parental forms. The highest values of the heterosis index associated with a higher amount of chlorophyll were made by the hybrids, Andrew xDjerbel (4.09), Andrew x Dh 260/18 (2.94), combinations in which there were large differences between the parental forms in terms of this character. The lowest values of the heterosis index, correlated with a lower chlorophyll content to the average parent on the background of close values between parental forms, were recorded in the hybrids: Dh260 / 18 x Djerbel (-1.43); Adi x Djerbel (-0.16).

Table 1. Heterosis Index for chlorophyll content in F1 Hybrids cultivated in stres conditions

Genitors	Andrew	Adi	DH 260-18	Djerbel
Andrew	-	0.75	2.94	4.09
Adi		-	0.42	-0.16
DH 260-18			-	-1.43
Djerbel				-

In terms of chlorophyll content in F1 hybrids, some of the hybrids were inferior to parental forms. Compared to parents' average, the hybrids of this generation showed average values of *cis* heterosis of 5.60% and the *trans* heterosis of 1.40%.The highest values of *cis* heterosis (19.26%) and trans (15.47%) were recorded in hybrids of the Andrew x DH260/18 combination, followed by hybrid of Andrew x Djerbel 8.59% for 7.46% for heterosis trans and hybrid Andrew x Adi 7.20% for cis and 2.31% for trans heterosis.

Fig .1. The content of chlorophyll for the F1 hybrids groups with the same recurrent parent (author elaboration based on the obtained results)

Considering hybrids with the same recurrent parent, the limits range from 30.61 to the hybrids of the Djerbel variety and 34.33 to the hybrids of the Andrew variety. Significant differences are observed between the Andrew hybrids, which have a higher chlorophyll content than the hybrids of the other varieties.Based on the data of fig. 1, it is observed that in most cases the hybrids showed a higher chlorophyll content than the recurrent parent, with the exception of the Andrew variety, whose hybrids registered an increase in this aspect.The highest amelioration potential of chlorophyll content is represented by the Andrew x Adi combination, which allows the identification in downstream generations of about 7.93% recombinant lines of at least 40 SPAD units for the chlorophyll content. Achieving this selection threshold in a proportion of 95% assume choosing a minimum 36 lines, respectively 84 lines for an accuracy of 99.9%.

Table 4. The amelioration potential of hybrid combinations in the terms of the recombinant lines percentage (LR %) with a minimum chlorophyll content of 40SPAD units and with the number of required lines to be selected (n)

Andrew x DH 260-18	35.45	1.01	0.01	29956	46049	69074
Andrew x Djerbel	32.99	3.83	3.36	88	135	202
Adi x DH 260-18	33.40	3.29	2.28	130	200	300
Adi x Djerbel	31.31	1.97	0.01	29956	46049	69074
DH 260-18 x Djerbel	27.53	3.91	0.07	4278	6577	9865

Based on the data presented in table 4, it is observed that the most significant contribution to the variability of the chlorophyll content was the additive variant (a), which is significant. Dominance variance (b) presents a significant value with a lower contribution to the variability of this character than the additive variance.Regarding the dominance and the way it acts in the genetic determinism of the character, it is found that the subcomponent of the variant b1 dominance which indicates the average deviation of the hybrids from the parental values, respectively the directional effects of the dominance, presents a statistically assured value. Since in most cases the average of this character in the F1 hybrids is superior to the average of the parents, the significance of b1 indicates in most cases the dominance of the parents with higher values of the chlorophyll content, but the differences are reduced.The sub-component of the dominance b2 variance through its statistically assured values indicates an asymmetry of the distribution of alleles with positive and negative effects that influence this character in the parental forms. Subcomponent b3 shows the existence of differences between hybrids due to dominance.

Table 5. Analysis of alternative for the chlorophyll content on the F1 hybrids in stress conditions

Cause of variability	SP	GL	PM	Test F
Repetition	89.00	2	44.50	7.72**
a	83.15	3	27.71	4.81*
b	99.64	6	16.61	2.88*
b_1	21.28	1	21.28	3.69
b_2	58.06	3	19.35	3.36*
b_3	20.31	2	10.15	1.76
Eroare	103.73	18	5.76	
Total	375.52	29		

Considering the distance between the right regression line and the parable and also the position of the parental genotypes versus the right regression line results that mainly the effects of dominance and additivity have an important role in the genetic determinism of this character, according to genetic variance analysis. Among the studied genitors Dh 260/18 and Djerbel varieties show the highest proportion of recessive alleles, while Andrew (76.6%) and Adi (69%) have the highest proportion of dominant alleles (table 6).

Table 6. The average values (Yr), alternative (Vr), covariance (Wr) and the proportion of dominant alleles of the parents used to obtain F1 hybrids in terms of the chlorophyll content under stress conditions

No	Genitors	Parents Average Yr	Variance Vr	Covariance Wr	Vr + Wr	Proportion of dominant allele
1	Andrew	30.70	3.301	-0.478	2.823	0.766
2	Adi	33.78	0.890	0.445	1.335	0.690
3	DH 260-18	28.75	13.103	4.215	17.318	0.025
4	Djerbel	30.06	4.260	2.446	6.706	0.391

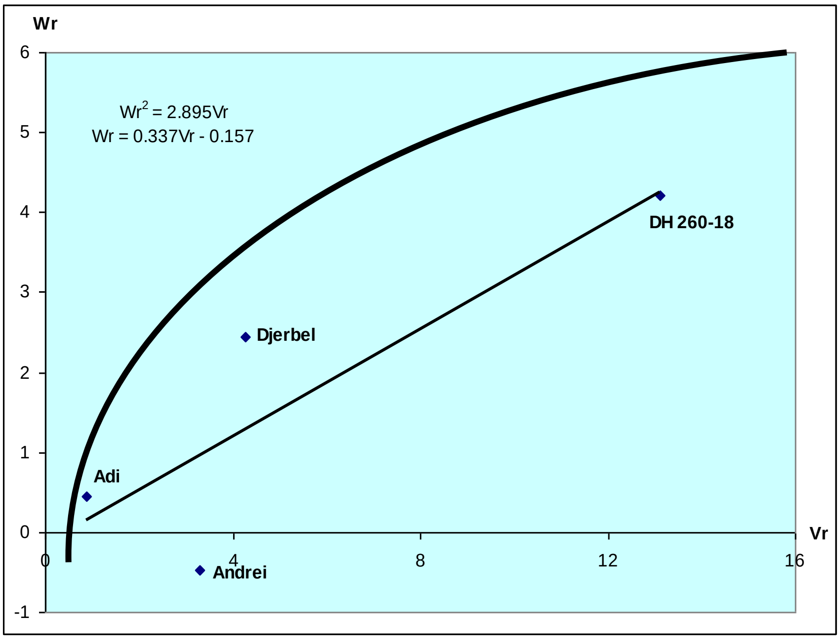

Fig. 2. The regrssion chart Wr/Vr for the chlorophyll content on the F_1 hybrids (author elaboration based on the obtained results)

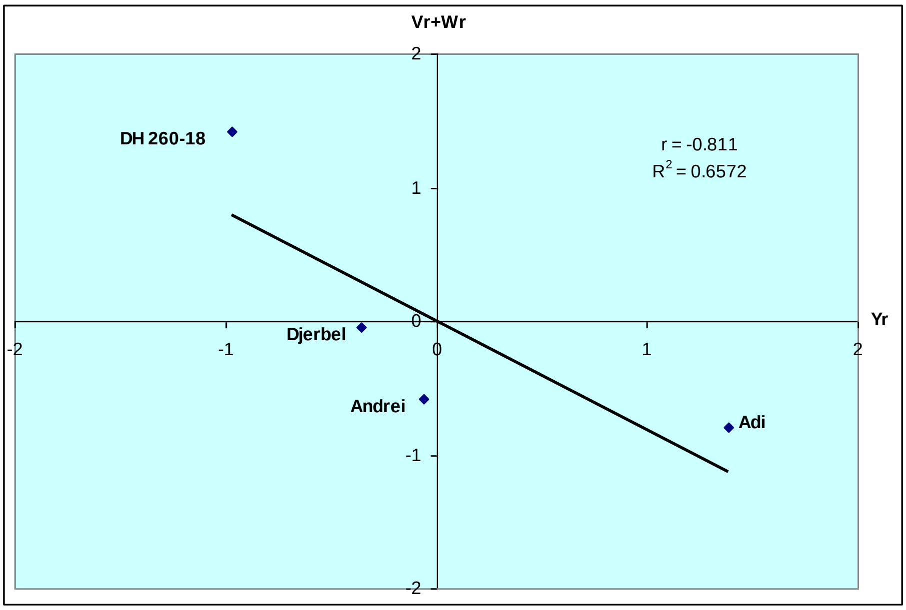

Fig. 3. Standard deviation chart (Wr + Vr) and yr for the chlorohyll content on the F_1 hybrids(author elaboration based on the obtained results)

The distribution of parental forms for this character can be assessed on the basis of standard deviations yr (Clorophila SPAD) and Wr + Vr, indicating a high proportion of recessive alleles at the genotype DH 260/18.

Conclusions

The highest values for the heterosis index associated with a higher amount of chlorophyll were accomplished by Andrew x Djerbel (4.09), Andrew x Dh 260/18 (2.94) hybrids.
Among the varieties studied the Dh 260/18 and Djerbel varieties show the highest proportion of recessive alleles, while Andrew (76.6%) and Adi (69.00%) have the highest proportion of dominant alleles.

BREEDING VEGETABLE ROOTSTOCKS TOWARD COPING WITH BIOTIC AND ABIOTIC STRESSES

Rezq BASHEER-SALIMIA*, Doaa NAJAJREH

Department of Plant Production and Protection, Hebron University, Palestine
*Corresponding author: rezqbasheer@hebron.edu

Abstract

In Palestine, cucumber (the second important vegetable crop after tomato), is usually grown sexually using their own seeds. Recently, its cultivation is facing some serious problems such as soil-borne diseases, salty soil conditions, drought, etc. To alleviate such problems, grafting is highly recommended. Toward this end, an experiment was conducted to study the effects of different squash rootstocks on growth, yield and quality of cucumber. Cucumber (var. Kareem) was grafted on four squash rootstocks (A-113, A-184, USA and Salah-2) using tube grafting technique (with 20 replicates), in addition to the control. The trial was set-up in a single-span greenhouse located at Hebron University campus, supported by drip irrigation system. All of the necessary cultural practices (irrigation, fertilization, spraying, ventilation, etc) were made. Different growth parameters, yield component and quality were regularly measured. In general, Rootstock A-148 presented significantly higher production (kg) and acceptable appearance (dark green color, symmetrical, regular), comparing to the other examined rootstocks and the control as well. Furthermore, Rootstock A-148 and the control (Kareem) presented earlier flowering and accordingly earlier production by 15 days compared to the other examined rootstocks. Dry weight of the total rooting system of A-113 rootstock was significantly higher than the other evaluated treatments, followed by USA and A-148, respectively. In contrast, the control revealed the lowest value. In conclusion, A-148 rootstock could be efficiently used as a promising rootstock for cucumber cultivation in Palestine.

Keywords: *Cucumber, breeding, grafting, biotic & abiotic stresses.*

Introduction

Cultivation of cucumber (*Cucumis sativus* L.) is considered the second important vegetable crop (after tomato) for greenhouse production in Palestine in terms of both areas covered as well as economic returns. Commonly, it is propagated sexually by seeds produced by specialized commercial companies. Due to its intensive and continuous cultivation (3 cycles per year); its cultivation is suffering from many damaging effects of different biotic (soil-borne diseases, soil nutrient imbalances, salty or alkaline soil conditions, etc., (Farhadi et al., 2016), and abiotic stresses (mainly drought), resulting thereby to severe crop loss as well as restrict its plantation and prevent its future expanding. Unfortunately, chemical pest control is expensive, not always effective, and harms the environment (Davis et al., 2008). Furthermore, drought and water scarcity as a direct result of global and regional climate change seems to be the most devastating stress affecting the overall Palestinian agriculture including vegetable production with no exceptional (Basheer-Salimia and Sayara, 2017). Indeed, detectable climate change has been observed as lower average precipitation rate, more marked changes in the distribution of precipitation from one year to the next, with winter getting shorter and extensive (Basheer-Salimia and Ward, 2014). Unluckily, a worst climate change scenario is expected to get more pronounced in the future. According to a realistic emissions scenario for the region, the IPCC predicts that warming over the 21st century will be larger than global annual mean warming – ranging between 2.2-5.1ºC. To overcome many of these biotic problems and to cope with drought, one promising approach could be breeding vegetables using grafting on different rootstocks that adapted to non-suitable factor/s for the desired cultivars. Though, choosing the proper rootstocks will give the scion the best chance to survive and produce good economical yield. The main goal of the present research is to study the effects of different squash species (*Cucumis maxima x Cucurbita moschata)* rootstocks on growth, yield and quality of cucumber.

Materials and Methods

In a well-controlled commercial nursery, cucumber (var. Kareem) was grafted on four squash rootstocks (A-113, A-184, USA and Salah-2), using tube grafting technique with 15 replicates each in addition to the control. After two weeks, seedlings were transplanted in med-autumn 2018, and accordingly maintained under a single-span greenhouse (12-18C^{o}) located at Hebron University campus using larger pots (9 liter volume) with a mixture-media of soil and peat-moss (1:1). The trial was set-up in a completely randomized design, and seedlings were supported with drip irrigation system. All necessary cultural practices irrigation, fertilization, spraying, ventilation, etc) were accomplished.

Different growth parameters (flowering date and fruiting, dry biomass of the rooting system), yield component and quality, were regularly measured.

Obtained data were statistically analyzed using one-way analysis of variance (ANOVA) and means were separated using the Tukey's pairwise comparisons at a significance level of $P \leq 0.05$ using the MINITAB package system.

Results and Discussion

Many vegetable species including squash are used as successful rootstock to overcome several biotic and abiotic stresses. In Palestine, unfortunately vegetable grafting is not yet commercialized and we still so beginners in this field. Here, is the first conducted pilot study. The combination of the grafted Kareem (commercial cucumber variety) on A-148 (Rootstock) presented earlier flowering and accordingly fruiting (similar to the control) by 15-20 days comparing to the remaining examined combinations. However, all examined combinations were under the same environment, therefore the existing variations are likely depends, to a great extent, on the rootstock–scion physiological interaction rather than the environment (Cohen et al., 2007). Furthermore, dry biomass of the total rooting system of A-113 rootstock was significantly higher than the other evaluated combinations, however the control revealed the lowest value (Table 1). Similar authors confirm this finding who stated that grafting is generally enhancing the vegetative growth and increase the vigorous root system (Goreta-Ban et al., 2014; Ferriol and Picó 2008). However, fibrous roots (control) are usually shorter, densely packed fine, and lighter.

Table 1. Mean production per plant (kg) and mean roots dry biomass (gr) of own rooted cucumber (var. Kareem) and grafted Kareem on four squash rootstocks (Mean* ± StDev).

Parameters / Treatments	Production per plant (Kg)	Roots Dry Biomass (gr)
Kareem (Control)	3.98 ^{b} ± 0.13	8.06 ^{c} ± 1.52
Kareem on A-148	4.93 ^{a} ± 0.15	17.33 ^{b} ± 2.14
Kareem on A-113	3.95 ^{b} ± 0.15	24.23 ^{a} ± 3.55
Kareem on USA	3.05 ^{c} ± 0.16	17.51 ^{b} ± 2.20
Kareem on Salah-2	4.00 ^{b} ± 0.16	16.49 ^{b} ± 3.42
P-value	0.000	0.000

*: Means within columns using different letters are differ significantly at the P≤0.05 level (using one way ANOVA analysis).

Regarding yield, Rootstock A-148 presented significantly higher production values of 4.93 kg per plant (=10.84 tones per dunum based on using 2200 plants per dunum) comparing with the control (8.76 tone) as well as the other examined treatments (Table 1). Both Salah-2 and A-113 rootstocks revealed similar and medium production with 8.80 and 8.69 tones respectively. However, Rootstock USA exhibited significantly the lowest production value with only 6.71 tones (Table 1). In addition, the rootstock A-148 presented acceptable overall appearance of the fruits (dark green color, symmetrical, regular), comparing to the other examined rootstocks as well as the commercial (Kareem) cultivar. Similar findings were also registered by Oda, 2002; Rivero et al., 2003; Davis et al., 2008; Koundinya & Kumar, 2014; and Kyriacou et al., 2017, who stated that using rootstocks improve plant ontogeny via avoiding damages caused by different biotic stresses; contributing to enhance tolerance to a biotic stresses; increase the vigorous root system; improve resistant to cold and warm; optimize water use, enhance of nutrient uptake; and improve fruit yield and quality. Based on the obtained primarily results with cucumber, introducing rootstocks to the other common cultivable vegetable crops would be a great interest and an added value to the Palestinian agricultural economy especially with tomato since it is considered the main bulk of the Palestinian vegetable cultivation in terms of area covered as well as economical returns.

Conclusion

A-148 rootstock could be efficiently used as a promising rootstock for cucumber cultivation in Palestine, whereas USA rootstock should be executed from any further studies.

Abstract

The effect of different doses of nitrogen fertilizers and variety on the yield and grain quality of winter triticale is given in this paper. The study was carried out in the vicinity of Bijelo Polje (Montenegro) during three growing seasons (2009/12.). The research included five varieties of triticale (Odissey, Kg-20, Triumph, Rtanj and Tango) and five variants of fertilization: control (without fertilization), N_{60}, $N_{60}P_{80}K_{80}$, $N_{90}P_{80}K_{80}$ and $N_{120}P_{80}K_{80}$. The experiment was set up as randomized block system in three replications. The grain yield, hectoliter weight and 1000 grain mass were monitored. The results of the study showed that both the variety and the different amounts of nitrogen, in combination with phosphorus and potassium, had a significant impact on grain yield and its quality. The highest average grain yield and a 1000 grains mass had the variety Tango (5304.0 kg ha^{-1}) or 47.9 g, while the lowest values of these characteristics were noted in the variety Kg-20 (4366.2 kg ha^{-1} and 32.7 g). On average, for all tested varieties, the highest grain yield was obtained in fertilization with 120 kg ha^{-1} nitrogen, but it was significantly higher only in relation to the control and the variant of fertilization where the minimum nitrogen (60 kg ha^{-1}) was used. The highest average hectoliter weight had the variety Triumph (72.1 kg), and the lowest variety Kg-20 (66.5 kg). Also, it was noted that the use of fertilizers caused an increase in hectoliter weight in the tested varieties. The $N_{60}P_{80}K_{80}$ rate was found to be economically optimal for these varieties of winter triticale in this area.

Key words: *Triticale, Nitrogen, Variety, Yield*

Introduction

The triticale, a species produced by crossbreeding of wheat and rye, was created with the idea of combining positive traits of parental species. The hope was that triticale would combine the high yield potential and good grain quality of wheat, and the resistance/tolerance to the biotic and abiotic stresses of rye (Mergoum et al., 2009; Fraś et al., 2016). The great possibility of using triticale for different purposes, as well as the emphasized varietal differences, imposes the need and importance of more complete study of new varieties, with the aim of their more efficient exploitation in commercial production. Triticale as the species is characterized by very rapid growth and development, adaptable to different cultivation technologies, and it achieves high and stable grain yields. In addition to high tolerance to soils with poor physical and chemical properties, triticale has also been shown to be suitable for cultivation at higher altitudes with pronounced resistance to biotic and abiotic stress (Villegas et al., 2010; Zečević et al. 2010). Also, it is often pointed out that triticale is a world-class species and that its growth and development depend largely on weather conditions and it is of great importance to understand the impact of climate change on the success of its production (Márton et al., 2007; Kádár et al., 2008 ; Đekić et al., 2010; Jamil et al., 2017). Within the technology of growing grain cereals, the special significance for forming yields is: sowing time, sowing density, variety characteristics, mineral nutrition and crop protection measures. According to the opinion of Claudio et al., (2010) and Kendal and Sayar (2016) those varieties which with high yields and good quality have the potential to produce high genetic potential for yield under different conditions of cultivation. In addition to the triticale genetics

growing season parameters affect the growth and yield of crop (Lobell and Asner, 2003) and cause yield variations. Jelić et al. (2004) and Popović (2010) state that the type and quantity of mineral fertilizers necessary for the formation of high yield and quality as well as the time of their application are different, depending on the fertility of the soil. In the opinion of Lestingi et al. (2010) and Zečević et al. (2010) mineral fertilization, especially nitrogen nutrition is one of the major agrotechnical factors which affect grain yield and enable farmers to take advantage of the high production potential of cereals. Similarly, Nefir and Tabără (2011) point out that the increased yield can best be achieved by using mineral fertilizers, and among the elements of mineral nutrition, nitrogen plays the most important role in increasing the yield (Kastori et al., 2005). Alzueta et al. (2012), and Wang et al. (2017) noted that there are two growing period when cereals take up nitrogen, first at tillering stage and second for spike formation stage. On the other hand, Nikolić et al. (2012) emphasize that high yield and good grain quality can be expected only if plants are able to adopt nitrogen during the entire vegetation period.
The aim of the conducted research was to determine the effect of the different doses of nitrogen fertilizers and variety on the yield and grain quality of winter triticale.

Materials and Methods

In order to monitor the influence of different quantities of nitrogen and varieties on the yield and grain quality of winter triticale, the experiment was set in the period from 2009 to 2012 in the vicinity of Bijelo Polje (Montenegro). The soil on which the experiment was carried out belongs to the type of Eutric Cambisol on alluvial coating. The outdoor experiment was set by the random block system in three repetitions. The plot size was 6 m^2 (3m x 2m). The research included five varieties (factor A) from different breeding houses and five variants of fertilization (factor B).
Varieties: Odyssey, Kg-20, Triumph, Rtanj and Tango.
Variants of fertilization: control (with no fertilization); N_{60} (60kg ha^{-1} N); $N_{60}P_{80}K_{80}$ (60kg ha^{-1} N, 80kg ha^{-1} P_2O_5, 80kg ha^{-1} K_2O); $N_{90}P_{80}K_{80}$ (90 kg ha^{-1} N, 80 kg ha^{-1} P_2O_5, 80 kg ha^{-1} K_2O); $N_{120}P_{80}K_{80}$ (120 kg ha^{-1} N, 80 kg ha^{-1} P2O5, 80 kg ha^{-1} K2O).
The sowing was done manually in the second decade of October in pre-drawn furrows with a distance of 12 cm. The other technology of production which was applied in the experiment was standard. Phosphorus and potassium in equal amounts of 80 kg ha^{-1} were applied prior to sowing, while nitrogen was introduced to a small extent (20 kg ha^{-1}) before sowing, and the rest to the envisaged amount was given as the nutrient, in the second decade of March. Harvest was done manually in a phase of full maturity. The yield is calculated per hectare at 14% moisture. After harvest, samples were taken to determine a 1000 grain weight and hectoliter weight. The obtained results were statistically processed using method of variance analysis using statistical softwer WASP 1.0, whereby the significance of the average treatments were tested with LSD test, with significance threshold of 1 and 5%.
Soil and climatic conditions.
Soil samples were collected prior to winter triticale sowing, to a depth of 0-30 cm and 30-60 cm. Based on the results, it was found that the soil has slightly acid reaction with total carbonate content of 5.62 to 5.63%, it is humus rich (3.35-3.96%) and poor in available phosphorus (5.12-4.24 mg 100g $^{-1}$) and potassium (7.5-3.8 mg 100g $^{-1}$).
The data in Table 1. for the researching period (2009-2012) clearly indicate that the years in which the study was carried out in meteorological conditions differed from the period average for the given area. In all three years of research, the average air temperature was higher in relation to the perennial average, while the amount of precipitation in 2009/10 was 98 mm higher, and lower in 20010/11 and 2011/12 by 18 mm and 231 mm compared to the perennial average. Higher rainfall in the autumn months in the first two years of the study compared to

the third year created more favorable conditions for germination, emergence and preparation of crops for the winter period. On the other hand, the crops in the third year of the research were exposed to abundant snowfall with long retaining of snow cover, which slowed down the vegetation in the spring, due to which we had later sowing and flowering crops. A significant amount of precipitation and their favorable distribution in the spring months of the first year of the study enabled unhindered pouring of the grain, which had a positive effect on the yield.

Table 1. Average monthly air temperature and precipitation amount

Results and Discussion

Grain yield, from an economic point of view, is the most important property, and it represents the end result of the vegetative and generative life cycle of the plant. On the other hand, a 1000 grain weight and hectoliter weight are grain quality parameters, which are largely determined by the variety, but at the same time they are significantly influenced by environmental factors and applied agrotechnology. Three-year average values of grain yield, a 1000 grain mass and hectoliter weight in the examined varieties of winter triticale, depending on the variation of fertilization are shown in Table 2.

The results of the study showed that different amounts of nitrogen in combination with phosphorus and potassium had different influence and intensity of action on the grain yield of the tested varieties of triticale. The data in the Table 2. show that the lowest grain yields for all varieties involved in the research were achieved on the control variant (3598.5 kg ha^{-1}) and that the application of fertilizers caused a significant increase in the grain yield relative to the control. The average grain yield of winter triticale, observed for all varieties and varieties of fertilizers in the three-year study period was 4917.8 kg ha^{-1}. On average for all tested varieties, the highest grain yield (5604.1 kg ha^{-1}) was obtained in fertilization with 120 kg ha^{-1} nitrogen, but it was statistically significantly higher only in relation to the control and variant where only nitrogen in the amount of 60 kg ha^{-1} was applied. From data in Table 2. it can be seen that on average, the highest grain yield was recorded with the variety Tango (5304.0 kg ha^{-1}), and the lowest with variety Kg-20 (4366.2 kg ha^{-1}).
These results are in great agreement with the results of Popović and Malešević (2011) and Lalević and Biberdžić (2016). The results of the study show that there was a significant difference in the values of a 1000 grain weight among the tested varieties, but also that the use of fertilizers significantly influenced the observed trait. Accordingly, the highest 1000 grain weight of the tested triticale varieties were achieved on the fertilization variant where nitrogen was used in the amount of 120 kg ha^{-1} (44.4 g) and was significantly higher than the same achieved on other variants of fertilization. The lowest value of the aforementioned trait was observed on the control (39.1 g). The values of the three-year average show that the highest 1000 grain weight was achieved with the Tango variety (47.9 g), while the lowest value of this characteristic was recorded in the Kg-20 variety (32.7 g). Our results are in accordance with the results of Jaćimović et al. (2008) who found that a 1000 grain mass was significantly higher with more intensive fertilization treatments, especially in cases when nitrogen was used. Also, our results are in agreement with Jelic et al. (2013), Lalević et al. (2016) who pointed out that a 1000 grain mass is a property that is largely determined by the variety, due to which, among rare varieties, there is a greater variation in a 1000 grain mass than among the variants of mineral nutrition.
The average values of hectoliter weight in the tested triticale varieties ranged from 66.5 kg in the Kg-20 to 72.1 kg in the Triumph variety. The research of Milovanović et al. (2004) showed that the variety Triumph, besides high and stable yields, is characterized by good quality parameters. The results show that the use of fertilizers led to a very significant increase in the value of this property in relation to control, but also that among the different variants of fertilization there were no significant differences in the value of the hectoliter weight which is in agreement with the results of and Lalević et al. (2012) who pointed out that despite the fact that the application of mineral fertilizers leads to an increase in the hectoliter weight, the variation between the different variants of fertilization is low.

Conclusions

The differences in terms of yield and grain quality were determined by the variety and the applied fertilizer variant. The application of mineral fertilizers had led to a very significant increase in grain yield in all tested varieties of winter triticale in relation to control. However, as between the use of the minimum and maximum nitrogen in combination with phosphorus and potassium, there were no statistically significant differences in grain yield. In terms of economy we can recommend the variant $N_{60}P_{80}K_{80.}$ The value of the 1000 grain weight on all variants of fertilization was significantly higher compared to control. The highest increase in the 1000 grain weight was achieved on a plot where nitrogen was used in the amount of 120 kg ha^{-1}. The hectoliter weight was changed depending on the variety and the amount of nutrients used. However, despite the fact that the highest average value of hectoliter weight was recorded in the use of the highest amount of nitrogen, there were no statistically significant differences between the different variants of fertilization. The most varied varieties in our research were Tango and Triumph. The obtained results provide the possibility to give reliable recommendations when choosing a variety of winter triticale for cultivation in the northern part of Montenegro, but also to popularize and expand this variety in production.

Abstract

Acidic soils are present in over 60% of the total arable land in Central Serbia. On such land, agricultural production takes place under unfavorable conditions, where beside acidity, the high content of mobile aluminum limits the maximum genetic potential of new varieties and hybrids. Researches in this paper were carried out on pseudogley lands of Čačansko-kraljevačka basin with different purposes (meadow, forest and field vegetation). Within the forest vegetation we oppened 13 profiles 16 meadow profiles and 8 field profiles, where the content of the active and substitution acidity of the soil and the content of mobile aluminum were tested at the depth of humus-accumulative (A_h), eluvial-pseudogley (E_g) and iluvial (B_{tg}) horizon. The results of the analyzes showed that the active acidity of the soil varied in the range of pH 4.45 to 6.10 in all open profiles, regardless of the manner of use. The state of substitution acidity of the examined pseudogleys in all three horizons (A_h, E_g and B_{tg}) showed an acidic and highly acidic reaction, excluding the Ah and Eg horizons at the location of Jarčujak. The influence of the manner of use largely affected the substitution acidity, most notably in forest profiles. Of the 13 profiles, all showed an extremely acidic soil reaction (pH/KCl<4.5), only one profile in the A_h horizon had a pH/KCl value of 5.36. Under meadow and field vegetation, 87.5% of the profile showed a very acidic reaction in the A_h horizon, which pointed to the tendency of reduction with depth. The content of mobile Al in the soil showed a large interval of variation from 0.14 to 53.33 mg/100 g of soil, depending on the pH, location and manner of use.

Keywords: *Pseudogley, Soil profiles, Soil acidity, Mobile aluminium.*

Introduction

Serbia characterised by a real mosaic of soil types, subtypes, varieties and forms, which is a consequence of a very complex geological and lithological base, diversity of relief and climate in some of its regions, as well as of anthropogenic activities. Acidic soils are widespread (over 60% of a total territory), and due to their low productivity have become a limiting factor of the successful plant production (Stevanović et al., 1995). Approximately 71% of extremely acidic soils are located under forest and grassland vegetation. A total of 27% of extremely acidic soils are distributed over total agricultural land, while 23% of strongly acidic soils cover plough field areas, gardens and perennial plantations (Čakmak et al., 2009). The majority of acidic soil areas are located in central and western Serbia, with a large presence of pseudogley soils. Unfavourable physical and chemical traits are the principal properties of pseudogley. Active acidity (pH/H_2O) of these soils varies from pH 5 to 6, while their humus content is low (1.5-3%). These soils are poorly supplied with available nitrogen forms due to unfavourable conditions for the processes of ammonification and nitrification and strongly pronounced de-nitrification. The content of available phosphorus is very low, predominately 1-3 mg/100 g of soil, which is a result of the phosphate ion binding to Fe, Al and Mn into hardly soluble phosphates. Pseudogleys are fairly supplied with available potassium forms (Dugalić, 1998).

Aluminium is one of the most abundant elements in the Earth's crust, and although it is not an essential element, its toxicity is the most common limiting factor of the plant production on acidic soils. Al exists in the form of insoluble alumosilicates and oxides in neutral and weakly acidic soils (Jelić and Milivojević, 2015), while small amounts are present in a soluble form that can affect biological systems (May and Nordstrom, 1991). The Al mobility in the soil increases with the intensification of soil acidification caused by leaching of Ca, Mg, Na and K ions (Matsumoto, 2000). The content of mobile Al in pseudogley soils in the Čačak-Kraljevo Basin is varies to a great extent depending on the soil pH and soil profile (Dugalić and Gajić, 2002).

Regarding the proportion of H^+ and Al^{3+} ions in the total exchangeable acidity, it is very important to determine which proportion is greater and especially to establish the content of Al ions. Namely, due to the fact that Al ions at the increased concentration are much more toxic to plants than H^+ ions, plants will, at the same value of the total exchangeable acidity of the soil, more suffer if the proportion of Al ions is greater. It was established that Al ions with the content of mobile Al ions of 6-10 mg/100 g of soil, quite unfavourably affect the growth and development of the majority of arable crops, which is a consequence of not only the immobilisation of phosphate ions in the soil, but also of a poorer development of the root system, as well as, disturbance of metabolism of carbohydrates, nitrogen and phosphorus in plants.

Considering the importance of soil acidity and the content of mobile Al in the process of nutrient absorption, and consequently the growth and development of plants and the achievement of stable, high-quality yields, the aim of the present study was to observe their vertical dynamics in the Ah, Eg and Btg horizons of pseudogley soils of the Čačak-Kraljevo Basin under various utilisation methods.

Material and methods

Field studies encompassed pseudogley soils of the Čačak-Kraljevo Basin that have been differently used. A total of 31 soil pits were dug including the following soil profiles: 11 forest, 14 meadow and 6 field profiles. Soil samples were separately drawn form the humus-accumulative (Ah), eluvial (Eg) and illuvial (Btg) horizons, during 2016 year. Samples were then dried to an air-dry status, finely ground and sieved through 2-mm mesh sieve.

Laboratory tests encompassed the determination of active (pH/H_2O) and exchangeable (pH/KCl) soil acidity by the application of the potentiometric method in suspension with water and KCl (1:2.5). The titrimetric method was used to determine the Al^{3+} ions in the extracts of 1 mol L^{-1} KCl solution, 1:10 (v/v) soil/solution ratio. The exchangeable acidity (Al^{3+} + H^+) was determined by titrations of 25 mL KCl extract with 0.025 mol L^{-1} phenolphthalein as an indicator. Then, the concentration of mobile Al was obtained by back-titration of the same KCl extracts, previously used, after the acidification with a drop of HCl and addition of 40 g L^{-1} NaF, with 0.025 mol L^{-1} HCl.

Results and discussion

Obtained results of active and exchangeable soil acidity, as well as the content of mobile Al show great variations in their magnitudes over both, various profiles and horizons Table. 1).

Active acidity in forest pseudogley soils, in the Ah horizon, was higher than 6, 5 and 4 in one, three and six locations, respectively, while it was less than 4 in one location. The greater depth in the Eg horizon was the greater active acidity was, but it decreased from the Btg horizon. The analysis of exchangeable acidity performed in the Ah horizon show that pH/KCl > 5 i.e. 4 was recorded in one i.e. three locations, respectively, while pH/KCl<4 was detected in seven locations. The utilisation method greatly affected exchangeable acidity in Eg and Btg horizons, most notably in the forest profiles, as pH/KCl was lower than 4 (3.53-3.87) in all profiles of the Eg horizon, while this range varied from 3.47 to 3.96 in the Btg horizon.

Table 1. Active and exchangeable acidity and the content of mobile Al in the soil

The values of the mobile Al content changed over horizons in accordance with changes in soil acidity. Namely, in one location where pH/KCl>5 in the Ah horizon, the content of mobile Al was 0.36 mg/100 g of soil, while in locations where pH/KCl>4, the content of Al ions was below 5 mg/100 g of soil, which can be considered as values tolerable for cultivated plants. In all other locations, in Ah, Eg and Btg horizons, the content of Al^{3+}ions was within toxic concentrations (above 10 mg/100 g of soil, Jakovljević et al., 1991). In addition to the pH value, the content of organic matter, the composition of soil minerals and other soil properties significantly affect the content of mobile Al in the soil (Naramabuye and Haynes, 2007).

The basic characteristic of active and exchangeable acidity in meadow soils was the greater uniformity among observed locations (Table 1). The $pH/H_2O<5$ was recorded in three out of 14 dug profiles in the humus-accumulative horizon, while it varied from 5.03 to 5.98 in remaining profiles. The values of exchangeable acidity varied from 3.90 to 3.94 in four locations, while it was above 4 in nine locations. This value amounted to 5.38 only in the estate of the Agricultural School in Kraljevo, due to anthropogenic activities. Exchangeable acidity increased over the soil depth, and its average value in Eg and Btg horizons amounted to 3.91 and 3.81, respectively. The content of mobile Al was directly dependent on soil acidity, because the content of Al^{3+} ions in the Ah horizon with profiles where pH/KCl ranged from 3.90 to 3.94 varied from 9.35 to 15.20 mg/100 g of soil. In remaining profiles in the Ah horizon, the content of mobile Al was below 5 mg/100 g of soil, except in the location Jarčujak where pH/KCl amounted to 4.01 and the content of Al^{3+} ions was 8.72 mg/100 g of soil. The greater soil acidity in Eg and Btg horizons was the greater participation of Al^{3+} ions in exchangeable acidity was (Eg - 15.95, Btg - 18.20 mg Al^{3+}/100 g of soil).

The toxic content of Al^{3+} ions (14.93 mg/100 g of soil) was recorded in just one of six dug field profiles in which active acidity of the soil was below 5 (pH/KCl - 3.74) (Table 1). The $pH/H_2O>5$ and pH/KCl >4 were recorded in all remaining dug profiles, while the average content of mobile Al amounted to 4.08 mg/100 g of soil, which was approximately three-fold lower than the average content of Al^{3+} ions in forest profiles in pseudogleys. Exchangeable acidity in Eg and Btg horizons was increased (Eg – 4.09 and Btg – 3.97 pH units), which resulted in the increased content of Al^{3+} ions (Eg -7.87 and Btg – 12.22 mg/100 g of soil).

Gained results show that the distribution of soil acidity and the content of mobile Al were strongly dependent on the soil profile, and that the content of Al^{3+} ions in pseudogley soils of the Čačak-Kraljevo Basin highly varied over the method of soil utilisation and the profile depths (Table 2).

Table 2. Average values of pH/KCl and the content of mobile Al over soil profiles

	Forest profiles	Meadow profiles	Field profiles
pH/KCl	3.79	4.00	4.12
Mobile Al	21.49	12.95	8.06
Ah- pH/KCl	4.07	4.27	4.30
Ah-mobile Al	13.83	4.70	4.08
Eg- pH/KCl	3.65	3.91	4.09
Eg-mobile Al	26.07	15.95	7.87
Btg- pH/KCl	3.65	3.81	3.97
Btg-mobile Al	24.58	18.20	12.22

Soil acidity has the greatest impact on changes in contents of Al^{3+} ions ($r = -0.74$). The highest average soil acidity was recorded in forest soils (pH/KCl 3.79), then in meadow (pH/KCl 4.00) and arable field soils (pH/KCl 4.12). The soil acidification was accompanied by high average values of mobile Al (21.49, 12.95 and 8.06 mg/100 g of forest, meadow and arable field soils, respectively), which had been previously established by Dugalić and Gajić (2002) and Dugalić et al. (2008). Furthermore, these studies confirmed conclusions made by Nikodijević (1964), who had studied the content and dynamics of Al^{3+} ions of pseudogley soils of western Serbia and had determined that soils with pH/KCl<4, pH/KCl 4-4.5 and pH/KCl>4.5 had contained 13-45, 3-13 and less than 3 mg of Al^{3+} ions/100 g of soil. High values of mobile Al in pseudogleys were established by Osaki et al. (1997) and Mládková et al. (2005).

The content of soil organic compounds (humic and citric acids) affects the content and distribution of Al^{3+} ions in a sense that they reduce acidity, and therefore the content of free Al ions. Binding of soil Al into organic complexes reduces the Al toxicity, which reduces its accessibility in the soil and its absorbability by plants (Parker et al.,1988). In his previous studies, Dugalić (1998) determined a low humus content in these soils, which reduced the ability of Al ions to bind to humic acid, which additionally affected the increase of its mobility in the soil.

Conclusion

The extensive studies of the vertical dynamics of active and exchangeable soil acidity and the content of mobile Al in forest, meadow and arable field pseudogley soils of the Čačak-Kraljevo Basin point out to a great variability of these parameters depending on the method of soil utilisation and the profile depth. The highest average soil acidity was established in forest soil profiles (pH/KCl 3.79), and then in meadow (pH/KCl 4.00), and field soil profiles (pH/KCl 4.12). The average content of mobile Al amounted to 21.49, 12.95 and 8.06 mg/100 g of forest, meadow and filed soils. The lowest acidity, and therefore the lowest content of mobile Al was determined in the Ah horizon, then in Eg horizon, while the highest acidity was recorded in the Btg horizon.

Abstract

The wastewater resulting from the recirculating aquaculture systems (RAS) is rich in nitrogen and phosphorus, which is why it could be used for plant cultivation, as a sustainable disposal management. The aim of this study was to test the effects of RAS wastewater on basil yield and essential oil quality. A green basil cultivar 'Genovese' was used for this study. Plants were divided into two groups, a control group watered with distilled water (50 ml H_2O / pot / day) and one treated with RAS wastewater (50 ml H_2O / pot / day). Chlorophyll content, plant height, lateral stems number, and the fresh biomass were assessed. The essential oil was also extracted and its composition determined by GC/FID and GC/MS techniques. The results showed that fresh biomass of basil was higher (+13%) under RAS wastewater treatment compared with control. The chlorophyll content was higher in the same group (+13%). Regarding the composition of the essential oil, 26 compounds were identified, including 8 monoterpenes, 16 sesquiterpenes and 2 phenylpropanoids. The main determined compounds were eucalyptol, β-linalool, eugenol, methyl eugenol, α-trans bergamotene, germacrene D. RAS wastewater treatment influenced the production of the main compounds as followes: -12% eucalyptol, +11% β-linalool, +1,5% eugenol, -1.9% methyl eugenol, -4.7% α-trans bergamotene and + 22% germacrene D, compared with control. This study demonstrates that the use of RAS wastewater can improve the fresh yield of basil and it can also stimulate the production of specific compounds in the essential oil.

Keywords: *Ocimum basilicum* L., chlorophyll content, fresh mass, essential oils

Introduction

Basil essential oil EO is utilized in numerous industries due to a wide range of bioactivities such as antibacterial, antioxidant, or chemoprotective (Pandey *et al.*, 2014). Generally, the constituent compounds of basil EO are terpenes and phenylpropanoids, and the proportion of compounds belonging to one of these classes depends on both genetic and environmental factors (Zheljazkov *et al.*, 2008). Due to the growing demand on the pharmaceutical and perfumery markets for certain compounds, such as linalool, eugenol, camphor, eucalyptol, etc. numerous studies have been aimed at stimulating the synthesis of a desired compound by various techniques of elicitation, fertilization and selection (Onofrei *et al.*, 2018).
Water is a very important factor for optimal growth and development of plants; consequently, there is currently a tendency to reuse water from different activities such as aquaculture, for irrigation. Irrigation of plants with water resulting from a recirculating aquaculture system (RAS) could be a preferred solution because it is nutrient rich. RAS is an important branch of aquaculture. This technology is based on the reuse of water using mechanical, biological and UV filtration. Due to the fact that water is reused in RAS systems, it results in reduced water consumption, so RAS systems are environmentally friendly. Depending on the species and the

growing technology, up to 36% of the feed is excreted by fish in the form of organic residues. Furthermore, 75% of nitrogen, 85% of phosphorus and 80-88% of carbon of aquaculture feed are released into wastewater (Endut *et al*., 2011).

Numerous studies have been carried out in order to re-use the aquaculture wastewater for production of valuable cultures such as Bell Peppers (Zheljazkov and Horgan, 2011), water spinach (Endut *et al*. 2009; Effendi *et al*. 2015), lettuce (Effendi *et al*. 2017; Wahyuningsih *et al*. 2015). According to these studies, positive results on plant growth are owed to the dissolved nutrients such as nitrogen and phosphorus, specific organic and inorganic compounds, and total suspended solids, which results from uneaten feed and metabolic wastes from the fish. Accumulation of high nutrients concentration in water can became harmful to fish, which is why, research for new technologies for water treatment and water reusing represent a preferred solution for both the welfare of fish and for the environment (Effendi *et al*. 2015).

The overall objective of this study was to evaluate the effect of RAS wastewater utilization on the plant morph-physiology and the quality of essential oil of basil.

Materials and methods

Plant growth conditions: sweet basil (*Ocimum basilicum* L.) was cultivated under controlled environmental conditions: 1 L black plastic pots; natural light was supplemented by florescent tubes 12 h/day; temperature 25°C; the soil was Florisol® (N-0.41%; P_2O_5-0.44%; K_2O-1.16; organic matter – 41%); plants were watered daily with 50 ml H_2O per pot.

After 4 weeks, plants were divided into two groups: group 1 - control variant (labeled V1 - control) that was watered with distilled water; and group 2 - watered with water from RAS (labeled V2 - RAS) (pH 7.9; dissolved oxygen 8.79 mg/l; electrical conductivity 1405 S/cm3; total dissolved solids 782 mg/l; NO_3^- 44 mg/l; NO_2^- absent; NH_3^+ absent; NH_4^- absent; phosphorus 0.9 mg/l). Each group consisted of 3 repetitions of 4 pots (1 plant/ pot).

After 2 weeks plants were harvested and fresh mass (g/plant), plant height (cm) and total chlorophyll content (CCI) were assessed.

Chlorophyll content index (CCI): was measured with a portable device CCM-200 plus (Opti-Sciences, USA).

Essential oil extraction: fresh plant material from the variants (10.0 g in 100 mL H_2O) was used for the volatile oil extraction by hydrodistillation for 2 h in a Clevenger type apparatus.

Essential oil characterization: the EO samples were analyzed by GC/FID and GC/MS techniques. The GC/MS analysis was carried out with an Agilent 5975C MSD system coupled to an Agilent 7890A GC (Agilent Technologies Inc., Santa Clara, CA). An Agilent J&W HP-5MS column, 30m, 0.32mm, 0.25µm was used with helium (purity 99.99%) as a carrier gas. Operating conditions were as follows: oven temperature 60 °C (3 min), 1°C/min to 80 °C (3 min); 5°C/min to 280°C (5 min); flow rate of 1.2 ml/min (He); injector T=260°C; FID T=270°C; 1.0µl injection volume at split ratio 20:1. The mass spectrometry conditions were: ionization voltage 70 eV, ion source temperature 230°C, transfer line temperature 280°C, solvent delay 4.00 min and mass range: 50-500 m/z. The MS was operated in scan mode. 1.0 µL of EO diluted with n-hexane (10%, v/v) was injected into GC/MS system. The GC analysis was carried out using an Agilent 7890A GC system. In order to obtain the same elution order with GC/MS, simultaneous triplicate injections were done using the same column and operational conditions.

Identification of the components present in the EOs was made by comparing mass spectra of components in EOs with those from NIST'08 and Adams mass spectra library, by AMDIS (Automated Mass Spectral Deconvolution and Identification System), and by comparing with literature data and estimated Kovats (retention) indices. These were determined using a mixture of homologous series of normal alkanes from C_8 to C_{40} in hexane, under the same

above-mentioned conditions. The percentage ratio of EO components was computed by the normalization method of the GC/FID peak areas, and average values were taken into further consideration (n=3).
Statistical analyses: results are expressed as means ± standard errors. Descriptive statistics, analyses of variances (ANOVA) were performed for fresh biomass, plant height and chlorophyll content index.

Results and discussion

Morph-physiological parameters
In order to test the effect of RAS wastewater on morph-physiology of basil, fresh mass, plant height, and chlorophyll content were analyzed (Table 1). Fresh mass and plant height were higher with 10% and 11%, respectively, in plants that were treated with wastewater from the RAS, compared with control (distilled water) (Table 1). The differences between treatments were statistically significant according to the ANOVA test ($p<0.05$) only for the fresh biomass.
Chlorophyll content increased by 13% in RAS treated plants compared with the control variant, the differences being statistically significant ($p = 0.03$). These changes in the photosynthetic apparatus may also explain the increase of fresh biomass in plants treated with water from the RAS (Table 1).

Table 1. Morpho-physiological parameters of basil treated with RAS wastewater

Parameter	Treatment	Mean ± standard error	Minimum	Maximum	F	p
Fresh mass (g/plant)	Control water	24.33±0.51	23.66	25.33	10.170	0.030
	RAS wastewater	26.89±0.62	25.66	27.66		
Plant height (cm)	Control water	15.17±0.84	13.76	16.67	2.840	0.160
	RAS wastewater	16.86±0.55	15.76	17.50		
Chlorophyll content CCI	Control water	6.23±0.22	5.83	6.60	10.610	0.030
	RAS wastewater	7.04±0.11	6.90	7.26		

The Research and Development Station for Aquaculture and Aquatic Ecology from Iasi is one of the largest RAS in Romania that is used for growing of sturgeons. In order to meet the objective of blue growth and circular economy, there is a need to reuse the wastewater from the RAS for various activities such as plant irrigation. RAS wastewater contains nitrates and phosphates that may explain the positive results in this study. The presence of nitrates and phosphates in RAS wastewater is resulted from the use of fish feed with up to 45% protein content (Effendi et. *al*., 2017). Fish excretes most of the nitrogen in form of urine through the gills, thus this element is completely dissolved in water. In the biofilter of RAS, nitrogen is transformed in nitrate, the preferred form for plants. Basil plants react positively to nitrogen fertilization, by increases of the mass and morphological parameters (plant height, number of lateral branches, number of leaves, etc.) (Bufalo *et al*., 2015; Burducea *et al*., 2018). Similarly, in our study, the use of RAS wastewater has led to the increase of both the fresh biomass and height of basil plants. Nitrogen plays an essential role in plant growth and development being used in protein synthesis. Likewise, phosphorus is another essential element that is used in the energy processes (Marschner, 1995). At the same time, the greater availability of nitrogen and phosphorus in RAS wastewater may be responsible for an improved physiological state of basil, as was estimated by the quantification of chlorophyll content. This is due to the fact that nitrogen enters the composition of ribulose 1,5-bisphosphate carboxylase/oxygenase (RuBisCO) and ribulose 1,5-bisphosphate (RuBP), molecules which together with carbon dioxide and in the presence of light leads to the synthesis of organic substances in the photosynthesis process (Marschner, 1995).

Essential oil composition

In the present study, 26 compounds were identified in the EO of basil (Table 2). The compounds belongs to two chemical classes: phenylpropanoids (eugenol and methyl eugenol), and terpenoids (8 monoterpenoids and 16 sesquiterpenoids). RAS wastewater treatment influenced the metabolic pathway for synthesis of terpenes. Accordingly, increases of 11.4% for linalool, 8.3% for β-caryophyllene, 22.8% for germacrene D were obtained for RAS wastewater treated plants compared with control. The variations of phenylpropanoid compounds were small (+1.5% eugenol and -1.9% methyl eugenol) of the essential oil belonging to the RAS wastewater group compared with the control group.

In our study, the main identified compounds (linalool, eucalyptol, eugenol and methyl eugenol) recorded quantitative changes depending on the water used as treatment (RAS or distilled water). Generally, the species belonging to the genus Ocimum sp. may be rich in terpenoids (40-70%) or phenylpropanoids (Zheljazkov et al., 2008). Terpenoids are formed through the metabolic pathway of mevalonic acid (MVA) in the cytoplasm and via the methylerythritol phosphate (MEP) pathway in plastids. The metabolic pathway for the formation of phenylpropanoid compounds starts with phenylalanine - the amino acid from which phenylpropanoids (eugenol and methyl eugenol) are formed, and intermediates used in the biosynthesis of lignin, anthocyanins, rosmarinic acid, etc. are also formed. These metabolic pathways can be influenced by internal factors: differentiated gene expression, microRNA, transcription factors, promiscuity of enzymes, as well as external factors such as light, radiation, temperature, growth substrate composition. Both terpenoid and phenylpropanoid compounds have a great utility in various industries such as food, cosmetics and pharmaceutics. Terpenes are used as dyes, flavorants and medicinal purposes. For example, linalool, which is a major compound in the volatile oil of many basil chemotypes, has a series of bioactivities such as: antimicrobial, anti-inflammatory, anticancer, antioxidant (Pandey et *al*., 2014). Furthermore, linalool is used in domestic products such as soaps, detergents and shampoos (Kamatou and Alvaro, 2008). Phenylpropanoid compounds such as methyl eugenol are known to have antifungal and insecticidal properties. An important constituent of the phenylpropanoids identified in our study is methyl eugenol (44-45%). Methyl eugenol is found in approximately 450 plant species, its role being protection against herbivores attack (Tan and Nishida, 2012).

Table 2. The composition of basil essential oil

No.	Name	Compound group	RT (retention time)	RI (retention index)	Control	RAS
1	β-Pinene	monoterpene	6.11	979	1.26	1.06

25	1.10-di-epi-Cubenol	sesquiterpene	22.62	1618	0.25	0.89
26	1-epi-Cubenol	sesquiterpene	23.18	1627	2.67	4.02

Conclusion

In this study, the fresh biomass and chlorophyll content of basil increased as a result of RAS wastewater treatment. Analyzing the composition of the essential oil, 26 compounds were identified, of which 24 are terpens and 2 are phenylpropanoids. Two of the main compounds (linalool and methyl eugenol) recorded an increase in the essential oil extracted from the plants treated with RAS wastewater. Our results indicate that the water treatment and water reusing represent a preferred solution for both the welfare of fish and for the environment.

Abstract

One of the most important winter cereals cultivated in Greece is *Triticum durum*. In this research we studied the effect of different fertilizer types containing nitrification inhibitor and conventional fertilizers at 4 different N-levels (0, 70, 140 and 210 kg ha^{-1})on two different durum wheat varieties at the Experimental Farm of the Technological Educational Institute of Thessaly in Greece (TEI; Larissa plain). The sowing of the crop took place on November 2018. Nitrification inhibitor ensured crops N-nutrition for longer period compared to conventional fertilizers and may lead to higher yields with higher protein content. There were not found any statistical significant differences on yield between the tested factors for both varieties but only numerically superiority of the fertilizers containing nitrification inhibitor. On the other hand, there were found statistically significant differences in protein and starch content for both varieties. It was found that the N-levels of 140 & 210 kg ha^{-1} produced seeds of higher protein content, ranging 15.87-16.03 and 15.48-16.20 %, for both varieties, respectively. Furthermore, protein and starch content have a linear relationship with nitrogen supply, where R^2 is very high (0.93 and 0.97), respectively.The above results were found through the first year of experimentation, and therefore safer conclusions expected to arise after the repetition of the experiments in the same place for a second and a third year.

Keywords: *Triticum, nitrification inhibitor, fertilizers, yield, Greece.*

Introduction

Durum wheat is grown on over 3.7 million ha in the European Union, largely concentrated in the Mediterranean countries (Italy, Greece and Spain), where prevailing the ideal growing conditions for producing quality grains (Nachit, 1998). This area accounts for82%of total EU production; however, grain yields are lower than those obtained in Northern European countries (European Commission, 2002).

The most influencing factor for the quality of the grains is N fertilization, although the degree of influence is governed by annual weather conditions and by residual soil N (L´opez-Bellido et al., 2001). It has been reported (Campbell et al., 1993) that there is a strong interaction between soil water use and crop fertilizer response in semi-arid conditions. Progressive design of nitrogen fertilizer program is essential to optimize wheat yield and quality (Grant et al., 2001).

Quality grain durum wheat is generally dependent on the protein content, at least in the range of protein percentages encountered in commercial wheat cultivars (Grant and Flaten, 1998; Anderson, 2000; Clarke, 2001). Carefully managing of nitrogen N application, may lead to higher yields while protein may be maintained or increased (Chaney, 1990; Gate, 1995).

It is therefore important to conduct research to determine the crop response to N fertilization and to develop rational practices for more efficient N use in this crop (Knowles et al., 1991; Anderson, 2000), which requires a higher level of management (Impligia and Anderson, 1998).

Farmers apply different N fertilizers such as urea, ammonium nitrate, ammonium sulphate and potassium nitrate to increase yields. However, this increase in N use, with N-response efficiency reported to be between 33 and 50%, is contributing to higher worldwide N losses via NH_3 volatilization and NO_3^-leaching that impact air and water quality (Raun and Johnson, 1999; Howarth and Marino, 2006; Nosengo, 2003).

Nitrogen is an important component of proteins and chlorophyll-building cells and plant tissues (Vickery and Vickery, 1981). It is also an important determinant of the rate of basic physiological processes in plants, such as photosynthesis and respiration (Lewis et al, 2000; Takashima et al., 2004). Nitrogen is often limited to most agricultural ecosystems, therefore, nitrogen fertilizers (ie, chemical or organic) are often applied to meet the N-requirements of growing plants and improve soil fertility.

Improvement of fertilizers that are already used is done through appropriate product design (Bröckel and Hahn, 2004). The product profile is determined by chemical and physical properties, environmental safety and stability against mechanical stress, hygrometry and temperature. The design of new solid fertilizers products is mostly done to improve handling properties. Increasing the efficiency of inorganic N in fertilizers is not easy, because plants occupy N normally at nitrate or ammonium form through their roots from the soil solution. However, ammonium-N, as opposed to N-nitrate, can be retained as soil components, so that soil and plants compete for ammonium-N, whether it is already available on the soil or applied (Amberger, 2006).

Urea is the basic type of chemical fertilizer. Since 50% of the world's demand for N is met by the use of urea, this large use of urea is due to a number of factors, including high levels of N (46% N by weight), high water solubility, easy transportation, handling and application.

Nowadays there are new N-fertilizers types using many inhibitors. One of these types is also the fertilizer that has a substance that inhibits the biological oxidation of ammonium-N with nitrate-N and it calls nitrification inhibitor.

This study was conducted in the main agricultural plain (Thessaly) to evaluate the effect of new N fertilizer types containing nitrification inhibitor on the yield of durum wheat in Greece.

Material and Methods

For the purpose of the study, two field experiments were established in a typical soil-climatic environment of Thessaly plain, in central Greece. The experimental site is located at the Experimental Farm of the Technological Educational Institute of Thessaly in Greece (TEI; Larissa plain, coordinates: 39.626100, 22.381363).

Field management and experimental design

Sowing was occurred using a modern cereal seeding machine (on November 2018), applying 225 kg ha^{-1} of seeds in a row-distance of 12.5 cm.

Basic fertilization (250 kg ha^{-1} of 20-10-0) applied one-two days before sowing using a dispenser and then the fertilizer was incorporated using a rotary cultivator. There was performed post-emergence herbicide application to control weeds.

The experimental design for both tested varieties (2 varieties were selected V_1: *Iride* and V_2: *Simeto*) was a split-plot design with major factor the fertilizer type (2 fertilizer types, F_1: conventional and F_2: fertilizer using nitrification inhibitor), and sub-factor the N-level (4 N-levels, L_1: 0, L_2: 70, L_3: 140 and L_4: 210 kg ha^{-1}) and three replications (blocks).

Soil characteristics

The soil of the experimental site is characterized as a calcareous (pH = 7.8), with low organic matter content (0.9) and low salinity (0.11) at a depth of 30 cm (Table 1).

Table 1. Soil characteristics of the field experiment.

Property	Soil depth (0-25) cm
Texture	Loam
pH	7.81
EC (dSm^{-1})	0.11
Organic matter (%)	0.93
N-inorganic (mg kg^{-1})	44.8
K-exchangeable (mg kg^{-1})	373.3
P –Olsen (mg kg^{-1})	13.1

Plant measures

Total biomass and seed yield measured by harvestsampling (according to Zadocks scale: ripening stage 91-99). To avoid any border effect, 1 m^2 in the inner plot was harvested in each sampling above the ground. The samples were weighed at the field and then a sub-sample was taken for further laboratory measurements.

Protein, starch and gluten content was determined in dry seeds of each sample by near-infrared reflectance (NIR) spectroscopy technique using the DA 7250 NIR analyzer (Perten Instruments, Hägersten, Sweden).

The statistical package GenStat (7th Edition) was used for the analysis of variance (ANOVA) within sample timings for all measured and derived data. The $LSD_{0.05}$ was used as the test criterion for assessing differences between means (Steel and Torrie, 1982).

Results and Discussion

Yield and Quality wheat characteristics

The results have shown none statistical significant differences between the tested factors for both varieties but only numerically superiority of few treatments (Table 2), especially in case of seed yield which is the product of economic value.

The fertilization using nitrification inhibitor have a numerically superiority for both tested varieties. The difference in seed yield between the different fertilizer types is 262 and 227 kg ha^{-1}, in case of Iride and Simeto, respectively. Moreover, it was found that the 3rd N-level for the fertilizer with nitrification inhibitor produced the same yield with the higher fertilization level of the conventional fertilizers (Table 2).

Unlike the quantitative characteristics, the quality characteristics have statistically significant differences. Particularly there were found differences in protein and starch content for both varieties. The results are presented in Table 3, where it is shown that N-levels of 140 & 210 kg ha^{-1} produced seeds of higher protein content, ranging 15.87-16.03 and 15.48-16.20 %, for both varieties respectively.

On the other hand, in case of starch content, the zero fertilization level is the treatment with the higher starch content indicating that seeds of higher protein content have lower starch content. Zou et al (2015) mentioned that proteins can have some obvious effects on enzymatic degradation of starch, such as by physically hindering access of degradation enzymes to starch, while Wenwen et al. (2017) concluded that the protein content significantly and negatively correlated with starch molecular structures in a study for barley cultivation, which is in agreement with our findings.

Protein and Starch content relation with N fertilization level

Plotting the protein (%) content according to the nitrogen supply (kg ha^{-1}) results in the protein- nitrogen supply relation illustrated in Figure 1.

It can be seen that a linear relationship apply that might explain 93% of the existing variation (R^2= 0.93), largely independent of fertilizer type and variety, where the higher nitrogen supply the higher protein content is achieved.

In a study in Mediterranean conditions (Abad et al., 2004), it was found that seed protein ranged from 14.1 to 16.4% with the increased content found at higher fertilization levels, which is in agreement with our findings.

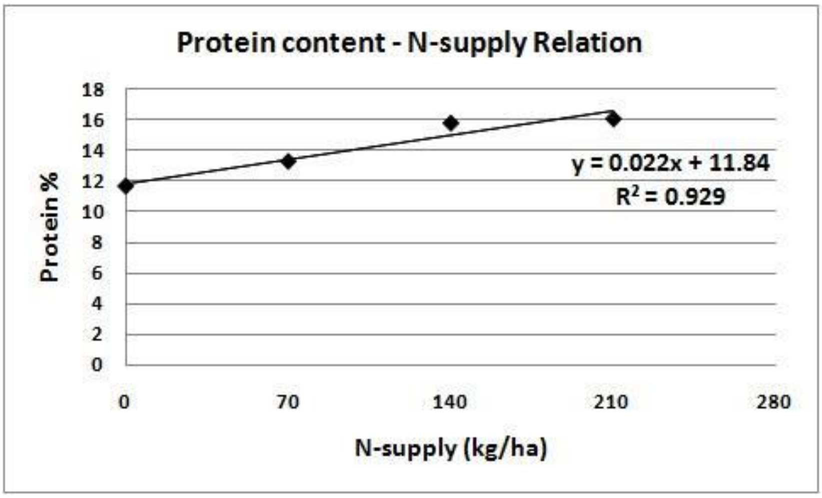

Figure 1. Protein % content – N-supply relation.

Plotting the starch (%) content according to the nitrogen supply (kg ha^{-1}) results in the starch-nitrogen supply relation illustrated in Figure 2.

It can be seen that a linear relationship apply that might explain 97% of the existing variation (R^2= 0.974), largely independent of fertilizer type and variety, where the higher nitrogen supply the lower starch content is achieved.

In a study (Wenwen et al., 2017) was concluded that starch has a negatively correlation with protein content. Therefore, if starch has a negatively correlation with protein, and protein has a positively correlation with nitrogen supply, then it is verified the negatively relation of starch content with nitrogen supply.

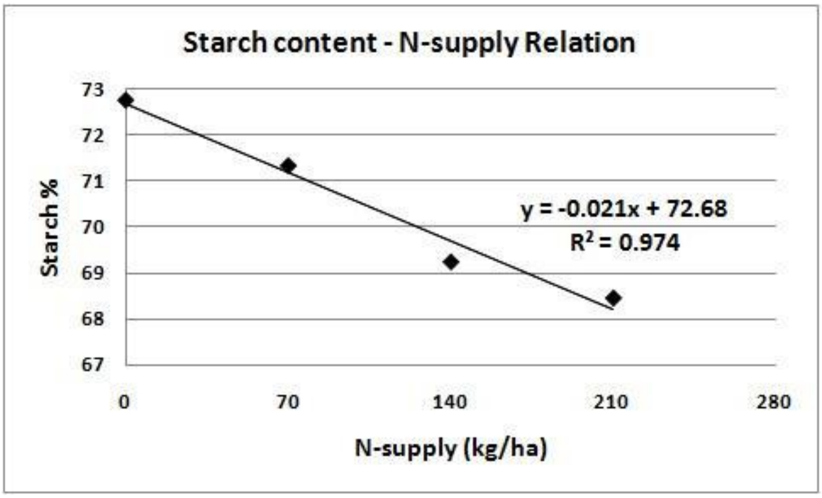

Figure 2. Starch % content – N-supply relation.

Conclusions

In both durum wheat varieties *Iride* and *Simeto*, there were not found significant differences for the quantitative characteristics but only numerically superiority of the fertilizers with nitrification inhibitor. On the other hand, statistically significant differences were found in case of the quality characteristics (protein and starch % content).Protein and starch content have a linear relationship with nitrogen supply, where R^2 is very high (0.93 and 0.97), respectively.Due to the fact that the above results were found through the first year of experimentation, safer conclusions expected to arise after the repetition of the experiments in the same place for a second and a third year.

Abstract

Variability of length of spike and number of spikelets spike^{-1} have share in forming of grain yield of wheat. The aim of this study was estimation of variability of length of spike and number of spikelets spike^{-1} in 20 genetically divergent wheat cultivars grown in different environmental conditions. The experiment was set up as a randomised block design in three replications. Obtained results indicated differences in average values of length of spike and number of spikelets spike^{-1} among tested cultivars in both years of experiment. In average for all cultivars length of spike was higher in the second year than in first year of experiment. Also, average value of number of spikelets spike^{-1} was higher in second year at the analysed wheat cultivars. The wheat cultivar Dejana expressed the longest spike (12.50cm) in the second experimental year while the wheat cultivar Sumadinka had the shortest spike (8.91cm) in the first year. On the base of results were established variability of both analysed spike traits in wheat cultivars. Also, this results showed significant differences among wheat cultivars according to length of spike and number of spikelets spike^{-1}, which are determined by genetic and environmental factors.

Keywords: *wheat, variability, spike length, spikelets, cultivars.*

Introduction

Wheat (*Triticum aestivum* L.) is one of the most important crops as a source of food for the people worldwide. Increasing of wheat grain yield is the main task of breeders which require effort in improving characteristics of spike traits, grain, stem, leaf and root traits. The long and fertile spike potentially can contribute to improvement of grain yield of wheat (Zečević *et al*., 2008; Knezevic *et al*., 2014). Spike length together with number of spikelets and number of florets per spike represent great potential for yield improvement (Zečević, *et al*., 2004; Dimitrijević *et al*., 2011) through developing grain number spike^{-1} and as a source of assimilate in grain filling period as well as forming grain yield. Increasing of number of spikelets potentially related to increasing of number of grains (Álvaro *et al*., 2008). Spike length had positive relationship with number of spikelets spike^{-1} at both genotypic and phenotypic levels (Akram *et al*., 2008). Floral development is an important part of the pre-anthesis stage. Anther and ovary growth as well efficient pollination connected to grain number per spike, grain size and grain weight (Guo *et al*., 2015). Grain number per spike is related to floret survival (Gonzalez *et al*., 2011; Sreenivasulu and Schnurbusch, 2012). Spike structure has advantages in utilizing light in compare to other parts of plant and contribute to increasing of yield. Also, spike together with awns contribute to longer stay green area duration. All these characteristics of spike contribute to accumulate in average 20-30% of dry matter depends of genetic and environmental factors as well as their interaction (Knežević *et*

al., 2015: Branković *et al*., 2015). The effect of genetic and environmental factor at the length of spike and development of number of spikelets per spike need further investigation. Increasing of genetic capacity of spike traits is a potential direction of increasing grain yield of wheat (Knezevic *et al*., 2012).
The aim of this paper was investigation of variability of length of spike and number of spikelets spike^{-1} in genetically divergent wheat cultivars grown in different environmental conditions.

Materials and Methods

The twenty geneticaly divergent winter wheat cultivars were used for study of length of spike and number of spikelets spike^{-1} during two season of vegetative growth year (2015/16 and 2016/17). The experiment was performed in randomized block design in three replications on the field in Kraljevo, Serbia. The seeds of varieties were sown at the distance of 0.05m in rows of 1m length among which was the distance of 0.2m. For analysis of length of spike and number of spikelets spike^{-1} were used 60 plants in full maturity stage (20 plants per replication). For statistical analysis used MSTAT C version 5.0. The significant differences between the average values were estimated by F-test values. The analysis of variance was performed according to a random block system with one factor and significant differences were tested by means of test value of $LSD_{0.05}$ and $LSD_{0.01}$.

Weather conditions

In the first year experiments 2015/206, the average temperature was 9.9 °C and the total amount of precipitation was 651mm. In the second year of experiment 2016/17 average temperature was 13.0 °C and the total amount of precipitation was 523 mm. The average rainfall in the first year (651mm) was significantly higher than in the second year (523.1 mm), and than for ten years - 417.8 mm (Table 1). For plants growth in the second year was more favorable regime of temperature and precipitation. During October-November, a greater amount of water residue in the second year (161.7 mm) was higher than in the first year (120.8 mm) but in both years weather condition in this period was favorable for seed germination and development of plants to be in good condition for survive in the future winter period. Also, in the two months (October-November) the average temperature values were similar in both year of experiment. During the February-April amount of precipitation in the first year (250.5 mm) was higher than in the second (174.0 mm), although the distribution of rainfall was more favorable in the second year experiment (Table 1).

Results and Discussion

The length of spike in the first year of experiment varied in range of 8.91-11.11 cm with average value 9.92 cm, while in second year varied from 10.03 to 12.50 cm with average value 11.09 cm. Number of spikelets spike^{-1} in the first year of experiment varied in interval of 20.85 - 24.38 with mean value 22.79, while in second year number of spikelets spike^{-1} varied between 21.23 and 25.0 with average value 23.53 (Table 2). The obtained results showed significant differences in the average values of length of spike and number of spikelets spike^{-1} per year, that indicating diversity of studied cultivars.

Similar results were reported in previous investigation of Serbian wheat (Zečević *et al.*, 2008; Knezevic *et al.*, 2012) as well as for Italian and Spanish wheat cultivars (Álvaro *et al.*, 2008).

The significant differences among the investigated wheat cultivars were established for the length of spike (Table 3). Also, the values of length spike of analysed genotypes were significantly different between first and second experimental years (Table 2). Generally, in average all studied wheat cultivar in both year expressed higher values in relation to average value of length of spike in the first year. This indicates response of genotypes to environmental conditions.

Differences among cultivars according to value of spike length are affected more by genotype than by relationships to the geographic origin (Dotlačil *et al.*, 2003). The length of spike controls by additive and nonadditive gene with prevalence of additive gene effects (Ljubičić *et al.*, 2014). Also, the sensitivity of length of spike under environmental variation noticed (Zečević et al., 2008; Knezevic *et al.*, 2014) and represent important components of wheat yield. The environmental factors as well temperature values, precipitation, nutrition have influence on increasing of capacity of spike (Petrović *et al.*, 2008; Knežević *et al.*, 2016) and grain yield (Marijanović *et al.*, 2010).

Table 3. Components of phenotypic variance for length of spike (cm) of wheat – in 1st and 2nd year

	First Year						Second Year					
Source of variance	DF	SS	MS	F	LSD		DF	SS	MS	F	LSD

The significant differences among the tested wheat cultivars, in both year of experiment, were established for the number of spikelet spike^{-1} (Table 4). The number of spikelets spike^{-1} at the analysed wheat cultivars variate and were significantly different among the cultivars and between the years of experiment. Generally, the all tested cultivars had higher number of spikelet spike^{-1} in second year than in first year of experiment (Table 2).

Table 4. Components of phenotypic variance for number of spikelets spike^{-1} in wheat

	First Year						Second Year					
Source of variance	DF	SS	MS	F	LSD		DF	SS	MS	F	LSD	
					0.05	0.01					0.05	0.01

Error	38	14.012	0.369	-	-	-	38	16.949	0.446	-	-	-
Total	59	62.922	-	-	-	-	59	58.902	-	-	-	-

The investigated trait highly depended to genetic and environmental factors (Zečević *et al.*, 2004; Dodig *et al.*, 2008). The spike length is yield components which highly positively correlated to number of spikelets spike^{-1} (Akram *et al.*, 2008). The spike length has strong indirect influence on yieald through number of spikelets spike^{-1} and futher on number of grain and size and weight of grain (Zečević *et al*., 2004). Improvements in the number of grains per spikelets related with increasing the number of grains spike^{-1}.

Conclusions

In this investigation the differences were determined among wheat genotypes according to values of length of spike and number of spikelets spike^{-1}. The highest values of length of spike expressed wheat cultivar Dejana (12.50cm) in the first experimental year while the least in wheat Šumadinka (8.91cm) in first experimental year, too. Breeding programs in the aim of improvement of spike traits of wheat need develop on the base of use wide germplasm resources and conduct in the different environments. Increasing of wheat grain yield is achievable through improving of all morphological, physiological traits of spike as well other organs of wheat.

PISTACHIO KERNEL CONTENT OF MINERAL ELEMENTS, PROTEIN AND TOTAL OIL UNDER RAIN-FED CULTIVATION IN SYRIA

Najwa M. ALHAJJAR*, Talat AMER, Bayan M. MUZHER

General Commission for Scientific Agriculture Research (GCSAR), Sweida, Syria
*Corresponding author: najwa81hj@yahoo.com

Abstract

This investigation was conducted at Sweida Agricultural Research Center and farmers' fields at altitude of 900–1,100 m above the sea to study the chemical content of 13 pistachio genotypes including kernel dry oil content, protein, micro and macro-elements. The results showed the precedence of Syrian genotypes concerning their content of dry oil (58.43%) in comparison with introduced genotypes (one Iranian and two Turkish genotypes). Protein content differed among all studied genotypes and it ranged between 15.18%–29.59% indicating high nutritional values of local genotypes in parallel with introduced ones. Potassium content was virtually low (0.54–0.82%) in all genotypes, whereas phosphorus concentration was widely variable in the samples (0.3–0.64%). Indeed, nitrogen content in pistachio kernels was by some means in an intermediate level (2.942–5.192%). Micro-elements concentration was extremely low in pistachio kernels concerning several elements (Cu, Zn and Mn). Cupper level ranged 3.45-8.3 ppm. The genotype Ash.6"Iranian genotype" was recognized by its high level of zinc element comparing with all other studied genotypes (30.05 ppm). The content of Fe was at high concentrations in all samples (81.6- 191.5 ppm). The recent outcomes indicated a negligible content of calcium which was assigned to the low soil content. Mg content was likewise low in all studied genotypes (0.0179- 0.0994%). Hence, it is fundamental to project fertilization programs accompanied with proper irrigation regulations appropriate to different soil granular structures particularly concerning the content of Ca as a vital structural element.

Keywords: *Pistachio, proteins, dry oil, mineral elements.*

Introduction

Pistachio tree is recognized by many economic and environmental features which makes it as an important species (Hadj-Ibrahim *et al.*, 1998). This tree occupies the fifth grade among the most important commercially crops all over the world (Surucu and Demirkiran, 2013). Many wild species of the genus *Pistacia* native to Syria as a natural habitat, some of which are used as rootstocks, whereas others serve as pollinators for different pistachio cultivars: *P. atlantica*, *P. terebinthus*, *P. palaestina*, *P. khinjuck*. Alternate bearing phenomena is considered as undesirable behavior in pistachio tree which affects the absorption process of the main minerals from the soil according to on-off-bearing years. Farther more, it effects the distribution of mineral elements among all plant parts. Previous studies indicated that the range of root growth decreased in the on-bearing years in comparison with off years, but there is not a clear correlation between the growth of the root system and the absorption of some elements from the soil, consequently nut's demands of mineral elements control the absorption and nutritional system (Rosecrane *et al*., 2002). Pistachio nuts content of different mineral elements was affected by fertilization applications, cultivation practices, soil structure, and environmental circumstances (Siahnouri *et al*., 2013). Ghaseminasab Parizi *et al*. (2016) mentioned that the chemical composition of pistachio relies on cultivar, rootstock, maturity at harvest, and moisture content. The type and concentration of nutrients taken up by plant affect its development and eventually the quality and quantity of the fruits (Aznarte-Mellado *et al*., 2016). In most cultivated areas in Syria, pistachio trees are exposed to the

severe deficiency symptoms of mineral elements which lead to a hole leaves disrobe on the brunches, and in harder conditions it causes leaves disrobe of all the tree leaving the panicles exposed to the direct sunshine and that directly effects the bearing in the recent and coming years. Nutrition requirements of the plant differ according to the growth stage, yet there are few previous studies which discussed the content of mineral elements at ripening stage which considers as an important indicator about the deficiency of applied fertilization in the soil.
This research aimed to determine the chemical content of different pistachio genotypes and cultivars including the ratio of oil content as estimated to the dry weight, protein content and macro and microelements.

Material and methods

This research was conducted in the General Commission for Scientific Agricultural Research and in pistachio fields at the green belt area (950–1150 m.a.s.).
Thirteen different genotypes and cultivars of pistachio were examined: Ash. 1, Ash. 2, Ash. 3, Ash. 4, Ash. 5, Ash. 6, Ajam. 1, Ajam. 2, Bat. 1, Bat. 2, Bead. 1, Turk. 1, and Turk. 2.
Pistachio fruits were collected at full ripening stage (August and September), then the kernels were dried and grinded into powder.
Nitrogen content in both of soil and the grinded kernels was estimated by Kjeldahel method. Phosphorus content was calculated using spectrophotometer according to Olsen (1954), and potassium content was estimated by flame-photometer.
Oil content/ dry weight was estimated according to Horwitz (2000).
Raw protein content was estimated according to the nitrogen percentage and nutritional protein indicator of plant material.
- the Nitrogen percentage ratio of the crushed kernels was calculated according to the following formula (Rain *et al*., 2003):

$$\%\mathrm{N} = \frac{(\mathrm{V} - \mathrm{B})\mathrm{x\ NxR\ 14.01x\ 100}}{\mathrm{Wt\ x\ 1000}}$$

R: The ratio between the total volume of the digested sample and the consumptive volume of distillation;
B: The calibrated volume of the digested instance (ml);
Wt: Dry plant weight (g);
V: The consumptive volume of sulfate acid solution (0.01 N);
N: Molarity of sulfate acid solution;
The extraction of microelements in the soil was taken place using DTPA method according to (Jones, 2001), and all of microelements in both of soil and grinded kernels were estimated by atomic absorption.
The experiment was designed as randomized complete blocks (3 replications of each genotype, and 3 samples of each replicate), and the mean values were compared at LSD 5% level using Gen Stat program (ver. 12).

Results and Discussion

The analysis of soil including physical, chemical and mechanical characters of the studied locations are elucidated in Table (1).

Table 1: Soil physically and mechanically properties in the areas of pistachio.

Region	pH	EC	CaCO3	Organic material	K	P	Mechanic analysis (%)		
							Sand	Clay	Celtic
Loc. 1	7.64	0.31	7.94	0.74	528.75	25.87	21.83	60.67	17.33
Loc. 2	6.72	0.13	1.2	0.87	195.00	34.15	19.67	49.67	30.33
Loc. 3	6.83	0.12	0.43	0.94	110.00	20.55	20.50	31.00	48.50

Total dry oil content

The content of dry oil of pistachio kernels ranged between 48.16% in Ash. 4 genotype to 58.43% in Ash. 2 genotype which means that the variance between Ashouri's genotypes was larger than the difference among the investigated cultivars (Figure-1). Mahmoodabadi *et al*. (2012) indicated to close oil percentages in the Iranian cultivars (54.93- 55.40%). The lowest content of total oil was in Turkish cultivars Turk. 2 (49.68%) of significant differences in parallel to all other studied genotypes except Beadi cultivar (50.78%). In comparison with Okay (2002) the total percentage of oil content of Turkish cultivars ranged from 55.85 to 59.73%.

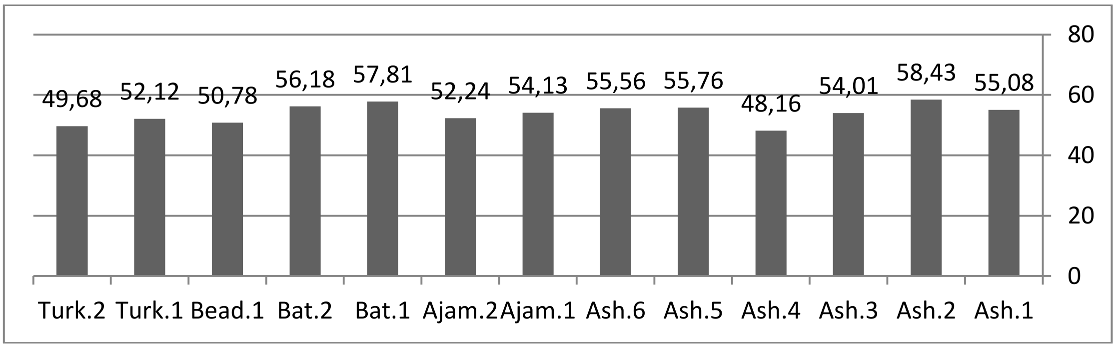

Figure-1: Dry oil content in all investigated genotypes

The content of protein in the genotype Ash. 2 was exceeded all other genotypes 29.5944 %. Two genotypes of Ashouri cultivar (Ash. 3 and Ash. 6) were adjacent to each other of their protein content (Figure-2). In parallel to previous studies Abdoshahi *et al*. (2011) mentioned that the protein content of different pistachio cultivars ranged between 16.265–20.703%. Similarly, Franz *et al*., (2002) pointed that the constituent of 100g kernel consisted of 15.0-21.2% protein.

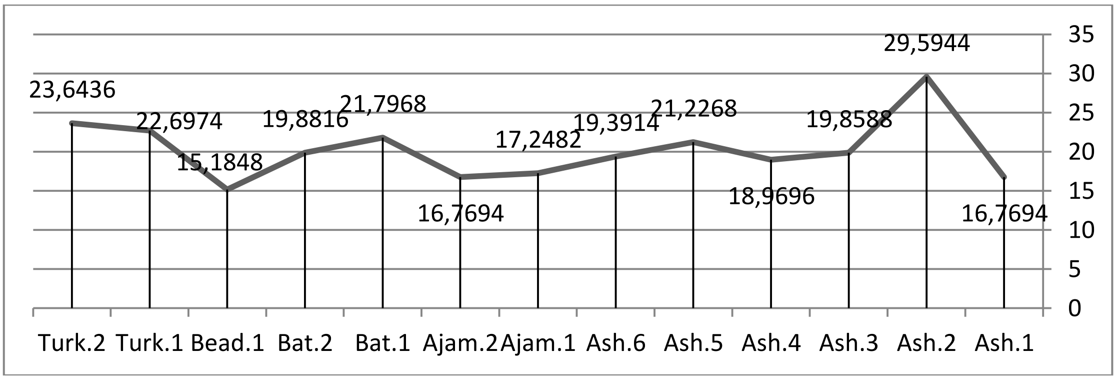

Figure. 2: Protein content in all investigated genotypes

The content of potassium was ranged between 0.54% in Ash. 3 genotype to 0.82% in Ash. 4 genotype. The contents of potassium in Beadi cultivar (Bead.1) and one Turkish genotype (Turk.2) were identical 0.73% (Figure 3). Tavallali and Rahemi (2007) indicated to high levels of potassium content in pistachio nuts in comparison with our results (1.28–2.2%).

The highest percentage of phosphorus showed significant difference in Ash. 4 genotype (0.64%) comparing with other studied genotypes except Ash. 6 genotype (Figure 3). Surucu and Demirkivan (2013) mentioned that the percentage of phosphorus content ranged between 0.08–0.13% in pistachio leaves. The standard content of P in pistachio kernel according to National Nutrients Database USDA (2018) is 0.490 %.

The highest nitrogen content was up to 5.19% in Ash. 2 genotype of significant differences with all examined genotypes except Turk. 2 genotype (4.15%), whereas the lowest percentage of nitrogen content was 2.66% in Bead.1 (Figure 3). Our results were in comparable percentages with Davarynejad *et al*. (2012) that the nitrogen content in *Pistcia atlantica* nuts ranged between 2.2– 4.5%.

	Tur k.2	Tur k.1	Bea d.1	Bat. 2	Bat. 1	Aja m.2	Aja m.1	Ash. 6	Ash. 5	Ash. 4	Ash. 3	Ash. 2	Ash. 1

% N آزوت	4,15	3,98	2,66	3,49	3,82	2,94	3,03	3,4	3,72	3,33	3,48	5,19	2,94

Figure 3: N P K contents of investigated genotypes

Two Ashouri genotypes (Ash.2 and Ash.5) significantly exceeded all other investigated genotypes of their content of copper (8 and 8.3 ppm). In parallel to previous studies, Mohammadabadi *et al*. (2012) referred to high amounts of copper in pistachio nuts ranged between 15.05–17.07 ppm. National Nutrients Database USDA (2018) referred to standard content of Cu in pistachio nuts 13 ppm.

Zink content analysis showed that the genotype Ash. 6 was significantly exceeded all other genotypes 30.05 ppm (Table.2). However, non-significant differences were detected between Batouri's genotypes Bat.1 and Bat. 2 (22.45 and 24.4 ppm, respectively). In comparison with previous studies our results were almost low, Siahnouri *et al*. (2013) obtained high zink contents in pistachio nuts (upward to 44.5 ppm).

The genotype Ash. 2 significantly exceeded all investigated genotypes of iron content (191.5 ppm), followed by Ash.3 genotype (170.45 ppm) which was also of significant differences at 5% level in comparison with the concentrations in all other investigated genotypes (Table- 2). Afshari *et al*. (2008) indicated to lower iron content in pistachio nuts ranged between 43–49 ppm.

Manganese content extensively differed among genotypes and ranged between 14.5ppm in two genotypes Bat. 2 and Bead.1 to 17.7 ppm in Turk.1 genotype, while Turk.2 genotype was too low of its content (6.55ppm). National Nutrients Database USDA (2018) referred to a standard content of Mn in pistachio nuts 12ppm.

The highest amount of Mg was in Bat. 2 genotype (0.0994%) of significant differences in comparison with all other studied genotypes, whereas the lowest content was 0.017% in Ash. 5 genotype (Table2). Evoli *et al*. (2015) indicated to an average content of pistachio nuts 0.121%. Same results were obtained by Bullo *et al*. (2015) whereat the Mg content in pistachio raw nuts was also 0.121 %.

All genotypes were of excessive subminiature ratios of calcium content due to the low calcium percentage in all locations. The highest ratio of calcium element was 0.3562% in Bat. 1 genotype of significant differences in comparison with all other studied genotypes, whereas the lowest ratio was extremely exiguous (0.0367%) in Turk.1 genotype (Table2). In comparison with Ling *et al*. (2016) the content of Ca in partially defatted unroasted flour was 0.154.01±0.00427%. Accordingly, serious determination of fertilization programs should be applied for pistachio trees in such poor soils including classical amounts of calcium carbonate or lime stones to supply the normal demands of calcium element as an essential structural element in all plant parts.

Table 2. The content of Cu, Zn, Fe, Mn, Mg and Ca in investigated genotypes

Genotype	Cu ppm	Zn ppm	Fe ppm	Mn ppm	Mg %	Ca %

Conclusion

All Syrian pistachio genotypes were rich of their content of total dry oil, in addition to high levels of protein content especially the genotype Ash.2. the basic rocky material and climatic factors "basically rainfall rates" play an important role of determining the nature of pedological activities in the region, also it regulates the distribution of calcium carbonate and the variation of soil content of different elements and determining the quality and the quantity of all minerals and their reflects on the viability usage to be well absorbed. From nutritional point of view, plant analysis is built on the base that the concentration of any nutritional element inside the plant is a result of the total interaction of all factors that work on together to be achieved. Consequently, the lack of rainfall ratios besides to non-applying of the complimentary irrigation for fruit trees widely affected the convenience of macro and micro mineral elements to be easily absorbed especially concerning potassium availability. This investigation revealed that it is of paramount important to apply fertilization programs which is congruous with the chemical and the granulated structure of different soil types in expanding areas of pistachio cultivation. Moreover, the recent results confirm the importance of adding calcium carbonate (soil fertilization or foliar spray) as calcium supplementary for pistachio trees due to its indispensable role as a structural element in the plant.

GENOTYPE ENVIRONMENT (GXE) INTERACTION AND ASSESSMENT OF BREAD WHEAT (*Triticum aestivum* L.) GENOTYPES UNDER RAINFED CONDITION

İrfan ÖZTÜRK*

Trakya Agricultural Research Institute, Edirne, Turkey
*Corresponding author: ozturkirfan62@yahoo.com

Abstract

Due to the various environment conditions yield and quality in bread wheat varies and GGE biplot analysis provides an easy and comprehensive solution to genotype by environment and it allows effective assessment of the genotypes and the target environments. In this experiment a total of 17 bread wheat genotypes were evaluated during 2008-2009 cycle at 4 environments under rainfed condition. The experiment was conducted in randomized completely block design with four replications. Grain yield, 1000-kernel weight, test weight, protein ratio, gluten value, gluten index, hardness and sedimentation were investigated. Mean grain yield across locations varied from 4742 kg ha^{-1} to 6601 kg ha^{-1}. Tekirdağ was the highest yielding location. Graphical result from PCI showed that the first principal component PC1, explained 42.85% of square interaction while the second principal component, PC2 explained 22.45% of square interaction. The result of PCA revealed that 2 principal components (PC1, PC2) contributed 65.30% of the total variability. The highest test weight and 1000-kernel weight in Tekirdağ location, protein ratio and gluten value in Edirne location were obtained. Cultivar Aldane was the best as it was more stable than the other genotypes based on sedimentation value, hardness, protein ratio and gluten value. The results of the study revealed that there was considerable variation among locations that could be used in selection of bread wheat genotypes for the development of cultivars. Cultivar Aldane was very stable for quality parameters and could be used in a breeding program to obtain quality characters of the genotypes.

Keywords: *Bread wheat, environment, quality parameters, GxE interaction.*

Introduction

Bread wheat (*Triticum aestivum* L.) is the most important and widely producing cereal crop throughout the Trakya region of Turkey. Although the amount of the rainfall (589.1 mm) during growing season is enough for wheat production, the distribution of this rainfall is not regular. This fluctuation of rainfall causes reducing grain yield and quality (Öztürk and Korkut, 2018a). Because of the various environment conditions yield and quality in wheat varies and GGE biplot analysis provides an easy and comprehensive solution to genotype by environment data analysis and it not only allows effective evaluation of the genotypes but also allows a comprehensive understanding of the target environment and the test environments (Öztürk and Korkut 2018b). Superior genotypes must be evaluated on the basis of multi-environment trials (MET) and multiple traits to ensure that the selected genotypes have acceptable performance in variable environments within the target region. For this reason, MET are conducted throughout the world for major crops every year in which multiple traits and characteristics are usually recorded (Yan and Rajcan, 2002). To develop varieties for different environments, very essential for breeders to evaluate their genotypes based on many years and several locations. Environmental variations are important in determining performance of elite materials. Genotype ranks consistently across different tested location has less response for highly unstable environment (Solomon et. al., 2018). Most breeding programs face complex mega-environments with unpredictable GEI and genotype evaluation based on mean performance and stability has been a perennial problem and challenge (Yan and Kang, 2003). Performance trials have to be conducted in multiple environments because of the presence of GE. Variety trials provide essential information for selecting and recommending crop cultivars. However, variety trial data are rarely utilized to their full capacity. Although data may be collected for many traits, analysis may be limited to a single trait (usually yield) and information on other traits is often left unexplored (Yan and Tinker, 2006). The objective of the study was to evaluate the performance of the advance genotypes and to investigate their yield stability and genotype-by-environment interactions under rainfed environment conditions.

Material and Methods

The experiment was conducted to assess genotype x environment interaction and diversity by biplot analysis for yield, and quality parameters. In this experiment a total of 17 bread wheat genotypes were evaluated under rainfed condition, during 2008-2009 cycle at four locations of Trakya Region, Turkey. Each plot was 6 meter long and had 6 rows, spaced 0.17 meters apart. A seed rate of 500 seeds m^2 was used. The experiment was conducted in randomized completely blocks design (RCBD) with four replications. Grain yield and quality parameters were investigated. In the study, 1000-kernel weights and test weight were determined by Blakeney et al., 2009, protein ratio, grain hardness, gluten value, gluten index, and sedimentation by Anonymous, 2002; Köksel et al., 2000; Perten, 1990, and Pena, 2008. The quality analysis of Zeleny sedimentation test and wet gluten content were determined according to ICC standard methods No. 116/1 and 106/2, respectively (Anonymous, 1972; Anonymous, 1984). In order to visually display relations of tested parameters and genotypes multivariate biplot analysis (genotype by trait biplot), described by Yan and Rajcan, (2002), Yan and Tinker (2006) and Yan and Kang (2003) was used. A positive correlation between two traits is represented by an acute angle between them, while obtuse angle represents a negative correlation. Correlations between all characteristics were calculated. Data were analysed statistically for analysis of variance the method described by Gomez and Gomez (1984). The significance of differences among means was compared by using Least Significant Difference (L.S.D. at a %5) test (Kalaycı, 2005).

Results and Discussion

Trakya region has various environment conditions. A genotype having stabile grain yield across the environment condition is very important in wheat. Genotypes (G) x Environment (E) interaction is a mainly issue for plant breeders in improving high yield across variable environments. Seventeen advanced genotypes were tested at four locations to investigate yield and quality components based on Principal Component Analysis (PCA). The analysis variance for yield and quality components was performed and given in Table 1, and 2. The results of variance analyses showed that there were significant differences ($P<0.01$) among genotypes based on locations. Mean grain yield across four locations ranged from the highest 6601 kg ha^{-1} to the smallest 4742 kg ha^{-1}, and mean grain yield was 5903 kg ha^{-1}. The highest grain yield performed by lines G12 and followed by G19 and G11 (Table 2). Because of the favorable environment condition Tekirdağ was the highest yielding location. The mean grain yield for tested genotypes was lower relative in Lüleburgaz location.

Table 1. Combined analysis of variance for wheat genotypes across four environments.

Source of variation	DF	SS	MS	F value
Environment	3	520031.86	173.34	51.87**
Genotype	16	127343.90	7.96	2.38*
Error	48	160406.59	3341.80	
Total	67	807782.35		

Note: *, ** Significance at respectively 5%, and 1% level probability.

There were significant differences among genotypes based on TKW and TW. 1000-kernel weights ranged from 28.5 g to 44.8 g among genotypes and mean was 36.9 g. Line G2 had the highest TKW and followed by Pehlivan, Aldane and Bezostaya cultivars. TW ranged in genotypes from 75.4 kg to 82.4 kg (Bezostaya) and mean value of the test weight was 78.9 kg.

Grain protein content is among the key determinants affecting of both end use and market value in wheat. Protein quality and quantity is the most important components of wheat grains governing end-use quality (Pena, 2008). Table 2 shows mean and range of variations for protein ratio in all genotypes were evaluated and found protein ratio varied from 10.4% to 12.74% in the genotypes. The mean protein content was 11.3% and the highest protein ratio was determined in Aldane and Bezostaya. Gluten value of genotypes ranged from 21.8% to 35.0% and mean was 29.4%, the highest gluten value was determined in cultivar Aldane. In addition, there was significant difference for sedimentation and cultivar Aldane had highest sedimentation value.

Figure 1a showed that to rank the genotypes based on performance in any environment, and to rank environments on the relative performance of any genotype. To develop varieties for different environments, very essential for breeders to evaluate their genotypes based on many years and several locations. Based on grain yield graphical result from PCI showed that the first principal component PC1, explained 47.09% of interaction some of square while the second principal component, PC2 explained 35.52% of some of square interaction (Figure 1a). The result of PCA revealed that the 2 principal components (PC1, PC2) contributed 82.61% of the total variability.

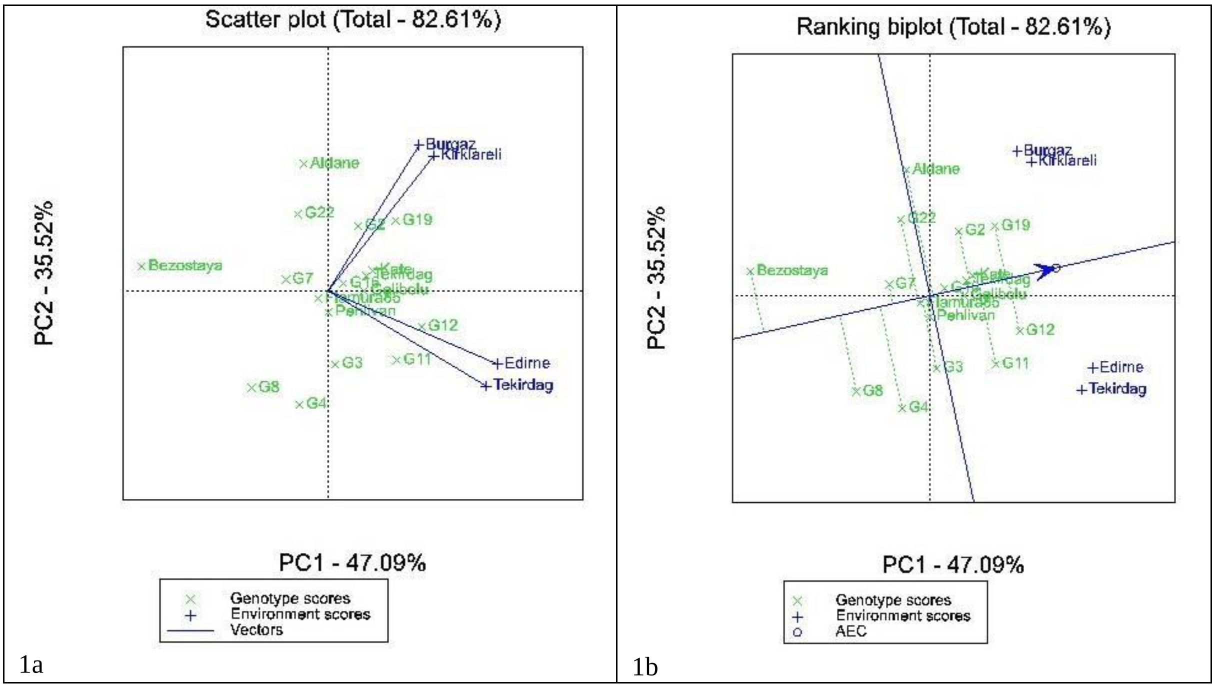

Figure 1. The GGE biplot showing the performance of each genotype in each environment (1a). Ranking genotypes based on performance across four environments (1b)

To rank the genotypes based on their performance across environment, a line is drawn that passes through the biplot origin and the environment. This line is called the axis for this environment, and along it is the ranking of the genotypes. Figure 1b ranks the genotypes based on performance across environments. Genotypes Bezostaya, G8, G4, and G7 had lower than average yield, cultivars Pehlivan, and Flamura85 had near average yield, and all others had higher than average yields. The highest yielder across environments was G12 line, and the lowest yielder cultivar Bezostaya.
A genotype by trait biplot can help understand the relationships among traits and can help identify traits that are positively or negatively associated, traits that are redundantly measured, and traits that can be used in indirect selection for another trait (Yan and Tinker, 2006; Yan and Kang 2003). The biplot in Figure 2a presents data of 17 genotypes determined for seven parameters. Across the 17 tested genotypes, sedimentation with protein ratio, protein ratio with gluten value, and test weight with 1000-kernel weight was positively associated. Gluten index with test weight and 1000-kernel weight was negatively correlated (Figure 2a).
The vertices of the polygon were the genotype markers located farthest away from the biplot origin in various directions, such that all genotype markers were contained within the resulting polygon. The vertex genotype in each sector represented the highest quality genotype in the environment that fell within that particular sector. The polygon view of the GGE-biplot analysis helps one detect cross-over and non-crossover genotype-by-environment interaction and possible mega environments in multi-location yield trials (Yan et al., 2007). Based on the GGE analysis the first two principal components explained about 65.30% of the total interaction variation. Aldane was the best genotype based on gluten, protein ratio, sedimentation value, and hardness. According to Figure 2b, the vertex genotypes were Aldane, G7, G16, Pehlivan, and Bezostaya. These genotypes were the best or the poorest genotypes based on quality parameters in some or all of the test environments since they had the longest distance from the origin of the biplot (Figure 2b).

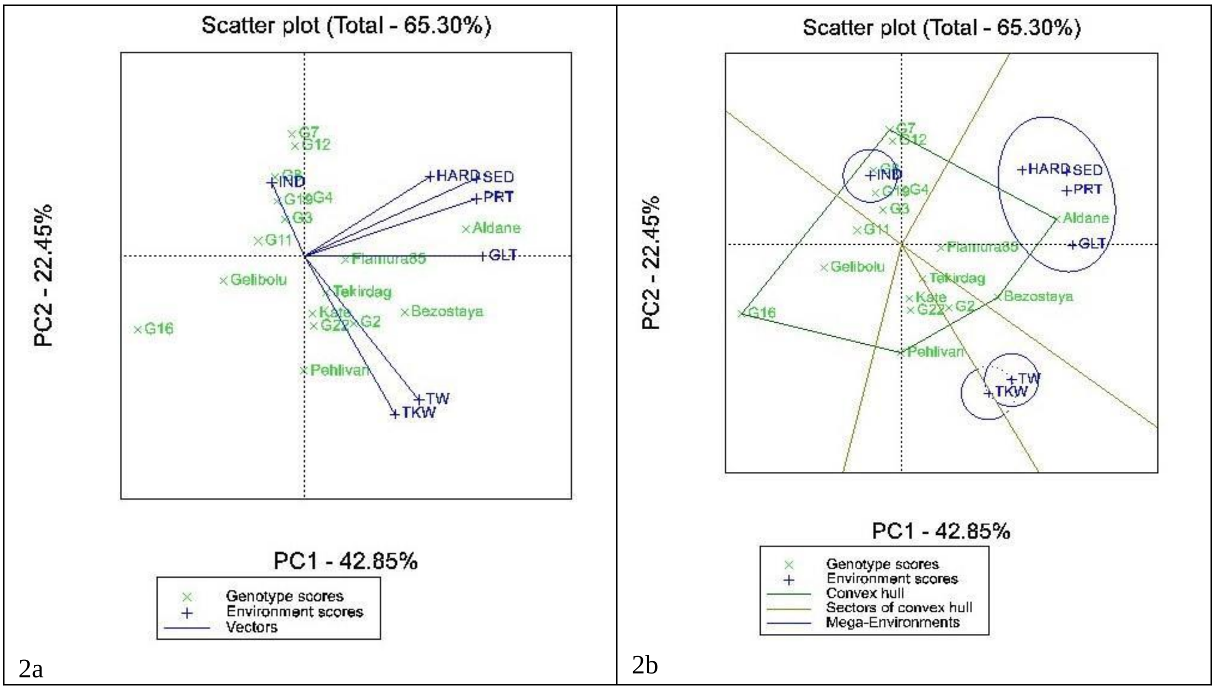

Figure 2. The GGE biplot to show which genotypes performed bets by trait biplot representing 17 winter wheat genotypes measured for 11 parameters (2a). Polygon view of the GGE biplot based on environment and investigated parameters and genotypes (2b)

Correlation coefficients based on parameters were determined by Pearson's correlation analysis (Table 3). It was found highly significant positive correlation between test weight and 1000-kernel weight (r=0.722**). There was a negative slightly relation with grain yield and TKW, TW, protein ratio and gluten value. In the study, no correlation was found between grain yield with gluten index and hardness. Protein ratio was highly significant positively correlated with gluten value (r=0.669**), and sedimentation (r=0.843**). The positive correlation between sedimentation with gluten value (r=0.566*) and hardness (r=0.514*) were significant. Gluten value was negatively associated with gluten index (r=-0.548*).

Table 3. Coefficients of correlation between grain yield and tested parameters.

Traits	GY	TKW	TW	PRT	GLT	IND	HARD
TKW	-0.249						
TW	-0.155	0.722**					
PRT	-0.459	0.200	0.255

Conclusions

Trakya region has various environment condition so genotype x environment interaction is a mainly issue in improving high yielding genotypes across variable environments. The results of analyses indicated that wheat grain yield and other quality parameters were highly affected by environmental effect followed by the magnitude of GEI. GGE biplot analysis permitted estimation of interaction effect of a genotype in each environment. To develop varieties for different environments, very essential for breeders to evaluate genotypes based on many years and several locations. The highest yielder genotype was G12, and the lowest yielder

Bezostaya. According to results, sedimentation with protein ratio, protein ratio with gluten value, TW and TKW was positively associated. Gluten index with TW and TKW was negatively correlated. Cultivar Aldane was the best genotype as it was more stable than the other genotypes based on sedimentation value, hardness, protein ratio and gluten value. The results of the study revealed that there was considerable variation among locations that could be used in selection of bread wheat genotypes for the development of cultivars. Cultivar Aldane was very stable for quality parameters and could be used in a breeding program to obtain quality characters of the genotypes.

Abstract

The Study was carried out in the climate room where normal atmosphere was provided in the Plant Physiology Laboratory. The main purpose of the normal atmosphere in the experiment is ensure that the effects of salt stress occur as normal circumstance. Thus, the stress level to which the plants are exposed in the outdoor environment will be measured with the least margin of error and the results obtained as a result of the application of the results obtained will show greater consistency with the study results. Morphological effects of calcium (Ca) applied in different doses to pepper plant under salt stress were investigated in this study. The study was carried out under controlled conditions in 16/8 hour light / dark photoperiod, 25^{o}C and 70% humid climate room. Root weight, stem weight, leaf weight, number of leaves, plant height and total plant weight were measured. In addition, salt resistance scales of plants were determined. In the growth parameters, the 1st (150 ppm) and 2nd (200 ppm) doses of Ca applications showed the highest decrease compared to the control. As the dose increased, the values approached the control but started to decrease again at the 5th (350 ppm) dose of calcium. In the scale evaluation, which was a morphological observation, the most damaged plants were observed at the 1st (150 ppm), 2nd (200 ppm), 3rd (250 ppm) and 5th (350 ppm) doses of calcium respectively, the least damage was the 4th (300 ppm) dose of calcium.

Keywords: *Pepper (Capsicum annum), Calcium, NaCl, Salt stress*

Introduction

Salinity problem arises naturally in arid and semi-arid areas where rainfall is low and evaporation is high. The main causes of soil salinity are the accumulation of soluble salts in soil layers and ground water, or transport of salts to the soil surface due to the rise of existing ground water, poor water quality in irrigation water, the presence of excess soluble salts in irrigation waters, and insufficient drainage in the root zone (Epstein et al., 1980; Stushnoff and Quamme, 1983).

Munns and Termaat (1986), Snap and Shennan (1992), Yasar et al. (2007a), Karanlık (2001) reported that the development of plants under salt stress in their studies adversely affected.

Salt stress is affected by growth and development, photosynthesis, protein synthesis, energy and lipid metabolism. In essence, the first response to salt stress manifests itself as a decrease in the growth of leaf surface area (Üzal, 2009).

Calcium (Ca + 2), an important macro nutrient, acts as the central regulator of plant growth and development. There is competition and exchange between calcium (Ca), potassium (K) and sodium (Na) in the regions of cell membranes. Ca in the form of pectins in the cell wall, cell walls and tissues undertook the basic task of strengthening (Kacar and Katkat, 2006). In plants under salt stress, it has been reported that potassium is a cofactor for many enzymes and may reduce the harmful effect of NaCl by external application of Ca (Hasegawa et al., 2000). High salt concentrations reduce the calcium uptake and transport of the plant and cause calcium deficiency (Cramer et al., 1986; Huang and Redmann, 1995). Calcium is an element that has a positive effect on salt stress. High doses of exogenous calcium reduce the permeability of the cell membrane to Na + ion. In this way, the accumulation of sodium in the cell and plant is prevented by passive uptake (Hoffman et al., 1989; Whittington and Smith,

1992). The common ideas of researchers trying to explain the role of calcium in the protection of salt stress through various mechanisms; calcium to strengthen the cell membrane and ion selectivity in the uptake and transport. Ca2 + ion, cross-linking the cell membrane with negatively charged basic groups and thus preserving the structural integrity of the cell membrane is also made in the description (Cramer et al., 1986; Lauchli, 1990). Rengel (1992), the calcium membrane of the cell membrane by controlling the permeability of the cell, the calcium in the cell prevents the release of the proposed.
In this study, morphological aspects of calcium (Ca) effects in pepper plant under salt stress were investigated. In accordance with this purpose, the effects of the application on the salt stress were determined by applying calcium compounds to pepper plant exposed to salt stress.

Material and Methods

This research was carried out in the climatic room of Van Yüzüncü Yıl University, Faculty of Agriculture, Department of Horticulture, Physiology Laboratory. Demre sharp pepper variety was used in the study.
The experiment was carried out in a split air-conditioned climate room with normal atmosphere and water culture. The main objective of the experiment is to ensure that the effects of salt stress occur as normal under normal conditions. In this way, the stress level to which the plants are exposed in the outdoor environment will be measured with the least margin of error and the results obtained as a result of the application of the results obtained will show greater consistency with the study results.
In the study, first of all, pepper seeds were sown in 40x25x5 cm plastic germination cups filled with pumice sieved and then watered with fountain water. This irrigation method has been used since it is not possible to use normal irrigation water or water in the environment where pepper is grown for internal irrigation. The bottom surface of the germination vessels has 9 holes with a diameter of 0.5 cm and the irrigation water is drained by the plants. After the pumice was thoroughly wetted and the irrigation water was drained, the germination pots were placed in the climate room with 25±2^{o}C temperature 70% humidity, covered with A4 paper and the containers were regularly checked and the pumice was continued to be irrigated with tap water. For the better development of the seedlings, the cotyledon leaves coming horizontally and the first true leaves (3-4) began to be seen, irrigation was started with Hoagland nutrient solution. (Hoagland and Arnon, 1938).

Table 1. Contents of the nutrient solution used (ppm).

Elements	App. 1 Control (ppm)	App. 2 Ca1+ NaCl (ppm)	App. 3 Ca2+ NaCl (ppm)	App. 4 Ca3+NaCl (ppm)	App. 5 Ca4+ NaCl (ppm)	App. 6 Ca5 + NaCl (ppm)
Nitrogen (N)	186	186	186	186	186	186
Phosphorus (P)	31	31	31	31	31	31
Potassium (K)	167	167	167	167	167	167
Magnesium (Mg)	49,28	49,28	49,28	49,28	49,28	49,28
Calcium (Ca)	**200**	**150**	**200**	**250**	**300**	**350**
Sulfur (S)	66	66	66	66	66	66
Iron (Fe)	3.3	3.3	3.3	3.3	3.3	3.3
Manganese (Mn)	0.031	0.031	0.031	0.031	0.031	0.031
Boron (B)	0.205	0.205	0.205	0.205	0.205	0.205
Copper(Cu)	0.015	0.015	0.015	0.015	0.015	0.015
Zinc (Zn)	0.023	0.023	0.023	0.023	0.023	0.023

The nutrient solution used was prepared according to (Hoagland and Arnon, 1938).
Seedlings, which also formed the 2nd true leaves in the pumice environment, were taken to water culture in 25x25x18 cm size plastic cuvettes filled with Hoagland nutrient solution.

Specially prepared and perforated for each seedling in plastic trays pepper seedlings were placed by wrapping with small sponge pieces. The trays were placed on the trays with the plant roots in the nutrient solution.
The aeration was done by immersing the thin plastic hoses connected to the aquarium pump into the nutrient solution. Seedlings were grown in water culture for two weeks and salt application was started on seedlings having 4-5 real leaves. The experiment was designed according to the exact chance design with three replications and 15 replicates per repetition. NaCl was added to the nutrient solution (1/2 Hoagland) with a salt concentration of 75 mM. During the regeneration of the repeating solutions every week, the same concentration of salt applications was maintained. Pepper seedlings with salt (NaCl) 5 different doses (150 ppm, 200 ppm, 250 ppm, 300 ppm, 350 ppm) Ca was added. As a result, 6 different applications were performed as control, salt + Ca (150 ppm, 200 ppm, 250 ppm, 300 ppm, 350 ppm). The ppm values of all nutrients in the nutrient solution are given in Table 1.
Sampling for measurements and analyzes was performed twice before the salt application (day 0) and on the 20th day of salt application. In these samples, some basic growth parameters (root weight (g), stem weight (g), leaf weight (g), total plant weight (g), plant height (cm), number of leaves (number), salt resistance scale were determined.
Determination of root weight, stem weight, leaf weight and total plant weight were weighed in 3 replicates with 1 / 10,000 precision digital balance. Plant height was measured in cm with ruler. The number of leaves is indicated in pieces.
A scale was established to determine the degree of damage that occurs morphologically in plants. For this purpose, plants were scored between 1-5 according to the degree of damage. Salt stress test pepper plants according to the following symptoms from 1 to 5 points were given (Üzal, 2009).
1: Plants are not affected by salt stress at all (control plants)
2: Local yellowing and curling of leaves
3: Yellowing of leaves and 25% necrotic spotting
4: 50-75% necrotic stain on leaves and deaths
5: Severe necrosis of 75-100% in leaves and complete death of plant
According to the experiment design randomized parcels with 3 replications were established as 15 plants per repetition. In order to evaluate the data obtained as a result of the study, Statgraphics was subjected to variance analysis in statistical analysis package program. Duncan multiple comparison test ($P < 0.05$).

Results and discussion

Table 2.Some growth and development parameters in the samples taken after the applications.

App..	Root weight (g)	Stem weight (g)	Leaf weight (g)	Total plant weight (g)	Plant height (cm)	number of leaves. (piece)
Control	3,804 A	3,497 A	10,362 A	17,664 A	15,4 A	14,0 A
Ca 1 +Salt	1,251 D	1,264 E	4,581 D	7,096 E	9,1 D	9,8 C
Ca 2 + Salt	1,046 D	2,087 D	5,269 D	8,402 D	14,9 AB	12,0 B
Ca 3+ Salt	2,454 C	3,008 B	6,743 C	12,206 C	14,1 B	11,4 B
Ca 4+ Salt	2,865 B	3,432 A	7,819 B	14,117 B	11,8 C	14,0 A
Ca 5+ Salt	2,724 B	2,703 C	6,653 C	12,081 C	12,6 C	12,4 B
P Value	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000

The difference between the means taking the same capital letter in the same column is insignificant according to $P \leq 0.05$.

The root weight (g), stem weight (g), leaf weight (g), total plant weight (g), plant height (cm) and number of leaves (pieces) of the Demre pepper plants subjected to salt stress at the end of the 20th day were measured and obtained values were given in Table 2.

As a result of 20-day salt stress, statistically significant decreases were observed in root weights (g) of all other salt treatments compared to the control group. The highest values of root weight among salt treated plants were measured in control (3.804) group, while the closest values to the control group were measured in Ca 4 + Salt (2.865) and Ca 5 + Salt (2.724) applications. The lowest values were measured in Ca 2 + Salt (1.046) and Ca 1 + Salt (1.251) applications in the same group. The highest values of body weight were measured in the control group (3,497), while the closest value to the control group was measured using Ca 4 + Salt (3,432) in the same group. The lowest value was determined in Ca 1 + Salt (1.264) application. It was seen that there were differences between salt applications in terms of body weights. The highest value in terms of leaf weight was measured in the control group (10.362 g), while the closest value to the control group was measured in Ca 4 + Salt (7.819) application. The lowest values of the same statistical group in the Ca 1 + Salt (4.581) and Ca 2+ Salt (5.269) were measured in the applications. There were differences between the salt applications in terms of leaf weight. The highest value in terms of total plant weight was measured in the control group (17.664), while the closest value to the control group was measured in Ca 4 + Salt (14.117) application. The lowest value was determined in Ca 1 + Salt (7,096) application. Ca 3+ Salt and Ca 5 + Salt were in the same group. There were generally differences between salt applications in terms of plant weight. The highest value in terms of plant height was measured in the control (15.4) group, while the closest value to the control group was measured in Ca 2 + Salt (14.9) application. The lowest value was measured in Ca 1 + Salt (9.1) application. Ca 4+ Salt and Ca 5+ Salt were in the same statistical group. There were differences between salt applications in terms of plant height. When the number of leaves was examined, the highest value was obtained from the plants in the control group (14.0), while the lowest value was measured in Ca1 + Salt (9.8) application. It was determined that the application having the same number of leaves as control plants was Ca 4+ Salt (14.0), Ca 2+ Salt, Ca 3+ Salt and Ca 5+ Salt were included in the statistical group. It was noteworthy that there were generally statistical differences ($P \leq 0.05$) between salt applications in terms of all plant growth parameters.

Scale values according to leaf symptoms

Seedlings were given a score of 1 to 5 as indicated in the scale-forming method used to demonstrate the degree of damage that occurs morphologically in plants (Table 3).

Table 3. Salt resistance scale according to the symptoms in the leaves (score)

Application	Scale Values
Control	1
Ca 1+ NaCl	4,5
Ca 2+ NaCl	3
Ca 3+ NaCl	2,5
Ca 4+ NaCl	1,5
Ca 5+ NaCl	2

High scoring values are the most affected by salt.

When the scale values are examined, it is seen that the least affected plants are in Ca 4+ NaCl application. This is followed by Ca 5+ NaCl, Ca 3+ NaCl and Ca 2+ NaCl applications respectively. The most morphologically damaged application is Ca 1 + NaCl application.

75 mM NaCl salt treated pepper plants were given nutrient solution containing Ca element in different doses. On the 20th day of stress application, growth parameters such as root, stem and leaf weight, plant height, number of leaves and total plant weight of pepper plants showed the highest decrease in the 1st and 2nd doses of Ca applications compared to the control. However, as the dose increased, the values approached the control but started to decrease

again at the 5th dose of calcium. Yaşar (2003) and Yaşar et al. (2007a, 2007b, 2013, 2016) stated similar results in plant growth parameters in their salinity stress studies with different species and stated that total plant weights were an important parameter in determining the response to salt stress. It reduces calcium uptake and transport in plants with high concentrations of salt, thus causing calcium deficiency and ion imbalance in the plant (Cramer et al., 1986; Huang and Redmann, 1995). Due to calcium is an element having a positive effect on salt stress, high dose exogenous calcium decreases the permeability of the cell membrane against Na + ion, prevents the accumulation of sodium in the cell and in the plant by passive uptake and provides ion balance (Hoffman et al., 1989; Whittington and Smith, 1992), therefore, that calcium protects plants against salt stress and is therefore less susceptible to salt stress. The results of our study showed that due to the deterioration in the ion balance of the plants in saline environments, growth and development of plants decreased due to the slowing of the respiration of the plants. The deterioration of the respiratory system affects the entire metabolic system, especially slowing down in the photosynthesis system of the plant, and consequently a decrease in the formation of assimilation occurs and decrease in plant growth and development (Çakırlar and Topçuoğlu, 1985; Yasar 2003; Yasar, 2007).
In our study, in order to provide control of all growth we examined in the scale evaluation, which is a morphological observation, by applying salt in our study, the most damaged plants were observed at the 1st dose of calcium according to the degree of damage. It was seen in 2nd, 3rd and 5th doses respectively. The least damage was the 4th dose. Aktaş (2002) in pepper, Yaşar (2003) in eggplant, Öztaş (2018) benefited from the scale they created in their studies in pepper. Both of these researchers indicated that the scale value had a very high correlative relationship with the total plant weights and especially the ratios of Ca / Na and K / Na ions.

Conclusions

Appropriate doses of calcium can protect the plant from the toxic effect of salt by maintaining ion balance in the cell, even under salt stress. As a result, Ca kept the plant at a level that could control the plant by limiting plant growth in order to control metabolic activity. In terms of both growth parameters of plants and scale values indicating the degree of damage of salt in the plant; It was concluded that the most appropriate Ca dose to be applied to the plants under salt stress conditions is the 4th dose (250 ppm).

Abstract

This investigation was conducted at Pome and Grapevine Division- Horticulture administration- GCSAR in Sweida governorate under rainfed conditions during 2014-2015 to study the influence of two apple rootstocks (*Malus domestica* Borkh and MM106 grafted by Starkrimson cultivar) on K, Ca and Mg mineral concentrations in leaves and fruits during the growth season. The results showed that *M. domestica* significantly revealed higher K concentration than MM106 rootstock of leaves and fruits in general, whereas MM106 revealed higher concentration of Ca in leaves and fruits. Mg concentration revealed discrepant rate among two rootstocks during the growth season. The highest leaves and fruits K concentration was in August in *M. domestica* (1.57%),while in MM106 rootstock (1.30%)it was in June. On the other hand, the highest leaves content of Ca was in October in two rootstocks which was below the sufficient range. Two rootstocks exposed the same rate of fruit Mg and Ca mineral concentrations which were decreased through the growth season. The K/Ca and K+Mg/Ca ratios in leaves and fruits "as an indicator for biter pit physiological disorder" were calculated for two rootstocks, which varied depending on growth stage analysis. Consequently, the results led to establishing an efficient strategy for fertilization management of apple orchards depending on the fertilizers requirements and nutrient accumulation track during growth season.

Key words: *apple, rootstock, Starkrimson, mineral concentrations*.

Introduction

Rootstocks are the main factor affecting tree growth and show different responses to nutrient (Kucukyumuk and Erdal, 2011), and effect on the concentration of leaf scion minerals of apple trees (Tagliavini, 1992). However, the ability of mineral uptake of rootstocks and cultivars should be considered for plant growth, yield and to get better fruit quality (Campeano *et al*., 2009). The different nutrient uptake capacity of apple rootstocks can be illuminated as a genetic effect on the nutrient concentration of trees (Jimenez *et al*., 2007, Kucukyumuk and Erdal, 2009). Somehow, the effects of rootstocks are not stable from site to site (Yahia *et al*., 2004) and depend on the structure and root growth which influence mineral uptake (Jimenez *et al*., 2004; Jobir *et al*., 2017). The analysis of growth parts in apple trees was taken into account to determine the nutrient requirements especially in fruits to provide sufficient information about fruit quality depending on previous known about adequate and critical nutrient content, then build the fertilization strategies to prevent mineral deficiencies and physiological disorders in fruits (Ernani *et al.*, 2002; Nachtigall and Dechen, 2006).The nutrient concentration rate during growth season is an important indicator of nutrient demand in each development stage in apple trees, many studies were achieved to evaluate the leaves and fruit nutrient seasonality accumulation of apple cultivars ((Nurzynski *et al*., 1990; Cheng and Raba, 2009; Jivan and Sala, 2014) .

In Syria, the nutrient concentration of vegetative growth in apple trees was evaluated in few sites and included the two main cultivars Golden Delicious and Starking Delicious (Muzher *et al*., 2016; Wassouf *et al*. 2017), furthermore the distribution of new economic apple cultivars and rootstocks and the application of new strategies of foliar fertilization on apple trees require enough information about the seasonality accumulation of nutrients especially where apple production is concentrated. Therefore, the current investigation aimed to study the influence of the two apple rootstocks *M. domestica* and MM106 which grafted by Starkrimson cultivar on seasonality accumulations of K, Ca and Mg mineral nutrients in leaves and fruits in Sweida governorate at the south of Syria which considered as the main important state of apple production.

Material and Methods

The current research was conducted at Pome and Grapevine Division- GCSAR which located 1,525 m altitude in Sweida governorate at the south of Syria under rainfed conditions. The soil is clay with low content of organic material (1.5%) and nitrogen, high concentration of phosphorous 60 $mg.kg^{-1}$ (Olsen et al., 1954), and moderate content of potassium (245 $mg.\ kg^{-1}$), pH 6.5-6.8.The annually rainfall 525 mm.

Plant material

Malus domestica Borkh is a seedling rootstock considered as vigorous rootstock with deep roots, tolerant to frost and drought, suitable for different soil types (Colett, 2011).

MM106 is a semi- vigorous vegetative rootstock, derived from the hybridization between M1 rootstock and Northern spy cultivar which has the resistance to woolly apple aphid, MM106 considered as moderate rootstock, high productive capacity, resistant to woolly apple aphid, moderate tolerant to spring frost and drought, susceptible to ring root, and compatible with most commercial apple cultivars (Preston, 1966).

Starkrimson cultivar is a bud mutation derived from Starking Delicious cultivar found in America in 1870, with moderate to vigorous growth, fruits are conical with dark red color and big size, successful cultivation in areas exceeded 1300m altitude in the studied area(Muzher and AlHalabi, 2012).

Methods

Leaves and fruit nutritional content: Potassium (K), calcium (Ca) and magnesium (Mg) mineral contents were studied in the leaves and fruits of 15 years old trees of Starkrimson cultivar which grafted on *M. domestica* and MM106 rootstocks during the growth season at 50 days alternate periods, under rainfed conditions. K was estimated at humid digestion method of plant material, and then K content measurement using flame photometer apparatus (Benton, 2001). Calcium and magnesium were estimated after digesting plant samples with concentrated perchloric acid nitrogen by 9:4 then determined by atomic absorption (Tandon, 2005).

- leaves were sampled from each replicate (30 x number of replication) in three alternate periods (June, August and October).Samples were washed two times with distilled water to remove surface residues, then dried enough at 68° c and grinded into fine powder for nutrient analysis.
- Fruits from each tree (20 fruits) in each replicate were collected in three alternate periods (June, August and October). Samples were washed in fountain water followed by distilled water to remove surface residues, then prepared as very thin slices and dried on 68° c until weight stability and powdery grinded for nutrient analysis.

Analysis of variance was performed using two way ANOVA to compare means of obtained data at the level of significance (LSD at $P< 0.05$). in completely randomized block design having four replicates was used.

Results and discussion

The results showed that K concentration was significantly varied in the two studied rootstocks during growth season. As seen in Table 1, the seedling rootstock *M. domestica* had significantly higher K concentration in comparison with the semi vigor rootstock MM106 at the three alternate growth periods except the first period. The highest leaf K concentration of *M. domestica* was in August (1.57%) which was at normal concentration according to Neilsen and Neilsen, (2003), whereas the highest K concentration was in June for MM106 rootstock (0.99%), then decreased until October, somehow, it was less than the sufficient amount in leaves during the growth season, which ranged between 1.5–2.5% after 110-125 days of full bloom (Neilsen and Neilsen, 2003). The variance of K concentration between the two rootstocks could be described as a genetic variance of which leads to different nutrient uptake and absorption capacities through roots (Kucukyumuk and Erdal, 2011).

Leaf concentration of Ca was significantly decreased during the growth season in the two rootstocks, which can explained due to the Ca immobility in leaf tissues, and no redistribution to other plant organs (Kucukyumuk and Erdal, 2011) . *M. domestica* revealed the highest leaf Ca value in October (0.75%) in significant variance compared with the other studied growth period. Likewise, MM 106 revealed the highest significant leaf Ca concentration in October (0.79%). In addition, MM106 revealed significant higher leaf Ca concentration in comparison with *M. domestica* rootstock during all studied growth periods (Table, 1). Leaf Ca concentration was significantly less than the optimal concentration during the growth season, which ranged between 1.2–1.6% according to (Joseph,2004). Velemes *et al*. (1999) stated that the leaf Ca sufficiency of Starkrimson cultivar was 0.8–1.2%.

Mg concentration revealed discrepant track among the two studied rootstocks, leaf Mg concentration was significantly increased in *M. domestica* that revealed the higher concentration in October (0.35%), whereas MM106 rootstock revealed continues significant reduction of Mg accumulation during the growth season, the highest Mg concentration was in June (0.29%) then decreased until October (0.18%). In general, the concentration of Mg in leaf was in the sufficient level (0.2-0.4%) according to Uepmnht, (1990), while Steve *et al*. (2004) mentioned that the sufficient threshold varied depending on the rootstocks and cultivars and ranged between 0.35–0.50 % .

Table 1. Leaf K, Ca and Mg concentrations (%) of leaf in *M. domestica* and MM106 grafted by Starkrimson cultivar.

Rootstock	K				Ca				Mg			
	June	Aug.	Oct.	LSD 0.05	June	Aug	Oct	LSD 0.05	June	Aug.	Oct.	LSD 0.05
M. domestica	1.05	1.57	0.8	0.044	0.45	0.57	0.75	0.009	0.26	0.29	0.35	0.009
MM106	0.99	0.78	0.62		0.72	0.74	0.79		0.29	0.28	0.18	
LSD.0.05	0.038			0.066	0.006			0.011	0.006			0.011

The ratio of K+Mg/Ca differed according to the rootstock, it was 2.91 in June then increased to the highest ratio in August (3.27) to decrease again in October (1.54) in *M. domestica*. Whereas, MM106 revealed different track, the highest K+Mg/Ca was in June (1.67) to decreases continuously until October (1.02). Buchloh and Bangerth, (1974) stated that the development of bitter pit is associated with K+Mg/Ca and differed from organ to the other in the tree and should be (1–2/1) in leaves. Likewise, K/Ca ratio significantly revealed the same track from June until October in the two rootstocks, and *M. domestica* revealed significant higher K/Ca ratio compared with MM106 rootstock (Figure 1). Nagy and Holb (2006) pointed that the optimal value of K/Ca is 0.87 in apple leaves, and the probability of bitter pit disorder is unpredicted when this ratio less than 1 (Derugen and Koluken, 1988).

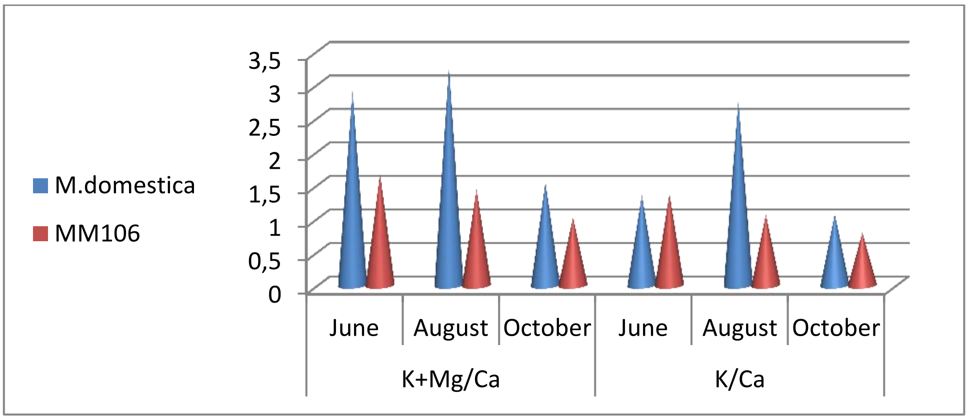

Figure 1. K+Mg/Ca and K/Ca ratios in leaves of *M. domestica* and MM106 rootstocks

In general, K concentration in apple fruit was higher in M. *domestica* and showed different track than MM106 rootstock,. As shown in Table 2, the two rootstocks revealed the same K accumulation (0.79%) in June, then increased in *M. domestica* until August (1.57%) to decrease again in October (0.61%), while the concentration of MM106 continuously decreased significantly until October (0.51%). Our results are in agreement with Kucukyumuk and Erdal (2011 **),** they found that the vigor rootstocks revealed higher fruit K accumulation than the semi vigor rootstocks, and K concentration varied depending on the apple varieties.
Concentrations of Ca and Mg in fruit were the same in the two rootstocks through the alternate growth stages except Mg concentration in October. The highest concentrations were in June, then decreased until October (0.03% for Ca) and (0.02 and 0.01% for Mg of *M. domestica* and MM106, respectively). However, Ca and Mg of Starkrimson fruit on the two studied rootstocks was too low in comparison with previous studies (Kucukyumuk and Erdal, 2011).

Table 2. Fruit K, Ca and Mg nutrient concentrations (%) in *M. domestica* and MM106 grafted by Starkrimson cultivar.

Rootstock	K				Ca				Mg			
	June	Aug.	Oct.	LSD 0.05	June	Aug	Oct	LSD 0.05	June	Aug.	Oct.	LSD 0.05
M. domestica	0.79	1.57	0.61	0.02	0.05	0.03	0.03	0.009	0.03	0.02	0.02	0.008
MM106	0.79	0.78	0.51		0.05	0.03	0.03		0.03	0.02	0.01	
LSD.0.05	0.017			0.029	-			-	-			-

According to the mean values of fruit nutrients, the two rootstocks showed different K+Mg/Ca ratios during the growth season. *M. domestica* revealed the highest ratio in August (53/1) then significantly decreased in October (21/1). Likewise, MM106 showed the highest ratio in August (26.67/1), then significantly decreased in October (17.3/1). Buchloh and Bangerth (1974) mentioned that the normal K+Mg/Ca ratio is correlated to the rootstocks and varieties and ranged between (20–50/1). Depending on the previous study, the fruit K+Mg/Ca ratio was in the normal track for *M. domestica* more than MM106 rootstock, which lead to establish sufficient nutrient management in MM106 orchards. Also, K/Ca ratio showed the same track among the two rootstocks during the growth stages, and the two rootstocks revealed the highest ratio in August (52.3/1 and 26/1 for *M. domestica* and MM106 respectively) then decreased until October (Figure 2).

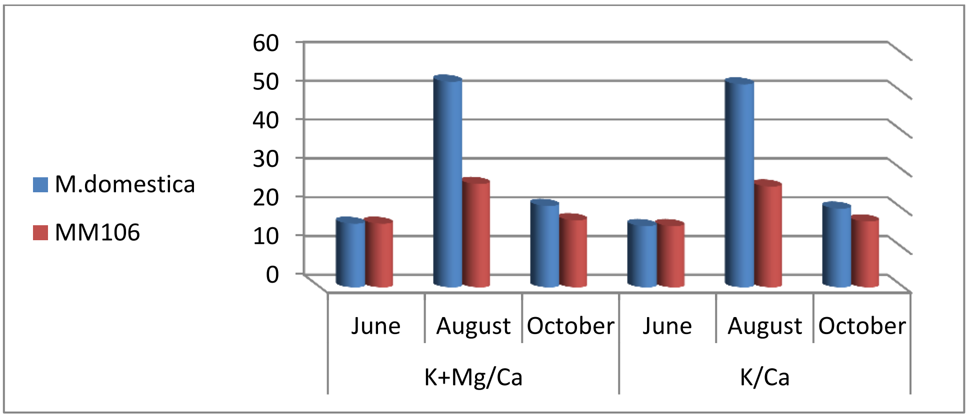

Figure 2. K+Mg/Ca and K/Ca ratios in fruits of *M. domestica* and MM106 rootstocks

Conclusion

The results showed that the nutrient concentration was particularly less than the sufficient nutrient level especially for Ca and Mg in October, and MM106 reveled less accumulation compared with *M. domestica* which may due to the surface distribution of its roots and prevent nutrient absorption under rainfed condition and high temperature in the second part of Summer. Since, the application of foliar spray of K, Ca and Mg should be taken into account in the fertilization management program at appropriate periods during growth season.

Abstract

Snake-bark maple is a small, deciduous tree that grows up to 10-15 m tall, with arching branching and a decorative bark and leaves. It is native in the mountain forests of Japan. Kyushu Maple is tolerant of frosts, smoke and urban sites. It is not an invasive species and it should be planted in green spaces in Serbia, especially as an alternative to invasive plant species. For this reason, we decided to investigate possibility of rapid and easy generative propagation of this species which has endogenous seed dormancy. Seeds were collected in the Arboretum of Swedish University of Agricultural Sciences in Alnarp. During the experiment, the seeds were cold stratified in a perlite or in bags *without* a *substrate* for 15 and 30 days. Parameters of seed germination were determined according to ISTA rules. The best results were achieved with seeds cold stratified in a perlite, for both treatments (15 or 30 days stratification). The highest germination rate and germination energy both 94% ,were achieved after the 30 days treatment.

Keywords: *Snake-bark maple, seed dormancy, cold stratification, generative propagation*

Introduction

Acer capillipes Maxim. (Red Snake-bark maple, Kyushu maple) is a deciduous small tree, usually low-branched, with a moderately slow growth rate and could reach up to 9 m high and 7 m wide. It has decorative leaves and vertically striped bark with green and white strips (Dirr and Warren, 2019). Foliage emerge redish, becoming dark green in the summer, followed by yellow, orange and red shades in autumn. It is native in the mountain forests of Japan. Snake-bark maple belongs to zones 5 – 7, and it is tolerant of frosts, heat, smoke and urban sites, but it does not like reflected heat and drought (Dirr and Warren, 2019; Rushforth, 1999). According to the DAISIE, a database of alien and invasive species in Europe *A. capillipes* is not an invasive species in Europe, and it deserves to be planted more often in Serbian green spaces. The common propagation method of this species is by seed (Dirr and Warren, 2019), but there is no much available data about its propagation. There is a recommendation that seed should be cold stratified for 3 months on 5° C, but there is no data about expected germination rate (Arnoldia, 1954). In more recent available publications there is no sufficient data about generative propagation of this species.

The majority of the other species from genus *Acer*, including *A. campestre*, *A. monspessulanum*, *A. opalus*, *A. platanoides*, *A. pseudoplatanus*, *A. glabrum*, *A. ginnala*, *A. cincinatum* and *A. palmatum*, requires cold stratification treatment before they will germinate, which is necessary in order to overcome internal dormancy in the seed (Tóth and Garrett, 1989; Suszka et al., 1996; Piotto and Di Noi, 2003; Zasada and Strong, 2006, Ylmaz 2007). Besides those species, for the *A. rubrum* and *Acer saccharinum* a pretreatment is not required for germination (Ellis et al., 1985; ISTA, 1996). The aim of this study was to establish a rapid and easy generative propagation of this species, investigating the possibility of reducing the stratification period from recommended three months to a shorter time period.

Material and Methods

Seeds were collected in the Arboretum of Swedish University of Agricultural Sciences in Alnarp. The seeds were stored in a plastic bags, at temperature 5°C before testing. Four pre-sowing chilling treatments were made. The seeds were stratified at 3-5°C for 15 or 30 days. There were two groups of treatments. The first one was chilling in plastic, transparent bags which were opened each week and moisture was controlled regularly (naked stratification). The second group of seeds was put in the chilling in perlite. Before stratification, the seeds were treated with Captan fungicide (0.6 %). The seeds in control treatment were tested without chilling pretreatments. After stratification, the seeds were examined and seeds that germinated during stratification were recorded and removed. The remaining seeds were placed on the top of two layers of filter paper in petri dishes. Humidity was controlled daily by adding distilled water if necessary. Temperature during germination was 21°C. Germination was carried out in long day conditions (light/dark period 16/8h). The germination was tested according to ISTA (1996) rules for the genus *Acer*. The first count was the 7th day (germination energy) and the last count was the 21th day after placing the seeds. In this period, the number of germinated seeds was recorded daily. Besides germination rate and germination energy, real germination rate was also calculated as a percentage of sound (viable) seeds that germinate (Grbić, 2003). Each treatment consisted of four replicates with 50 seeds per repetition. The obtained data were statistically analyzed using the program Statgraphics Plus, Ver 2.1.

Results and Discussion

In the control treatment the germination rate was low, only 8% of seeds germinated (Table 1), thus indicating that a chilling pretreatment is necessary for *A. capillipes* generative production. However, considerably better results and high germination rate were obtained after stratification thus indicating that endogenous dormancy of *A. capillipes* is not deep. Germination rate was influenced by both the treatment duration and stratification substrate and better results were obtained after 30 days of stratification (85.9 % - chilling in plastic bags and 94.0% - chilling in perlite). The germination energy was very high, mostly the same as germination rate, which means that almost all seeds germinated during the first 7 days after placing them for germination. This high germination energy has a practical importance, because during a nursery production, we can expect that the seeds will germinate rapidly and uniformly. Real germination rate or the percentage of sound (viable) seeds that germinate was as same as the germination rate after 30 days of stratification in perlite, but higher than germination rate after 30 days of naked stratification (Table 1). This finding suggests that all the seeds put on stratification in perlite were viable, and the difference between germination after 30 days of naked stratification was caused by the certain amount of non-viable seeds. For that reason, we can consider that both stratification in perlite and naked stratification would give similarly good results, depending on the quality of the seeds.

Table 1. Germination of collected seeds

Treatment	Germination rate (%)	Germination energy (%)	Real germination rate (%)
Control	8.0[d*]	1.0[c]	8.0[d]
15 days stratification in perlite	80.5[bc]	79.0[b]	82.1[c]
15 days naked stratification	75.4[c]	75.4[b]	87.5[bc]
30 days stratification in perlite	94.0[a]	94.0[ab]	94.0[ab]
30 days naked stratification	85.9[b]	85.9[a]	94.9[a]

*Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

Some *Acer* species have a much deeper endogenous dormancy and the seeds of *Acer pensylvanicum* L. should be soaked for 48 h, followed by moist chilling for 16 weeks, for successful germination (92%) (Burgoin and Simpson, 2004). Germination of *A. opalus* after 3 months of cold stratification was only 50%, and even in wild condition, the seeds of this species needs 2 years (winters) to germinate (Gleiser et al. 2004). The other problem with some *Acer* species, including *A. saccharinum* and *A. pseudoplatanus,* is recalcitrant seed (seeds that can not survive if desiccated) so it is very important to store these seeds in the appropriate humid conditions (Dickie and Pritchard, 2002; Hong and Ellis, 1996). To the contrary, the species *A. campestre*, *A. platanoides* and *A. pensylvanicum* have orthodox seeds (seeds that can tolerate water loss during storage) (Suszka et al., 1996; Greggains et al., 2000; Connor and Bonner, 2001; Bourgoin and Simpson, 2004).
Besides cold stratification treatments, a treatment with gibberellic acid can also have a positive effect on germination of *Acer* spp. (Stejskalová et al. 2015, Marshall et al. 2000).

Conclusions

Selected genotype of *A. capillipes* can be successfully propagated by seeds. The seeds do not have a deep endogenous dormancy and they requires cold stratification pretreatment for only 30 days, in perlite, at the temperature of 3-5°C. Good results can also be obtained with the naked stratification of seeds, in plastic bags. Germination rate obtained in this research was high (94%). However, there is a possibility that a treatment of seeds with gibberellic acid can improve the germination rate of this species, which should be further investigated by additional research.

MORPHOLOGICAL PROPERTIES OF DIRECTLY SOWED AND TRANSPLANTED SWEET CORN PLANTS CULTIVATED WITH COVERING TECHNOLOGIES

Ferenc OROSZ

Sapientia University, Department of Horticulture, 540485 Targu Mureş, Şoseaua Sighişoarei 1C, Romania
*Corresponding author: oroszferenc67@gmail.com

Abstract

Aim of experiment set up in 2014 was, to investigate shortening of sweet corn growing period with application of some technological elements: propagation time, propagation method, floating row cover. The choosen variety was a conventional, very early ripening sweet corn hybrid, 'Spirit'. The following growing technologies were compared: 1. direct sowing of plants with floating row cover, early period, 2. plants transplantation with floating row cover, early period 3. plants transplantation with floating row cover, normal period and 4. direct sowing of plants without row cover, normal period (regarded as control). The influence of above mentioned technological elements on some important morphological properties of sweet corn plant was studied such as: evolution of phenological phases, plant height, tassels length, ear weight, height of ear insertion.

Key words: *earliness, sweet corn, fleece covering.*

Introduction

Based on its present growing area, the sweet corn is the vegetable which is grown on the greatest area in Hungary. After dates of Hungarian Fruit & Vegetable Interprofessional Organization from 2005 the growing area was about 30,000 hectares. Sweet corn (Zea mays L. convar. saccharata), considered a vegetable, is a special type of corn destined exclusively for human consumption, less in fresh form or more in processed (canned or frozen) foods (Riverti *et al*., 2018). Near 50% of world sweet corn production came from US (Slezák *et al.*, 2012).

In order to promote fresh consumption, as well as to maintain and increase the sweet corn exports, it is necessary to promote investigations so as to be able to ensure a further increase in the growing area and yields of sweet corn with the help of the experiences. The literature mainly is concerned with maize growing technology, but a lot of dates could be used by sweet corn. Of the production technology elements, a number of researchers studied or are currently studying the sowing time of sweet corn.

As early as at the ending of 19^{th}- and the beginning of the 20^{th} century some researchers (Cserháti, 1901) highlighted the importance of the sowing date. Ripening can occur earlier when sowing earlier and using high quality seeds as compared to normal or late sowing. I'só (1969) and Pásztor (1966), after their multi-year sowing date trial, concluded the following: in the case of an earlier sowing seed germination will be more protracted, but silking and harvesting occur sooner than by lately sowing time. After multi-year trial Berzsenyi et al (1998) had studied the effect of different sowing times on maize development.

Because transplanting provides optimal environmental conditions for seed germination, and earlier development stage, sweet corn has been transplanted, as majority of other vegetables, experimentally in an attempt to improve stands and hasten maturity (Di Benedetto and Rattin, 2008, El Hamed et al., 2011). About the covered early sowing as a technological variation Aylswirth (1986) mentioned, that from an early sowed crop, made in first week of April, arranged in twin rows (42 cm) and covered by plastic, we could harvested marketable cobs by the fourth of July. In case of direct sowing, as propagation method, another earliness

increasing solution is the temporary covering with plastic or vlies, used in different combinations (Hodossi and Kovács, 1996).
The most widespread method of seedling production is the use of soil blocks (Pereczes, 1999) which can also significantly increase earliness. The combined application of seedling growing and floating row cover can advance harvest by three weeks as compared to the traditional technology and can give farmers a three to four times greater income (Kurucz, 1998). Rattin et al., (2006) compared direct sowed and transplanted sweet corn varieties, without covering and concluded no difference, in ear weight and ear length, between transplanted treatments plant's, in comparison to direct sowing treatments.

Materials and methods

The experiment was set up in 2014 on an area eqiupped for irrigation at Tg-Mures, Mures County, situated in Central part of Romania. Conventional, reliable and sufficiently known among growers sweet corn variety, Spirit, was used as a reference variety in the variety comparison trials of the Central Agricultural Office. Hybrid has short growing period of 85 days and yellow kernels. Average height of plants is 159 cm, average ear height is 37 cm, ear length 19.6 cm and average ear weight is 245 g. The variety was granted official recognitions in 1988 and has been the dominant variety of the early ripening category till now. In the year prior to the experiment the area was under wheat.
The following treatments, each with four replications, were applied during the experiment:
P1 = direct sowing, with floating row cover (April 8th)
P2 = plants transplantation with floating row cover (April 8th)
P3 = plants transplantation, with floating row cover (April 25th)
P4 = uncovered direct sowing (April 25th), (regarded as control).
For the frame structure of the treatments with cover we used ø 4.2 mm zinc coated wire coils. The fleece, 60 cm in width, was stretched over a small tunnel of 40 cm in height and then its edges (25-25 cm, respectively) were covered with soil using a hoe and the its ends were tied to the stakes hammered down. The construction of the frame structure and the setting out of the fleece cover were carried out at the same day as direct seeding and out planting.
At the two propagation times the treatments P1 and P3 were covered with Novagryl floating row cover, having a weight of 19 g/m^2, (using the small tunnel technique) in order to enhance earliness. The stand was created to contain 60,607 plants per hectare, according to the recommendations of the owner of the variety, at a spacing of 110+40x22 cm in twin rows. Each plot had an area of 6x3.5m (8 parallel rows and 16 seeds sown in each row). Sowing depth was 3 cm. The edge was the respective outer rows of the 4 twin rows of the plot.
In October 2013, 35 t/ha of farmyard manure was worked into the soil with ploughing on area. Nitrogen fertilizer (120 kg/ha) was applied at the 6-7 leaf stage, the form of top dressing. The fertilizer application was worked into the soil with a rotary hoe.
During the experiment, we studied plant growth rates and recorded the time of the occurrence of the major phenological stages. For this purpose, we carried out regular observations (every 3 to 5 days) according to the following:
appearance of tassels (by 50% of the plants),
beginning of tasseling (pollen shed has begun on the axes of tassels),
50% silking (silks have reached a length of 2 cm on half of the ears) "milky stage" (harvest).
highness of plants (cm),
length of tassels (cm),
highness of ear insertion (cm).
For measurements, were selected 10 plants/treatment/replication, from the four central (two twin) rows.

The statistical analysis of the results was carried out by using the programme *RopStat 1.1*. When the standard deviations were identical the mean values were compared by pairs using the *Tukey-Kramer* test, while in the case of the non identical standard deviations the means were compared using the *Games-Howell* test (Vargha, 2007).

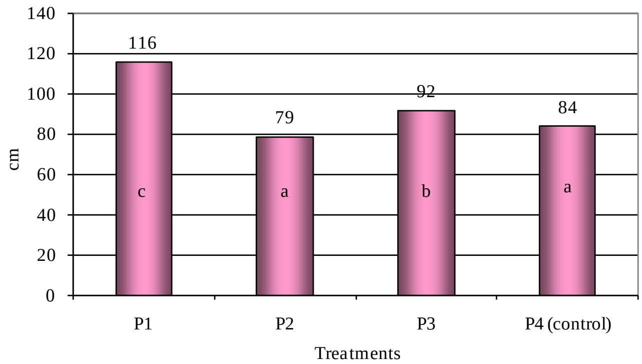
Results and discussion

Table 1. illustrates the times in days elapsed to different phaenological stages.

Treatments (sowing, outplanting day)	Tassels appearance by 50% (days)	Beginning of male flowering (days)	Stigma appearance by 50% (days)	Starting harvest (days)
P1 (IV. 8)	50 (V.28.)	64 (VI.11.)	70 (VI.17.)	85 (VII.2.)
P2 (IV. 8)	41 (V. 19.)	55 (VI.2.)	60 (VI. 7.)	76 (VI. 23.)
P3 (IV. 25)	28 (V. 23.)	43 (VI. 7.)	49 (VI. 13.)	64 (VI.28.)
P4 (control) (IV. 25)	57 (VI. 21.)	67 (VII. 1.)	71 (VII. 5.)	85 (VII. 19.)

Table 1: Rhytm of generative phaenophases

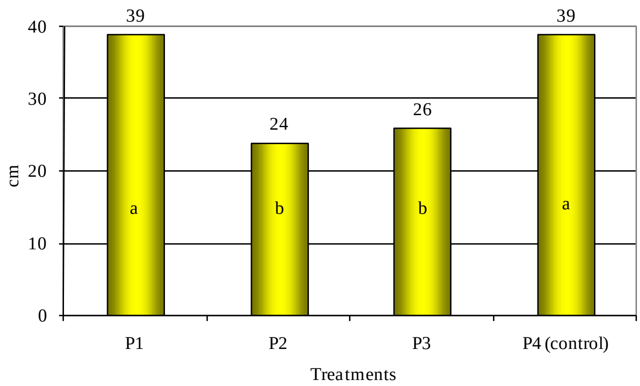
Covering helped in earlier appearance of generative phaenophase (tassels) P1treatment by 7 days respectively, in case of harvesting by 17 days earliness, compared to P4 (control). In the case of the plants sown at the second sowing date the emergence could be considered practically normal as common. According to our results of experiment, the male flowers (tassels) appeared in the shortest time by transplanted treatments. The transplant growing, at this stage of development, resulted in 9 days earliness as considers the treatment P2, compared to the treatments P1 which had been direct seeded at a similar time. Compared to the control (P4), the P3 treatment transplanted at the same date, tassels and stigma appearance started earlier by 29, respectively 22 days and could be harvested 21 days earlier.
The highness of plants indicator of general condition is represented by Figure1.



F(4;176)=40,356; Sd=99%

Fig. 1. Highness of plants (cm).

The highest value of plant highness was registered by plants of earlier sowed (P1) covered treatment, difference was significantly (at $p<0.01$ level), compared to all other treatments. Covering (P1) had favourable effect on plant highness in normal time outplanted treatment P3 compared to uncovered, earlier sowing time (P4, control) treatment. Among all covered (P1, P2, P3) treatments plant highness resulted significantly (at $p<0.01$ level) differences.
Evolution of tassels length, supposed to carry more male flowers and implicite better pollination, is summarised on Figure 2.

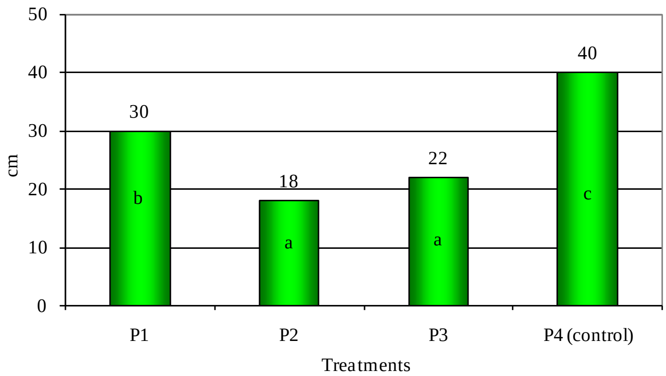


F(4;174)=7,561; Sd=99%

Fig. 2. Tassels length (cm).

In case of tassels length propagation method of sowing (earlier, normal) had higher influence. Plants from earlier sowed P1 treatment and later sowed uncovered, control (P4) treatment had significantly (at p<0.01 level) longer tassels compared to earlier transplanted (P2) and normal time transplanted (P3) treatments. Covering had no effect on tassels length evolution.

Highness of ear insertion is a very important morphological plant property in case of mechanical harvesting, because adapters of usual harvesting machines can cut only de sweet corn ears inserted higher than 40 cm, is illustrated on Figure 3.



F(4;174)=10,473; Sd=99%

Fig. 3. Highness of ear insertion (cm).

Obtained data confirmed significantly (at p<0.01 level) higher insertion of ears in case of earlier and later sowed, covered and uncovered (P1 and P4) treatments compared to earlier transplanted P2 and normal time transplanted P3 treatments. Covering on earlier sowed (P1) treatment produced favourable effect on highness of ear insertion. P4 (control) treatment offers significantly (at p<0.01 level) higher insertion of ears compared to all other covered treatments. Only P4 (control) treatment seems to offer possibility applying mechanical harvesting on sweet corn crops in open field production. Mechanical harvesting by P1 (earlier sowed) and P2 (earlier transplanted), P3 normal time transplanted treatments can not be used.

Conclusions

Based on the results of the 2014 year experiment, the following conclusions can be made:

In case to compare the earlier sowed P1 and normal time sowed P4 (control) treatments, covering shortened with 7, respectively 1 days, appaerance of generative organs (tassels and stigmina) and no difference in growing period, 85 days in both treatments.

The growing period was significantly shortened with transplantation of sweet corn plants, combined with covering compared to direct seeded. Harvest time occurred 9 days earlier in the case of transplantation and floating row cover, earlier transplanted (P2) application compared to direct sowed, uncovered, control (P4) treatment, and earlier to direct sowed, covered P1 treatment.

At the same time the floating row cover produce 11 days shortening in growing season between P2 (earlier transplants with floating row cover) and P3 (normal time transplants with floating row cover) treatments.

In case of earlier, direct sowed treatment (P1) the effect of covering had positive effect on plants highness, tassels length and highess of ear insertion.

Insertion point of ear, higher than 40 cm, offer possibility, in case of normal time sowed, uncovered P4 (control) treatment. of sweet corn crop, to use mechanical harvesting.

Covering has no significantly positive effect on highness of ear insertion.

Abstract

The pea germination process begins when the seeds absorb a certain amount of water relative to the seed mass. The lack of water in the germination phase inhibits the growth of plants and reduces the production of crops. By solving the problem of providing soil moisture during vegetation we are aming to create technologies for maximum savings and efficient water supply for the plants. The main goal of this research is to determine the influence of the "Tverdaya Voda" on germination, as well as on the length and mass of germs and roots, in laboratory conditions. The experiment involved six treatments: control variant (A_0), super absorbing agent "*Tverdaya Voda*" (A_1), super absorbing agent "*Tverdaya Voda*" enriched with growth stimulator (A_2), super absorbing agent "*Tverdaya Voda*" enriched with microorganisms (A_3), super absorbing agent "*Tverdaya Voda*" enriched with microelements (A_4) and super absorbing agent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements (A_5), and two soil types (alluvial soil and humofluvisol). The experiment was performed in the laboratory of the Faculty of Agriculture in East Sarajevo. For all examined characteristics, the best results were found in the use of super absorbing agent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements (germination energy, germination, mass and length of the hypocotyls), while the control variant had the lowest results.

Keywords*: absorbent, soil, germination, hypocotyl, root.*

Introduction

Pea (*Pisum sativum* L.) is annual legume plants, of winter and spring type. It grows from 20° to 67° north latitude, and it has a large growing area, thanks to its good adaptability, a large number of varieties, short vegetation and diverse use (Gagro, 1997). Pea is a multipurpose crop, with the main purpose in the human nutrition and nutrition of domestic animals, and can be used in the form of green fodder, dry matter, forage fluor, unripe grain, ripe grains and straw, and green manure as well (Mikić et al., 2006). It is known that seed quality affects germination, as well on the production and profitability of crops (Finch-Savage and Bassel, 2015). Germination of seeds is one of the most important components of seed quality (Van Gastel et al., 2007), which is determined by the standard method of ISTA (The International Seed Testing Association) germination testing. Ecological factors such as temperature, light, pH and soil moisture affect the germination of seeds (Canossa et al., 2008; Ikeda et al., 2008; Rizzardi et al., 2009). Availability of water is a basic prerequisite for the start of the germination process, that begins with its adoption. The process of pea germination begins when the seeds absorb a certain amount of water relative to the seed mass, about 115% (Jevtić et al., 1986). Drought stress is one of the main environmental factors that limits the growth of plants, and the most common cause of it, is the increase in temperature and the reduction of available water to the seed or plants (Nazar et al. 2015). The lack of soil water in the germination phase inhibits plant growth and reduces crop production. (Yan, 2015). By solving the problem of moisture protection during vegetation, we are aming to create technologies for maximum savings and efficient water supply for the plants. In this regard, it is interesting to use environmentally friendly biodegradable sorption materials that can retain moisture in the root zone of plants. In this way, plants can be provided with sufficient amounts of water and the influence of stressful weather conditions during vegetation can be reduced (Lukin et al., 2018). The agent with qualities of super absorbing agent, was synthesized in accord with traditonal methods (Bellamy, 1975). During the last phase of polymerization to the reaction mass (concentration ratio 4: 1), organic and inorganic matter are added (Kuznetsov et al., 2016a; Kuznetsov et al., 2016b). Super absorbing agent can be actively used in agriculture to improve soil structure and preserve moisture in arid areas, but it is also used as an additional source of mineral fertilizers. The main goal of this research is to determine the influence of different compositions of the super absorbing agent "*Tverdaya Voda*" on germination, as well as on the length and mass of germs and roots, in laboratory conditions.

Material and methods

To examine the influence of super absorbing agent "*Tverdaya Voda*" on pea germination, a control variant (A_0) was used, together with other variants: super absorbing agent "*Tverdaya Voda*" (A_1), super absorbing agent "*Tverdaya Voda*" enriched with growth stimulants (A_2), super absorbing agent "*Tverdaya Voda*" enriched with microorganisms (A_3), super absorbing agent "*Tverdaya Voda*" enriched with microelements (A_4) and super absorbing agent "*Tverdaya Voda*" enriched with stimulants growth, microorganisms and microelements (A_5).

We took soil samples from experimental parcels in East Sarajevo and Bijeljina After laboratory analysis it was established that alluvial soil (B_1) from East Sarajevo has pH_{H_2O} 6.63, it contains 3.62% humus, 0.23% N, and in 100 g^{-1} soil, it has 14.75 mg of soluble P_2O_5 and 15.59 mg of soluble K_2O, while humofluvisol (B_2). from Bijeljina had pH_{H_2O} 7.16, containing 4.12% humus, 0.27% N and 100 g^{-1} of the soil had a 40 mg soluble P_2O_5 and 36.41 mg of soluble K_2O. Soil samples (alluvial soil and humofluvisol) dried were in an electric oven at 105°C to constant mass.

After that, the land was put in 1 m^2 containers and mixed with various combinations of super absorbing agent (2g per m^2). We took soil samples to the depth of 15 cm from containers, using a plastic cylinder with a diameter of 5 cm, then a gauze is placed on the lower opening of the cylinder, which leaks the surplus of the soil dilution and retains the soil. Distilled water was poured in the cylinders. The surplus of soil solution that passed through the cylinders, was collected in glass containers and used to treat quartz sand during peas germination.

The germination energy and germination analyzes were carried out according to the standard method for laboratory germination of pea seed, germination in quartz sand, which was sterilized before it was used. The sand is placed in the ventricle container for germination, filling 2/3 of its height. The seed that was previously washed with distilled water, was placed in the dishes properly, dispersed to the same depth, and it moistened soil dilution up to 80% of filed water capacity. The containers were placed in a thermostat at a temperature of 20° C, and the humidity of 90%. To test the energy of germination and germination, 100 seeds are used in 4 replications (Haramija, 2007). Germination and energy of germination are expressed in percentages. It takes 4 days to determine the germination energy, and 7 days for determining germination.

When calculating the energy of germination and germination, normally developed germs were count after each repetition separately. The examination of the influence of super absorbing agent "*Tverdaya Voda*" with different composition on the length and weight of the germs, as well as on the length and mass of the roots, was also performed according to the standard method for laboratory pea testing. Each plant was segregated from the sand separately, length of the germ, mass of the germ, and the length of the main germ root were measured. The length of the hypocotyl is measured from the point where root crosses to hypocotyl (the root's last hair) to the top of the hypocotyls (basal part of the cotyledon). The root length is

measured from the crossing of the root into the hypocotyl, to the longest part of the root. The length of the germ and root is expressed in centimeters (cm), and the weight in grams (g).
The obtained results are analyzed by the twofactorial reflection variance analyze (super absorbing agent, soil types), and the individual differences tested by the LSD test, using the SAS / STAT program (SAS Institute, 2000).

Results and discussion

The influence of different combinations of absorbents and soil types on germination, germination energy of pea seeds in laboratory conditions, as well as length and mass of germ, length and root mass are shown in Table 1.
The use of microorganisms as biofertilizers and/or biopesticides in the production of different plants allows for better utilization of growth potential both plants and microorganisms (Frame, 2005; Avis et al., 2008; Hayat et al., 2010). In the researches of Shaukat et al. (2006) bacterialization (Azospirillum, Pseudomonas and Azotobacter) of sunflower and wheat seeds had a positive effect on germination and length of germ, which is in accordance with our researches, because the application of the super absorbing agent "*Tverdaya Voda*" enriched with microorganisms, gave better results compared to the control variant, and variant where only the super absorbing agent "*Tverdaya Voda*" was applied. The use of microelements, especially in combination with growth stimulators, can increase plant growth up to 10% (Chau et al., 2019), which is in accordance with our results. More attention is now devoted to alternative methods, where biopreparations, created on the basis of natural substances of biological origin, are used to stimulate seeds. Their application is not only allowing seed protection from microorganisms, but also facilitating the adoption of biogenic substances in plants (Mukhrjee et al., 2007).
In the treatment of super absorbing agent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements, a significantly higher germination energy (70.62%) was found compared to other treatments, while the control variant had the lowest germination energy (51.00%). The use of humofluvisol , used in the surveys had a significantly higher energy of pea grain (65.62%) compared to alluvial soil (58.54%). For both soil types, in average, super absorbing agent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements compared to other treatments had significantly higher germination energy, while the control variant had the lowest energy of germination.
By analyzing the effects of different combinations of absorbents on pea grain germination, it was found that in the treatment of "*Tverdaya Voda*" super absorbing agent enriched with growth stimulators, microorganisms and microelements, higher germination (94.50%) was significantly higher compared to other treatments, while the control variant had the least germination of pea grain (79.12%).
The land from humofluvisol used in the surveys had a significantly higher pea grain germination (89.92%), compared to alluvial soil (84.75%). For both soil types, in average, super absorbing agent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements

Table 1. Influence of super absorbing agent and soil types on germination energy, germination, length and mass of germs, length and mass of roots

compared to other treatments had significantly higher level of germination, while the control variant had the lowest germination of pea seed. The peas had the longest hypocotyl (6.28 cm) in the treatment with super absorbing agent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements, and the shortest hypocotyl had the peas treated with the control variant (2.42 cm). The observed differences were statistically highly significant. The influence of soil types on the length of the hypocotyls was not statistically significant, but on both localities a significant effect of the super absorbing agent "*Tverdaya Voda*", enriched with growth stimulators, microorganisms and microelements was determined.

The length of the root was significantly influenced by the use of different combinations of absorbents, while the soil types, as well as the interaction of the absorbent x soil types, had a statistical significance. The longest root (7.12 cm) was determined in variant A_5, and the smallest (4.39 cm) in control variant. At the soil types B_2, the root (6.95 cm) is significantly longer compared to the soil types B_1 (6.04 cm). At the soil types B_1, the longest root had the application of super absorbing agent "*Tverdaya Voda*" enriched with microelements, and at the soil types B_2 the application of super absorbing agent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements, while the control variant had the smallest roots at both l soil types.

The examined factors, as well as their interaction, exhibited a high influence on the mass of the hypocotiles. The highest mass of hypocotil was in treatment A_5 (1.990 g), and the smallest in the control variant (1.160 g). The B_1 soil types (1.319 g) had a lower weight of the hypocotil compared with the soil types B_2 (1.787 g). At the alluvial soil, the hypocotil had the highest mass in the use of the absorbents A_4 and A_5, while at the humofluvisol the highest mass of the hypocotyl was when absorbents A_3 and A_5 were applied. The examined factors exhibited a high influence on the mass of the hypocotile, while their interaction had a significant effect. The highest root weight was in treatment of A_5 (1.286g), and the smallest one was in control variant.

The B_1 soil types (0.819 g) had a lower weight of the hypocotyl compared to the B_2 soil types (1.250 g). At the alluvial soil, the root had the highest mass when absorbent A_4 was applied, while at the humofluvisol the highest mass of root was by using absorbent A_5.

Conclusion

Based on the research taken in the laboratory of the Faculty of Agriculture in East Sarajevo, the following can be concluded:

- The application of the absorbent has exhibited a very significant influence on the examined pea grain characteristics. For all examined properties, the best results were when super absorbing agent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements was applied, and the the lowest germination had the control variant (no absorbent applied). Better results were obtained by applying enriched absorbent (super absorbing agent "*Tverdaya Voda*" + growth stimulants, super absorbing agent "*Tverdaya Voda*" + microorganisms, super absorbing agent "*Tverdaya Voda*" + microelements and super absorbing agent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements) in comparison with pure super absorbing agent "*Tverdaya Voda* ".Highly significant differences between soil types were recorded for germination energy, germination, hypocotil mass, and root mass, while the soil types had a significant influence on the length of the root.
- By using super absorbing agent "Tverdaya Water" enriched with growth stimulators, microorganisms and microelements at both localities, significant differences in germination energy, germination and mass of the germs and significant differences in the length of the hypocotil were found.
- After finishing the experiments in the laboratory, they should be continued in the experimental field of the Faculty of Agriculture and the acquired results should be presented to the agricultural producers.

Abstract

In two years of research (2016-2017), five varieties of peas (NS Javor, Baccara, NS Dukat, NS Junior and Sasa) were examined at two localities: 1) field in the vicinity of East Sarajevo (experimental field of the Faculty of Agriculture in East Sarajevo), and 2) field in the vicinity of Banja Luka (experimental field of the Agricultural Institute of Republic of Srpska), to determine the effect of agroecological conditions and mineral nutrition on the mass of 1000 seeds and the yield of peas. In order to determine optimal needs for mineral nutrition, three variant of fertilizer were applied: control variant - without fertilizer use, basic fertilization with 350 kg ha^{-1} $N_8P_{24}K_{24}$ and basic fertilization with 350 kg ha^{-1} $N_8P_{24}K_{24}$ + top dressing 27 kg ha^{-1} N (KAN 27% N). The following yield components were determined: the mass of 1000 seeds and the yield of pea grain. The average mass of 1000 seeds was 194.4 g. The largest mass of 1000 seeds was found in the genotype NS Javor (232.09 g), and the smallest mass was found in the genotype NS Junior (139.57g). The average yield of pea seeds was 4014.5 kg ha^{-1}. The seeds yield was under significant influence of the genotype and varied within the limits of 2561.9 kg ha^{-1} in the genotype NS Junior, which we consider to belong to a group of combined genotypes, while the highest yield was found in the protein pea genotype NS Javor (4666.5 kg ha^{-1}).

Key words: *peas, genotype, yield, the mass of 1000 seeds, locality, fertilization.*

Introduction

The cultivation of annual fodder legumes, such as fodder peas (*Pisum sativum* L.) and their use in feeding domestic animals, provides one of the best solutions for the lack of plant-based protein in livestock breeding (Mihailović and Mikić, 2014). Grain pea is an economically significant agricultural plant species, which iz primarily grown because of the high proteins content in the grain. Favorable biological features, including short vegetation, modest requirements regarding production conditions, versatility, high and stable yield, as well as the quality of biomass and grains, make fodder peas significant factor in the solution of plant protein deficiency (Čupić et al., 2010; Čupić et al, 2013). Despite the great importance of fodder peas in the production of fodder and grain, and favorable agro-ecological conditions, the production in our country is very small and official statistics does not cover the areas of production, production itself and yield of fodder peas or protein peas.

By examining various varieties of peas and using different amounts of mineral fertilizers at different localities, the selection of appropriate varieties for viable fodder production can be achieved.

The aim of this research was to determine the influence of genotype, mineral nutrition and agroecological conditions quantitative traits of fodder peas.

Material and method

Field experiments were set up in 2016 (Y_1) and 2017 (Y_2) at two locations: 1). locality in the territory of the city of East Sarajevo (experimental field of the Faculty of Agriculture in East Sarajevo), altitude of 550 m (43°49'01" NGW and 18°20'57" EGL) (L_1) and 2). locality on the territory of the city of Banja Luka (experimental field of the Agricultural Institute of Republic of Srpska), altitude of 163 m (17°4912'19" NGW and 44°48'13" EGL) (L_2). The basic soil treatment was carried out in the autumn, at a depth of 25 cm and the pre-sowing preparation at a depth of 10 cm. In order to determine optimal pea nutrition, three fertilizer treatment were applied:

- control variant - without fertilizer use (F_1),
- basic fertilization with 350 kg ha^{-1} $N_8P_{24}K_{24}$ (F_2) and
- basic fertilization with 350 kg ha^{-1v}$N_8P_{24}K_{24}$ + top dressing 27 kg ha^{-1}N (KAN 27% N) (F_3).

The sowing was done at row spacing of 12.5 cm and the distance in the row of 8 cm in the basic plot of the total area of 5 m^2. For sowing, inoculated seed of five spring fodder pea varieties were used: NS Javor (G_1), Baccara (G_2), NS Dukat (G_3), NS Junior (G_4) and Sasa (G_5). Three varieties were cultivated at the Institute for Field and Vegetable Crops in Novi Sad - Republic of Serbia (NS Dukat, NS Junior and NS Javor), Baccara is a variety cultivated in France, while Sasa is variety cultivated at the Agricultural Institute of Republic of Srpska in Banja Luka. The following yield components were determined:

- mass of 1000 grains (g) (based on the mass of 5x100 grains taken from the randomly selected samples) and
- Grain yield (kg ha^{-1}) was determined by weighing yield after harvest on elementary plot and its conversion to hectare.

Statistical analysis of experimental data was done by four-factor analysis of variance: Y-year, G-genotype; F-fertilization and L-locality.

The original experimental data were processed, analyzed and evaluated using the mathematical and statistical methods, factor impact on the plant characteristics (variance analysis) with the use of the statistical package STATISTICA 12 for Windows. Applied mathematical and statistical methods for the experimental data processing, analysis and evaluation of the research results enabled the correct understanding of all results. Significance was calculated based on LSD test for probability levels 0.05% and 0.01%. Stability tested traits were determined by the coefficients of variation (%).

Growth conditions

Soil in Banja Luka where experiments were set has good physical characteristics with a depth of 35 cm. According to agrochemical analyzes conducted at the Agricultural Faculty in East Sarajevo, it contains 0.13% total N, 2.05% organic matter, 40 mg 100 g^{-1} phosphorus and 38.48 mg 100g^{-1} potassium. The soil reaction is neutral, pH in nKCl is 6.97. According to the agrochemical analyzes conducted at the Agricultural Faculty in East Sarajevo, the soil at the experimental field of the Faculty of Agriculture (Eastern Sarajevo) contains 0.27% nitrogen, 4.12% humus, 40.40 mg 100g^{-1} phosphorus and 36.41mg 100g^{-1} potassium. The soil reaction is moderately acidic, pH in nKCl is 6.39. The distribution of total monthly rainfall and average monthly air temperature for research years and the long term average for Banja Luka and East Sarajevo are shown in Table 1. Average monthly air temperatures for the locality Banja Luka in both years were higher than the perennial average, and only in May 2016 the average monthly temperature was slightly lower than the long term average. In the period of vegetation, the precipitation varied from year to year and from month to month. In 2016, in April, there was only 0.5 mm of precipitation, while in 2017, precipitation in June (35.1 mm) and July (38 mm) was well below the long term average.

Table 1. Average monthly air temperature (°C), monthly rainfall (mm) and long term average for Banja Luka and East Sarajevo

Month			I	II	III	IV	V	VI	VII
Banja Luka	2016	°C	2.3	7.6	8.0	13.5	16.2	21.5	23.3
		mm	109.7	108.5	122.2	0.5	100.6	117.8	125.9
	2017	°C	-3.6	5.5	9.7	11.8	17.5	22.9	24.4
		mm	87.2	100.4	124.0	148.4	92.1	35.1	38
	Average 1981-2010	°C	0.6	2.3	6.8	11.5	16.5	19.8	21.8
		mm	69.7	59.1	87.5	84.3	89.4	112.4	81.4
East Sarajevo	2016	°C	1.2	7.4	7.1	12.9	13.9	19.5	21.1
		mm	46.6	87	131.7	60.5	82.1	96.4	104.5

		mm	57.9	69.1	43.6	132.4	73.8	55	66.5
	Average 1961-1990	°C	-0.8	1.7	5.5	10	14.8	17.7	19.7
		mm	74	63	73	76	85	94	83

At the locality East Sarajevo, in 2016, there were higher average monthly temperatures, compared to perennial average. The exception was May when the average monthly temperature was lower for 0.9 °C. The amount of rainfall was lower than the perennial average in April and May. In April and May 2017, the mean temperatures were lower than the averages for the given months, while in June and July they were significantly above the perennial average. The amount of rainfall was significantly lower than the perennial average for January, March, April, May, June and July.

Results and Discussion

Tables 2 and 3 show the average value of the 1000 grains mass and yield of examined pea genotypes per year, level of fertilization and localities. The mass of 1000 grains is the most stable yield component, because it depends, to a higher extent, on the genetic structure (Poggio al., 2005) and is highly inheritable trait. The average mass of 1000 grains ranged from 137.81 g in the second year in G_4 (NS Junior) to 232.81 g in the first year in G_1 (NS Javor). The mass of 1000 grains ranged from 137.61 g in control variant in the genotype G_4 (NS Junior) to 234.63 g in the third fertilization variant in the genotype G_1 (NS Javor). The genotype G_1 had the highest mass of 1000 grains at both localities compared to other genotypes. The genotype G_4 had the lowest mass of 1000 grains at both localities. In genotypes G_2 and G3, the mass of 1000 grains ranged from 214.38 g to 222.14 g. The highest difference between localities was observed in the genotype G_3, while the lowest difference was in the genotype G_1. The lowest variation was in the genotype G_2. Results of Tan et al. (2013) confirmed the existence of 1000 grains mass variations. They found huge variations of 63.3g (Balcesme) to 207.7 g (Incili) in the local populations in Anadolu (Turkey).

The average yield of the examined genotypes of peas was different. The highest values were recorded in the genotype G_1 (NS Javor), with the yield of 4666.5 kg ha^{-1}. The yield of 2561.9kg ha^{-1} was the lowest one found in the genotype G_4 (NS Junior). Examined genotypes of peas gave different yield regarding fertilization variants, shown in Table 3. High yields were achieved in genotypes G_1, G_2 and G_3, among which the genotype G_1 stood out with 4200.2 kg ha^{-1} in control variant, and 5126.6 kg ha^{-1} in the third fertilization variant. Low yield was found in the genotypes G_5 (Sasa) and G_4 (NS Junior), while the lowest average yield was found in the first fertilization variant in the genotype G_4 (NS Junior) of 2346.9 kg ha^{-1}, which was for 2779.7 kg ha^{-1} less than the highest achieved value for this characteristic. Regarding yield variations concerning different fertilization variants within the same genotype, the highest variation was observed in the genotype G_1 (NS Javor) with the difference of 926.4 kg ha^{-1} between the first and the third fertilization variant, while the lowest variations were found in the genotype G_5 (Sasa) with the difference of 108.3 kg ha^{-1} between the first and the third fertilization variant.

The choice of locality influenced the yields of pea genotype (Table 3), which is in agreement with the results of Đurđić et al. (2017) Đurđić et al. (2018). The genotype G1 had the highest yield at the second locality, while the genotypes G_2, G_3, G_4 and G_5 had highest yield at the first locality. The highest yield was in the genotype G_1 of 4735.5 kg ha^{-1} at the second locality, while the lowest yield of pea grains was found in the genotype G4 of 2490.3 kg ha^{-1} at the second locality. The lowest difference between localities was observed in the genotype G_2 (36.8 kg), and the highest in the genotype G_5 (184.3 kg).

In 2016, in Banja Luka, average monthly temperatures, except January, were higher than the average perennial values. In that year, for period Januar – July, there was 101.4 mm more precipitation. In 2017, the average monthly temperatures were lower than the average perennial values, compared with 41.4 mm higher precipitation in that year compared with the average perennial values. Favorable meteorological conditions in 2016 led to higher pea yield in that year, compared to 2017. In East Sarajevo, in 2016, the average monthly temperatures were higher than the perennial average, and in comparison with the perennial average values for the period January-July, there was 60.8 mm more precipitation. Compared with 2017, in 2016, rainfall in January-July was higher by 110.5 mm. January and April 2017 were colder than the perennial average and 2016. The yield of grain peas is influenced by the right choice of varieties, application of agrotechnical measures, and also the interaction of the genotype x environment have a significant influence (Lakić et al., 2018). Average grain yield in peas in this experiment was 4014.4 kg ha^{-1}, which is in accordance with the results of many authors analyzing grain yield achieved in agroecological conditions of Serbia (Mihailović et al., 2003; Erić et al., 2004; Karagic et al., 2008), and Croatia, Osijek, which is very similar to our agroecological conditions. Rapčan et al. (2010) achieved grain yield from 1780 to 3420 kg ha^{-}

[1], but also Spies et al. (2010) and Rasaei et al. (2012). Grain yield was under significant influence of genotype and ranged from 2561.9 kg ha^{-1} in the genotype NS Junior, which belongs to the group of combined genotypes, to 4666.5 kg ha^{-1}achieved in the genotype NS Javor which is a protein pea. In their research, Acikgoz et al. (2009) found significant interactions of genotype x years, genotype x locality and genotype x locality x years, and our research found significant interactions of years x genotype; genotype x fertilization; genotype x locality and genotype x fertilization x locality.

Conclusion

Significant interactions of year x genotype; genotype x fertilization; genotype x locality and genotype x fertilization x locality. In this experiment, the average mass of 1000 grains was 193.27 g. The average grain yield was 4014.4 kg ha^{-1}. The grain yield was under significant influence of certain genotype and varied from 2561.9 kg ha^{-1} in the genotype NS Junior, combined genotype, to 4666.5 kg ha^{-1} in the protein pea genotype NS Javor.

Abstract

The Mediterranean region is one of the regions most affected by global warming. Therefore, optimizing applied irrigation levels and finding alternative cultivation practices are vital for the plant species including strawberry. In this study, the responses of strawberry cultivars 'Rubygem' and 'Kabarla' to irrigation levels and bio-stimulant use were investigated by evaluating the berry size parameters (diameter, length and weight) under high tunnel conditions in this region throughout the growing season of 2016-2017. The amounts of irrigation water applied were 0.50 (IR 50), 0.75 (IR 75), 1.00 (IR 100) and 1.25 (IR 125) times the water surface evaporation. Application of IR 50 was found to be significantly different from the other 3 applications, which partaking in the same group with the lowest fruit diameter, length and weight values in both cultivars. While it was determined that bio-activator applications did not provide significant increases in fruit diameter and weight values in 'Kabarla'; cultivar 'Rubygem' fruit diameter was increased 4.7% and weight by 9.0%. It was also detected that bio-activator applications did not provide significant differences in fruit length in both cultivars, and 'Rubygem' produced wider, lengthier and heavier fruits than the 'Kabarla'. It can be concluded that permanent damage in the diameter, length and weight of the fruits representing the quality are dependent on the level of water stress and strawberry cultivars.

Keywords: *Mediterranean region, Water stress, Fruit weight, Fruit quality*

Introduction

Strawberries are produced mostly in China, USA, Mexico, Turkey and Spain. Turkey provides about half of the production of strawberries from the Mediterranean region. Drought that more frequent and long-term are expected worldwide due to climate change, and the Mediterranean region is thought to be one of the most affected regions. Farmers generally uses of experiences on weather and plant conditions to determine the irrigation water amount. But they uses excessively or inadequately applied water, which can have a negative impact on berry size (Liu et al., 2007; Ghaderi et al., 2015, Sardas et al., 2017). It is known that during the growing period, products are often exposed to water stress. However, water stress, especially during certain stages of growth, such as seedling and flowering, causes a number of damages to product development, leading to major losses in yield and quality (Pessarakli, 1999; Çeliktopuz., 2019). Optimizing applied irrigation levels and finding alternative cultivation practices such as bio-activators are vital for the whole plant species including strawberry, due to fact that it is clear there will be reductions in product yield and quality under these conditions. Bio-activators are environmentally friendly applications that increase abiotic tolerance such as water stress and help increase yield and fruit quality (Spinell et al., 2010; Bulgari et al., 2015). Although there has been a large number of studies on water stress tolerance for numerous plants (Bota et al., 2001; Herralde et al., 2001), there are lack of information on determining changes in fruit quality parameters under conditions that water availability of soil is reduced or increased for different strawberry cultivars. Understanding the effects of water stress on fruit quality characteristics and developing strategies to minimize the damages caused by water stress are essential for the future of agriculture. The aim of this study was to determine the effects of excessive and inadequate irrigation on the diameter, length and weight of the fruit in order to achieve fruits with greater physical characteristics.

Material and Methods

The trial was conducted inside the high tunnel at the experimental farm of the Çukurova University in Turkey. Strawberry frigo seedlings (*Fragaria x ananassa Duch. Kabarla and Rubygem cv.*) were planted from 20th September in 2016 until 15th June in 2017. Fertilization and spraying processes were carried out in accordance with our previous studies in line with the requests of plants and soil. The study was planned in 4x2x2 factorial order (irrigation levels, bio-stimulants, cultivar), and in split-split plot randomized block design with 3 replicates, totally 48 plots. Bio-activator applications were designed as main plot and different irrigation levels were arranged as sub plot.

The content of the bio-activator which was named ComCat was certified by the BCS Öko-Garantie GMBH, Nurnberg, Germany as seaweed extract. The composition of bio-activator was organic matter (67%), K_2O (1.5%), alginic acid (18%) and gibberellic acid (250 ppm). The bio-activator was applied by foliar spraying on strawberry 4 times as 40 gr extract in 30 L water per decare. Moreover, fertilizer was applied uniformly to all treatments during the trial by drip irrigation and foliar spraying. After planting, equal amount water (179 mm) was applied to all plants until the plants were reached trifoliate and then 4 different irrigation levels were introduced. The water quantities were calculated by using Eq (1) as 0.5 (IR50), 0.75 (IR75), 1.00 (IR100) and 1.25 (IR125) times and the pan evaporation measured by the Class A pan.

$$t = (A \times Ep \times Pc \times Kcp) / (q \times n) \qquad (1)$$

where, t is the irrigation time (hours), A: the area of plot (m^2), Ep: the cumulative free surface water evaporation at irrigation interval (mm), Pc: the plant cover (%), Kcp: the crop-pan coefficient which is taken 1.25, 1, 0.75, 0.5 throughout the trial, q: the flow rate of emitters and n: the number of emitters in the plot.

The effects of different irrigation levels and bio-activator applications on fruit diameter, length and weight during the active harvest period (March–May) were determined for 'Rubygem' and 'Kabarla' strawberry cultivars. While fruit diameter and length were measured by a digital caliper, fruit weight was measured by precision scales (precision of 0.1 g). The obtained data were analyzed with the statistical program JMP version 5.0.1.

Results and Discussion

Total irrigation amount were applied as 451, 397, 343 and 288 mm to IR125, IR100, IR75 and IR50 from beginning of the trial to the end, respectively. In previous studies, they reported that irrigation water applied to strawberries vary from 250 mm to 825 mm (Kanber, 1986, Yuan, 2004; Kumar, 2011; Lozano, 2016, Kapur, 2018). The fruit diameter, length and weight values for both cultivars were presented in Table 1 and Table 2.

Differences due to irrigation x month interactions on fruit diameter, length and weight values were statistically significant for both cultivars. While IR 125 (40.7 mm and 33.1 mm) had the highest, IR 50 (36.3 mm and 29.5 mm) had the lowest fruit diameter values for both cultivars. Whereas in the 'Rubygem' cultivar IR 125 (42.3 mm) had the highest, IR 50 (40.0 mm) had the lowest fruit length value, in the 'Kabarla' cultivar IR 100 (36.0 mm) had the highest, IR 50 (40.0 mm) had the lowest fruit length value. While in the 'Rubygem' IR 125 (32.4 g) had the highest, IR 50 (26.1 g) had the lowest fruit weight value, in the 'Kabarla' IR 100 (20.1 g) had the highest, IR 50 (14.6 g) had the lowest fruit weight value. Besides IR 50 application in both cultivars, the smallest fruit diameter, length and weight values were significantly different from the other three applications in the same group. Giné Bordonaba and Terry (2016) reported that deficit irrigation on strawberries caused reductions in fruit length. Kapur and Şahiner (2019) found that water stress significantly reduced fruit size in the 'Fortuna' strawberry cultivar. Also, Çeliktopuz et al. (2019) determined that IR50 irrigation application caused significantly decreased (11 %) on fruit weight in 'Fortuna' cultivar.

It was determined that in cultivar 'Rubygem' in which applied bio-activators produced 1.8 mm wider, 1.2 mm longer and 2.6 g heavier fruits than the control plants. However,in cultivar 'Kabarla', bio-activator application did not significantly affect the diameter, length and weight values of the fruit. The lowest average fruit diameter, length and weight values for both cultivars were obtained from the fruits harvested in May on the end of the growing period. As the season progresses, factors such as increasing evapotranspiration and temperatures, decreasing plant growth and increasing vegetative structure are thought to adversely affect fruit diameter, length and weight. Similarly, Bogunović et al. (2015) reported that the average fruit diameter of strawberry cultivars decreased towards the end of the season. Moreover, Wang and Camp (2000), and Kruger et al. (2012) reported that fruit length and weight decreased at high temperatures.

Cultivars were differed in their response to different irrigation levels and bio-activator applications. While cultivar 'Rubygem' produced average of 39.0 mm fruit diameter, 41.6 mm fruit length and 30.3 g weight, 'Kabarla' produced 32.0 mm, 34.8 mm and 18.4 g weight. Cultivar 'Rubygem' was found to produce wider, longer and heavier fruits than cultivar 'Kabarla'. Giné Bordonaba and Terry (2016) reported difference in fruit size of strawberry cultivars under water stress.

Conclusions

It was thought that the application of IR 50, where water stress was most frequently, reduces the sweating by closing the stomata and consequently disturbing the active water and nutrient carrier mechanism, decreasing fruit diameter, length and weight values. Moreover, application of more water than the need for plants (IR 125) in both cultivars, had not been found to have a positive effect on fruit quality parameters such as diameter, length and weight. Bio-activator applications significantly affected on the fruit diameter and weight for cultivar 'Rubygem' in this study. It can be said that the permanent damages in diameter, length and weight representing the quality of the fruits depend on the level of water stress and cultivar. Although less irrigation water was applied, it is suggest that IR 75 irrigation application should be used together with higher dose bio-activator application in future studies in order to produce fruits with good physical characteristics.

Abstract

Maize assumes worldwide significance owing to its utilization as a human food and livestock feed. Besides high yield as the most important goal, production of hybrids with better nutritional properties is also of great importance. Developing maize varieties with improved grain quality traits can be achieved through breeding, which involve the use of natural genetic variation existing in the breeding pool. The aim of this study was determination of carotenoids and tocopherols content as well as insights into genetic diversity in set of maize inbred lines. Twenty-one maize inbred lines with different kernel type (dent, flint, sweet corn, popcorn) and kernel color (yellow and orange) were evaluated under RCB design with two replications in Zemun Polje during 2017 and 2018 and their carotenoid and tocopherol contents in grain were determined by high-performance liquid chromatography. Analyses of maize inbreds revealed wide genetic variation for lutein and zeaxanthin (14.94–39.21/14.30-38.19 μg/g), β-carotene (1.95–15.34/1.40-14.03 μg/g), α tocopherol (3.95-18.0/ 3.72-17.70 μg/g) and γ tocopherol (18.25-88.05/20.97-88.60 μg/g) in 2017 and 2018, respectively. The highest value of β-carotene had inbred line P21, L+Z one sweet corn inbred line and α – tocopherol inbred GR-9. Also, cluster analysis based on 21 SSR primers polymorphism was done. A total of 134 alleles were detected with average number of alleles 6.3. The dendrogram consisted of two clusters, each cluster was composed of several sub-clusters. Most sub-clusters comprised genotypes belonging to different kernel type/color groups. The lines with high content of particularly micronutritients may be used in breeding program to improve nutritional value.

Keywords: *carotenoids, genetic diversity, maize, tocopherols.*

Introduction

The carotenoids present in maize grain are classified into carotenes (*β*-caroteno e *α*-caroteno) and xanthophylls (lutein, zeaxanthin and *β*-criptoxanthin), with higher concentrations of lutein and zeaxanthin compared to other carotenoids. These compounds have great importance for human health, acting in mechanisms related to cancer, cardiovascular diseases and macular degeneration prevention in humans (Fraser and Bramley 2004). Also, maize kernels are rich in total tocopherol consisting α-, β-, γ- and δ- isoforms. Tocopherols, which are vitamin E compounds, play an important role in maintaining human health. The deficiency leads to age-related macular degeneration, neurological disorders, cancer, cataracts, Alzheimer's-, cardiovascular-, and inflammatory-diseases (Bramley *et al*. (2000)). The efforts thus directed to increase carotenoids and tocopherols in maize will have positive impact on the health and well-being of humans. Food fortification has been used worldwide to alleviate micronutrient deficiencies, but not had been found to be viable in the long run (Tanumihardjo *et al.* 2007). On the other hand, development of micronutrienten riched plant through biofortification holds promise for sustainable and cost-effective food-based solutions to combat micronutrient deficiencies (Pfeiffer and McClafferty 2007).

For breeding purposes and biofortification improvement in maize, it is necessary to have naturally occurred variability, and the first step is to identify concentration of micronutrient of interest, e.g. carotene, xantophylls, tocopherol etc. Information pertaining to the extent of variation for kernel carotenoids among diverse maize germplasm and the effect of environment on the performance of the genotypes, if any, assume tremendous significance to formulate an effective breeding strategy. Intensive efforts are currently being undertaken to develop maize inbreds enriched with carotenoids especially provitamin A (Babu *et al*. 2013; Gupta *et al*. 2013; Frano *et al*. 2014).

Maize exhibits great natural variation considering carotenoids and tocopherol contents. Provitamin A carotenoids (β-cryptoxantin, α-and β-carotene) usualy represent 10-20%, whereas zeaxantin and lutein are dominant carotenoids with 30- 50% of total content in maize grain (Ortiz- Monasterio *et al*., 2007). Compared with other staple foods, maize grains contain high level of tocopherols. α-tocopherol is the major vitamin E in nearly all green plants, in non-green plant parts, such as seeds and fruits, γ-tocopherol is preferentially found instead (Matea *et al*., 2008). Several studies have shown significant differences among maize inbreds for carotenoid and tocopherol levels (Quackenbush *et al*., 1963; Egesel, 1997).

Maize is one of the most important food, feed, and industrial crops globally. It can be classified based on endosperm and kernel constitution as flint, dent, floury, waxy, sweet, and pop corn; kernel colour (white, yellow, orange, blue) and maturity. Maize Research Insitute „Zemun Polje" gene bank contains maize genotypes with enormous genetic variability which could be potential sources of beneficial alleles for various traits of interest.

SSR markers have been utilized extensively in maize to characterize the genetic structure and diversity, to construct phylogenetic trees, to define potential heterotic groups, and to identify unique sources of allelic diversity. Carneiro Vieira *et al.* (2016) disscussed importance and wide application of SSR markers in plant genotyping and stated that over the period from 2010 to 2015, the 930 articles applying this technique in the genetic analysis of cultivated plants were published according to Web of Science. This report proves the relevance of SSRs in plant genotyping in spite of the fact that SNPs are stated as improved marker technique with many advantages relative to other types of molecular markers.

Material and methods

Twenty-one genotypes from Maize Research Institute gene bank with different kernel type (sweet corn L7-L11, popcorn L12-L14) and kernel color (orange L1-L6, and yellow L15-L21) was analyzed for carotenoids and tocopherols content by high performance liquid chromatography (HPLC). Maize grain, from selfed ears, from field trial conduct in Zemun polje in 2017 and 2018, were milled into flour (particle size less than 500μm). Standards for carotenoids (lutein, zeaxantin and β-carotene) and tocopherol (α-, γ+β and γ) were produced by Sigma Aldrich (Germany). Carotenoid content and composition was determined using HPLC, slightly modified method proposed by Rivera and Canela, (2012). Tocopherols (α-, γ+β and γ) were extracted using method described by Gliszczyńska-Świgło *et al.* (2007).

Twenty-one genotypes from Maize Research Institute gene bank with different kernel type and color were selected for molecular characterization using 21 highly informative SSR markers. For each group of kernel type/colour, leaf samples were prepared for DNA isolation taking tissue from five individual plants for each tested line. Genomic DNA extraction was performed applying modified Dorokhov and Klocke (1997) protocol. Total volume of each PCR reaction was 25 μl and final concetrations of components were as follows: 1xbuffer, 0.5μM primers, 0.8mM dNTPs each, 1U of Taq Polymerase (Thermo Scientific), 2 μl of 25 μg/μl genomic DNA and sterile water. PCR amplificaton was done using following program: 5 min intial denaturation step at 94°C, followed by 35 cycles of 94°C for 30s, 1 min of annealing at temerature specific for each primer, 2 min of extension at 72°C and final exension for 10 min at the same temperature. Polyacrylamide electrophoresis was done for PCR products separation (8% gels, 1 hour at 60mA, BioRAD tetra cell) and results were documented by photographing the gels under UV light using Biometra BioDocAnalyze Live gel documentation system. Cluster analysis was done with MEGA 7 using matrices of genetic distances calculated in PowerMarker V3.25 applying Rogers' coefficient and UPGMA method.

Results and disscussion

The estimation of carotenoids and tocopherols using HPLC revealed the existence of considerable variation among the maize inbreds. Analyses of 21 maize inbreds revealed wide genetic variation for lutein+ zeaxantin (14.94–39.21/14.30-38.19 μg/g) and β-carotene (1.95–15.34/1.40-14.03 μg/g), α tocopherol (3.95-18.0/ 3.72-17.70 μg/g) and γ tocopherol (18.25-88.05/20.97-88.60 μg/g) in 2017 and 2018, respectively. The mean lutein + zeaxantin concentration was 26.08 μg/g, while the same for β-carotene was 6.70 μg/g. The orange lines have the highest average lutein+zeaxantin content 29.60 μg/g and 10.34 μg/g for β –carotene, folowing with yelow inbreds (25.43/5.56 μg/g), sweet corn (24.06/5.11 μg/g) and popcorn have the lowest (23.98/4.74 μg/g). Among the lines included in our diverse maize panel, β carotene levels reached as high as 15.34 μg/g in L6 (P21). The sweet corn inbred L7 (38.7 μg/g), and two orange inbreds L3 (37.47 μg/g) and L1 (36.65 μg/g) were found promising for lutein+zeaxantin, while four orange inbreds L6 (P21, 14.69 μg/g), L3 (10.80 μg/g), L4 (10.63 μg/g) and L5 (10.68 μg/g) were identified with high β-carotene (Table 1). The observed variation for carotenoids is in agreement with the reports of Egesel *et al*. (2003), Menkir and Maziya-Dixon (2004) and Menkir *et al*. (2008). Chander *et al*. (2008) also observed a similar trend of variation while evaluating a set of Chinese germplasm, and found less provitamin A concentration and more of lutein and zeaxanthin. Promising inbred P21 with >15 μg/g of provitamin A showing potential for use in breeding programme (Zhang *et al*.2012; Babu *et al*. 2013). The content of lutein+zeaxantin (26,54 μg/g /25,64 μg/g) as well as β-carotene (6,83 μg/g /6,57 μg/g) was higher in 2017 than in 2018, respectively.

L19	yellow dent	22,20	27,39	4,80	4,53	15,61	16,43	30,80	36,47

L20	yellow dent	31,21	31,12	4,62	4,90	14,26	14,60	30,55	39,56
L21	yellow dent	29,53	24,91	8,72	8,56	10,89	10,96	70,54	72,38

As it was previously shown (Combs and Combs, 1985), the most abundant form of tocopherols in maize kernels were γ+β. The content varies from 18,25 to 88,05 μg/g in 2017 and from 20,97 μg/g to 88,60 μg/g in 2018 (Table 1). Average content of α tocopherol was 11.79 μg/g and for γ tocopherol 52.14 μg/g. The content of α tocopherol (12,26 μg/g /11,32 μg/g) as well as γ+β tocopherol (54,80 μg/g /49,47 μg/g) was higher in 2018 than in 2017, respectively. The popcorn lines have the highest average α tocopherol content 14,21 μg/g, folowing with orange inbreds (12,69 μg/g), sweet corn (11,13 μg/g) and yelow inbred lines have the lowest (10,45 μg/g). While, sweet corn lines have the highest average γ+β tocopherol content 77,17 μg/g, folowing with popcorn inbred lines (51,00 μg/g), orange inbreds (43,12 μg/g), and yellow inbred lines (42,47 μg/g). Two inbred lines, one with orange kernal (L5) and one with yellow kernal (L18) have the higest content of α tocopherol (18,0/18,7 μg/g and 16,84/17,68 μg/g, respectively). The high γ+β tocopherol content have three swet corn inbred lines L8 (88,65/88,60 μg/g), L11 (75,16/80,15 μg/g) and L9 (74,44/79,53 μg/g). The level of most important, α-tocopherol is about 20% of total tocopherols in maize and increased α-tocopherol is commercially desirable because of its higher anti-oxidant activity than γ-tocopherol (Rocheford *et al.*, 2002).

A panel consisted of 21 maize inbreds differed according to kernel type (dent, flint, popcorn, sweet maize) and kernel color (orange, white, yellow) was tested using 21 microstelite markers. All of the genotypes studied could unequivocally be distinguished with the combination of the SSRs used. In total, 134 SSR alleles were identified, with a mean of 6,3 alleles per locus. PIC values ranged from 0.56 to 0.89, average 0.73. Wende *et al.*, (2013) analysed 20 inbreds using 20 microsatellites and detected 108 allels with an average of 5.4. This result corroborates the finding of Liu *et al.* (2003) that 9–12 SSR markers are sufficient to genotype maize inbred lines. In order to gain further insight into the genetic diversity among different groups of the maize inbreds, a neighborjoining tree based on Roger's genetic distance was constructed. The dendrogram (Figure 1) consisted of two clusters (I and II). Each cluster was composed of several subclusters. Most subclusters comprised genotypes belonging to different kernel type/color groups. Cluster I included two subclusters. One of them, Ia was divided in two smaller groups. One group consisted of four swet corn inbred lines and one orange and the other consisted of two orange and one yellow inbred lines. The second group have four yellow inbred lines. Ib cluster have also two groups. First group comprised three popocorn and two yellow inbred lines and second one three orange and one swet corn inbred lines.

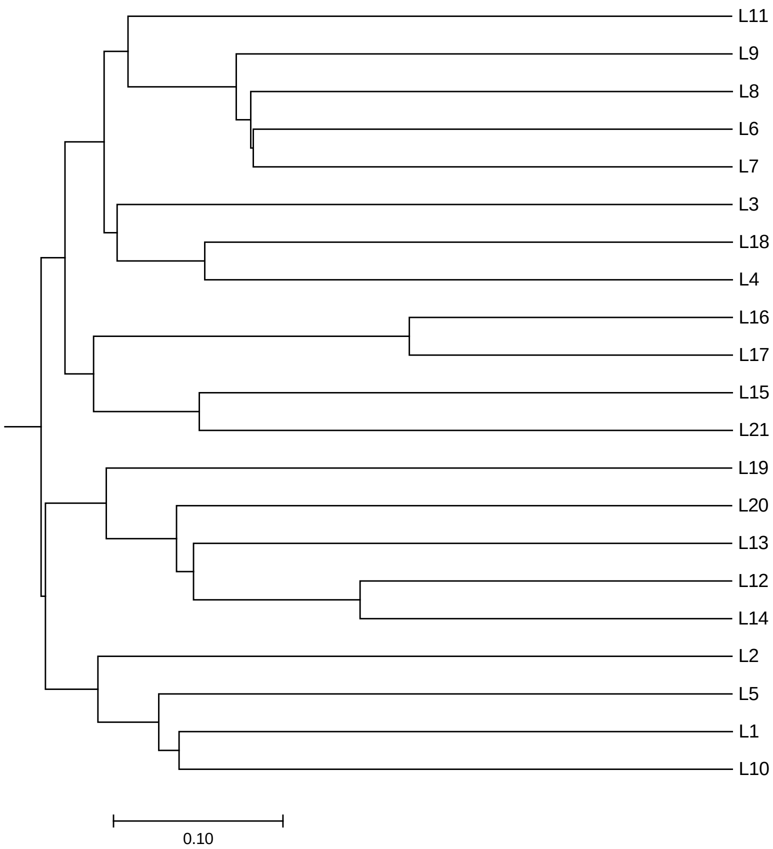

Figure 1. Dedongram of 21 maize inbred lines based on 21 SSR markers

Conclusion

The great natural variation for carotenoids and tocopherolos are presented in maize inbred lines with different kernal type (normal, sweet corn, popcorn) and kernal color (white, yellow, orange**).** The sweet corn inbred L7 and two orange inbreds L3 and L1, promising for lutein+zeaxantin, orange inbreds L6 (P21) with high β-carotene as well as two inbred lines, one with orange kernal (L5) and one with yellow kernal (L18) with high content of α tocopherol have potential for use in breeding programme.

Thus, inbreds with high lutein and zeaxanthin identified in the study can be used in developing hybrids specifically for poultry industry, and inbred identified with high β-carotene would be useful in eveloping provitamin A enriched hybrids.

Acknowlegment

This results is part of project TR31068 Ministry of education, science and tecnological development Republic of Serbia.

Abstract

The aim of this study was to evaluate mineral composition of two commonly cultivated pepper varieties from Serbia (cultivars *Kalifornijska* and *Slonovo uvo*), at three ripening stages. Concentration of macro (K, Ca, Mg, Na) and micro elements (Zn, Fe, Mn, Cu, B, Cr, Mo, Se, Li, Al), and heavy metals (Pb, Hg, Cd, As, Ni) was determined, using AAS and ICP-MS, after microwave-assisted digestion. Relative standard deviations of AAS and ICP-MS measurements, for the most of analyzed elements, were between 0.08 - 9.28 %, indicating that precision was satisfactory. Potassium was the most abundant element in all samples, followed by Mg and Ca. Among the investigated micro elements the average content of zinc was the highest, followed by iron, for most of analyzed samples. Zinc and iron were followed by copper, manganese and boron. Semi-mature peppers of cultivar *Kalifornijska* were richer in K, Ca, Mg, Fe and Zn compared to other maturity stages. For cultivar *Slonovo uvo* results were different compared to cultivar *Kalifornijska*. The content of K and Ni increased with ripening of fruit, while the content of magnesium decreased with ripening of fruit, which was not case for cultivar *Kalifornijska*. The higher values of Mg, Fe, Zn; lower values of Ca and higher values of Cu in cultivar *Slonovo uvo* were reported by different authors for other pepper varieties.

Keywords: *pepper, mineral composition, maturity stage, AAS, ICP-MS.*

Introduction

Sweet red pepper (*Capsicum annuum* L.) is an important vegetable crop in the world and Serbia (Tebić, 2010; Bhandari, 2016). Many varieties that are cultivated differ in shape, size and aroma (Todorova, 2017; Ilić, 2013). Peppers are good sours of minerals, vitamins C, A, E, phenols and carotenoids and have important antioxidant properties (Kolton, 2011; Martinez, 2007; Guil-Guerrero, 2006). Composition of peppers is influenced by growing conditions, variety, maturity, harvest period, pre-harvest and post-harvest handling (Martinez, 2007; Guil-Guerrero, 2006). Peppers are mostly consumed as fresh or dried, but also as frozen, smoked and fermented (Berke, 2012). Pepper fruits are consumed in different stages of maturity, green and red ones are the most used. Due to intensive respiratory and metabolic processes green (immature) peppers have shorter shelf-life than the mature ones (Silva, 2013; Martinez, 2007).

Pepper fruits are rich in macro elements (potassium, phosphorus, magnesium, calcium, sodium) and some micro elements such as iron and zinc, while content of other micro elements vary significantly (Angeles Botella, 2017; Lopez, 2013; Rubio, 2002).

Trace elements or micro elements are those that are needed in small quantities, less than 100 mg/day, for normal functioning of plants and human body. They include Co, Mo, Mn, Zn, Cr, Fe, Cu, and Se. Nickel, B and Al are also trace elements, but their biological role in human is still unknown (Rattanachaiwong, 2019; Fillipini, 2019). Beside their essential role, some of them may be toxic at higher concentration (Cu, Cr, Mo, Ni, Se, Al and Zn) (Tokalioglu, 2018; Tokalioglu, 2019).

On the other hand, heavy metals, such as cadmium (Cd), mercury (Hg), lead (Pb) and arsenic (As) are of more concern, because they are toxic and have cumulative properties. These elements mostly accumulate in liver, kidneys, lungs, fat depots and muscles and can cause many damages and problems to the human body (Papadomichelakis, 2018; Tokalioglu, 2018). Contamination of vegetables is mainly caused by irrigation water, environment, fertilizers and pollutants from industry and vehicle (Li, 2018; Tokalioglu, 2019).
The aim of this study was to determined mineral composition and heavy metal content of two pepper varieties commonly cultivated in Serbia, at three maturity stages.

Material and Methods

Two pepper cultivars, at three ripening stages: green, semi-mature and mature were obtained from local farmers in Serbia. Samples were collected in September 2018. After collection, samples were washed, dry with paper towel, milled to pepper pulp and then frozen in thin layer until analysis.
Nitric acid (65% w/w) and hydrogen peroxide (30% w/w) were purchased from Sigma Aldrich (St. Louis, USA). Distilled water was used for dilution of digested mixture, while HPLC grade water was used for preparation of standard solutions. Individual single-element stock solutions of K, Na, Ca and Mg, with concentration of 1000 mg/dm^3 were supplied by AccuStandard (New Haven, USA). Multi-element standard solution for ICP-MS, with concentration of each element 10 μg/cm^3, was supplied by AccuStandard (New Haven, USA).
Water content was determined by gravimetric method after drying to constant weight at 105^{o}C.
Microwave-assisted digestion was performed in closed-vessels (PTFE vessel). Peppers were weighted (0.5 g), placed in vessels and mixed with 5 ml HNO_3 and 2 ml H_2O_2. After that vessels were closed and placed in microwave oven. Digestion lasted 35 minutes with following regime: 10 min to 150^{o}C and hold 5 min; then 15 min to 190^{o}C and hold for 15 minutes. After cooling of vessels, obtained mixtures were diluted to 50 cm^3. One blank solution was run with set of 12 pepper samples. The concentrations of micro elements and heavy metals were determined by ICP-MS (iCAP Q, Thermo Scientific, UK), while the concentrations of macro elements were determined by AAS (Agilent Technologies, 200 Series AA, USA). In this study concentrations of following macro elements were investigated: K, Na, Ca and Mg; concentrations of following micro elements : Zn (64), Cu (65), Se (77), Mo (95), Li (7), Al (27), B (11), Cr (52), Fe (57), Mn (55), and heavy metals: Pb (206), Hg (200), Cd (111), As (75), Ni (60). The wavelengths selected in measurements of Ca, Mg, Na and K were 422.7 nm, 285.2 nm, 589.0 nm and 404.4 nm; respectively.
Results are expressed as mean ± SD (standard deviation). The significance of differences between mean values was determined by an analysis of variance using MINITAB software package (Release 15, Minitab Inc., State College, PA). Differences were considered significant at $p < 0.05$.

Results and Discussion

The moisture contents were 91.3%, 92.9% and 93.4% for green, semi-mature and mature peppers, respectively of cultivar *Kalifornijska*, and 92.7%, 93.7% and 91.9% for green, semi-mature and mature peppers of cultivar *Slonovo uvo*, respectively.
In Table 1 are given the mean values of minerals and heavy metals, expressed on fresh weight, in pepper *Kalifornijska* at three ripening stage. In pepper *Kalifornijska* at all three ripening stages there was no detection of Mo, Li, Al, Cr and Hg. Potassium was the most abundant mineral in all three ripening stages, which content ranges from 135 mg/100g fresh weight to 162 mg/100 g fresh weight, followed by Mg, Ca and Na. Such order of the content of macro elements is in agreement with research of Rubio et al (2002) and Martinez et al

(2007), while the content of magnesium is higher than the content of calcium for other pepper varieties and researches of other authors (Bernardo, 2008; USDA database; Bhandari, 2016). Macro elements are followed by microelements. The most abundant micro element was Zn at all three ripening stages, followed by Fe, Cu, Mn and B. The content of Fe and Zn in analysed samples was higher compared to data of other authors, while the content of Cu and Mn were similar (Rubio, 2002) or lower compared to Martinez et al (2007). At all three ripening stages heavy metals Pb and Ni were detected, while Cd and As was detected in green and mature pepper. The lead content is significant and ranges from 173 μg to 289 μg per 100 g of fresh weight samples.

Table 1. Mineral and micro element content of pepper *Kalifornijska* in different ripening stages, per 100 g of fresh sample

Metal	Ripening stage		
	Green	Semi-mature	Mature
	mg/100g		
K	$135 \pm 0.02^{b,c}$	$162 \pm 0.02^{a,c}$	$144 \pm 0.03^{a,b}$
Na	$2.10 \pm 0.06^{b,c}$	$1.60 \pm 0.30^{a,c}$	$3.47 \pm 0.14^{a,b}$
Ca	$10.9 \pm 0.02^{b,c}$	$13.7 \pm 0.20^{a,c}$	$10.7 \pm 0.03^{a,b}$
Mg	$33.3 \pm 0.38^{b,c}$	$37.0 \pm 0.25^{a,c}$	$32.6 \pm 0.33^{a,b}$
	μg/100g		
Fe	949 ± 41.8^{b}	1686 ± 207^{a}	1277 ± 393
Zn	1515 ± 418	2499 ± 466	2465 ± 1767
Cu	$74.9 \pm 3.30^{b,c}$	$55.3 \pm 4.96^{a,c}$	$186 \pm 2.88^{a,b}$
Mn	$54.8 \pm 0.42^{b,c}$	$50.4 \pm 1.39^{a,c}$	$47.0 \pm 1.09^{a,b}$
B	17.5 ± 0.18^{c}	16.1 ± 0.95^{c}	$18.8 \pm 0.13^{a,b}$
Ni	$164 \pm 1.72^{b,c}$	$51.1 \pm 1.57^{a,c}$	$65.2 \pm 1.89^{a,b}$
Pb	$173 \pm 0.38^{b,c}$	$289 \pm 11.1^{a,c}$	$238 \pm 5.28^{a,b}$
Cd	$2.68 \pm 0.33^{b,c}$	n.d.	0.81 ± 0.50^{a}
As	0.94 ± 0.65	n.d.	0.40 ± 0.60

Mean value ± SD. a-significantly different from green; b-significantly different from semi-mature; c- significantly different from mature.

The highest content of K, Ca, Mg, Fe and heavy metal Pb was obtained in semi-mature pepper. Due to the fact that the size of the fruit and water content, for this pepper cultivar, increased with the degree of ripeness, it can be concluded that peppers fruits of this cultivar adopted minerals from soil to a certain stage of maturity, after which the content of the minerals decreased due to further maturation, as it is likely to continue adoption of water, while the adoption of minerals stops.

The content of Mn and Ni is higher in green peppers, which means that these metals are accumulated in pepper fruit while it is green, and with further growth their content decreased due smaller absorption and dilution with further water adsorption. The content of Na and Cu was the highest in mature peppers, which indicates that these minerals were still absorbed from soil until full maturity.

The mean values for minerals and heavy metals, expressed on fresh weight of *Slonovo uvo* cultivar are listed in Table 2. In pepper fruits of cultivar *Slonovo uvo* at all three ripening stages there was no detection of Mo, Li, Al, Cr and Pb. The order of the levels of the macro elements was the same as for cultivar „*Kalifornijska*", at all maturity stages: K>Mg>Ca>Na. The most abundant micro element in semi-mature and mature pepper was Fe, while in green pepper it was Zn. These minerals are followed by Cu, Mn and B. The concentration of K and

Ni increased with ripening of pepper fruit, while the concentration of Mg decreased with the ripening of pepper fruit.

Table 2. Mineral and micro element content of pepper *Slonovo uvo* in different ripening stages, per 100 g of fresh sample

Metal	Ripening stage		
	Green	Semi-mature	Green
	mg/100g		
K	161 ± 0.005^{b,c}	170 ± 0.02^{a,c}	197 ± 0.002^{a,b}
Na	0.57 ± 0.03^{b,c}	0.95 ± 0.06^{a,c}	0.74 ± 0.00^{a,b}
Ca	12.9 ± 0.02^{b,c}	8.47 ± 0.01^{a,c}	14.7 ± 0.18^{a,b}
Mg	36.8 ± 0.23^{b,c}	17.9 ± 0.62^{a,c}	16.3 ± 0.18^{a,b}
	μg/100g		
Fe	377 ± 118^{b}	1171 ± 71.7^{a,c}	524 ± 118^{b}
Zn	573 ± 73.7^{b,c}	306 ± 13.2^{a}	411 ± 16.8^{a}
Cu	144 ± 4.94^{b,c}	98.8 ± 4.70^{a,c}	127 ± 2.32^{a,b}
Mn	60.7 ± 1.01^{b}	55.6 ± 1.85^{a,c}	64.1 ± 2.06^{b}
B	20.4 ± 0.49^{b}	32.1 ± 0.93^{a,c}	23.3 ± 0.74^{b}
Ni	44.9 ± 2.53^{b,c}	56.3 ± 3.03^{a,c}	150 ± 5.62^{a,b}
Hg	n.d.	n.d.	31.5 ± 3.9^{a,b}
Cd	n.d.	0.08±0.77	0.47 ± 0.88
As	0.29 ± 0.88	1.80 ± 1.16	n.d.

Mean value ± SD. a-significantly different from green; b-significantly different from semi-mature; c- significantly different from mature.

Zinc and Cu are the most abundant in green peppers, which indicated that these minerals are probably most absorbed while the fruit is green, and with further ripening theirs contents decreased due to dilution (semi-mature fruits). The fact that the concentrations of these minerals were higher in mature then the semi-mature fruits was in agreement with the change of water content for this cultivar. Mercury was detected in mature fruits, while the concentration of Cd in semi-mature and mature peppers; and As in green and semi-mature peppers were low and closed to instrumental limits of detections.
Contents of K and Mn, in fruits of cultivar *Slonov uvo*, are comparable with results reported by Rubio et al (2002). Bernardo found similar values for iron and zinc, higher values for Cu and lower for K and Mn (Bernardo, 2008).

Conclusion

It can be concluded that mineral composition of cultivars *Kalifornijska* and *Slonovo uvo* was influenced by maturity stage, and also by cultivar. The most abundant mineral of analyzed elements was potassium in all samples, followed by magnesium and calcium. Cultivar *Kalifornijska* had higher concentrations of micro elements Fe and Zn, and lead was detected in all samples at different ripening stages, which wasn't case for cultivar *Slonovo uvo*. For cultivar *Kalifornijska* content of K, Ca, Mg, Fe and Zn was the highest in semi-mature fruits. This analysis showed that concentration of K and Ni increase with fruits maturation of cultivar *Slonovo uvo*. When compared to bibliography, data the concentrations of Mn, Fe and Zn in this two pepper varieties were higher and the concentration of Ca was lower in all investigated samples.

Abstract

In China and African countries, the production of the root vegetables especially sweet potato is facing several factors concerning the environmental storage conditions and the need for increased shelf-life of the bulbs. In fact, the storage of the bulbs is considered as one of the critical points of the production of the sweet potato crop around the world. Some of the vintage goals of the Department of Vegetable and Mushroom Growing at the Szent Istvan University were to inspect the influence of storage temperature on the quality change of the stored sweet potato bulbs and detect the weight loss changes during cold and ambient storage. In addition, non-destructive texture measurement of the stored bulbs was carried out using the acoustic response technique. This experimental work consists of two parts: the first part stores the washed and the unwashed bulbs in cold storage at two different temperatures (6 °C and 10 °C) in relative humidity of 85-90 % and determines the weight loss during the storage for washed and unwashed bulbs. The second part is carried out at ambient storage conditions at 20-25 °C and relative humidity of 60-70 %. This experiment proceeds in controlled environmental conditions in laboratories of the Department of Postharvest Science and Sensory Evaluation at Szent Istvan University for cold storage period, while the ambient storage was carried out in the Department of Vegetable and Mushroom Growing lab. According to our results, as it was expected, the percentage of the weight loss during cold storage has increased in different ways. After removal to ambient conditions (shelf-life), mass loss and negative textural changes (softening) became more extent and rapid. However, it was different in case of the examined varieties as well.

Keywords: *Sweet potato, Ipomoea batatas, Washed bulbs, Cold storage, Ambient storage.*

Introduction

Sweet potato (*Ipomoea batatas* L.) belongs to the family *Convolvulaceae* (morning Glory). It is an herbaceous dicotyledonous plant. It is originated in Central and South America (Steinbauer and Kushman, 1971; Yen, 1982; Thurston, 1984; Otterdijk, 1999). It was introduced to Europe in the 16th century and gradually in the 18th and 19th century became an essential food crop. Sweet potatoes are now widely grown throughout the temperate and warm tropical regions, where an adequate water supply is available to support their growth (Tai-Hua and Peng-Gao, 2019).

The nutritional value of the sweet potato is 50% higher than potato (Ofori et al., 2005), while the edible part is not only the bulb, but also the leaves. Concerning the storage of the bulbs, one of the major limitations is its postharvest perishability and the need for increased of the shelf-life (Mpagalile et al., 2007). Also, there are many traditional methods used to store the sweet potato such as heap storage, in-ground storage, platform and pit storage. These methods have been practiced in Nigeria and across African countries by farmers, but the most common traditional method is the pit storage. Pit storage can generally be considered as a cheap

method for the rural communities since it requires minimum materials and it has been reported in many countries for example Indonesia, Malawi and Zimbabwe (Woolfe, 1992). The pit storage method is considered as the best traditional method to store the tubers considering decay, such as sprouting, moisture loss and pathological losses, if compared to other possible storage methods (Yakubu, 2005). According to an experiment concerning storage temperature carried out by Cushman and Smart (1954) earlier, the results showed that the storage of the bulbs at 12-15 °C is advisable (in a fixed relative air humidity at 85 %). Later this was confirmed by Maynard and Hochmuth (2007), who defined the temperature and air humidity in 12-15 °C and 85-95 % for 4-7 months. According to Thompson and Scheuerman (1993) short exposures to temperatures as low as 10 °C may not cause damage.
Quality of bulbs depends on firmness of flesh, however during the storage the weight is reduced due to the loss of water, but this change is closely related to the loss of sugars in the respiration process in the tubers, and in the end the product can soften. The transformation of the carbohydrates especially the decrease in starch and increase in sugar contents (Kimbrough, 1942). However, according to Thompson and Kelly (1957) the taste and the consistency in the cooked product is different. Also the soft product is not marketable, so it is advisable to follow the rate of postharvest softening.
This experimental work objective was also to investigate the influence of different storage temperatures on the physical and the inner contents change during storage, especially focusing on the loss of weight and increase of softening by the use of non-destructive measuring methods.

Materials and methods

The measured parameters focused on physical state and inner contents as well. In this article, the percentage of the weight loss, textural change determined as acoustic stiffness coefficient change, and change of water-soluble dry material content (Brix %, Anthocyanin and β-carotene) were analyzed. The samples of sweet potato were grown at the Experimental and Research Farm of Szent Istvan University at Soroksar, Hungary. The experimental and research farm is sited on the Danube casting site, the physical properties of sandy soil. During the experiment, two varieties were used as the orange variety ('Ásotthalmi-12') and ' Purple' variety (Fig. 1). The propagating material was ordered from Asotthalom, Southern Hungary, and 'mother-bulbs' was propagated and grown in the experimental farm in 2017 in 300 m^2-s.

Figure 1. (A) 'Ásotthalmi-12' Orange Sweet Potato Variety (B) Purple Sweet Potato variety (Photos: author).

This experiment was carried out in a small range space with two varieties of sweet potato bulbs. Two temperature-controlled household fridges were used to store the sweet potato bulbs under two different temperature conditions at the Department of Postharvest Science and Sensory Evaluation, Faculty of Food Science, Szent Istvan University. The relative humidity and temperature were collected by a relative humidity and temperature meter and data logger (Trotec Bl-30 climate data logger). 80 bulbs were stored in two fridges with 5 bulbs in 4 repetitions in 4 treatments. Markings of our treatments and storage conditions are shown in Table 1.

Table 1. Treatments and environmental conditions during the cold and ambient storage.

Variety	**Treatments**		**Rel. Humidity (%)**	**Storage temperature**	**Sign**	
Control (Orange and Purple variety)	-			-	O	P
Ásotthalmi-12' orange fleshed and **Purple fleshed**	Cold storage	Unwashed	80-90%	6 °C	AO	AP
				10 °C	BO	BP
		Washed		6 °C	CO	CP
				10 °C	DO	DP
	Ambient storage		60-70%	20-25 °C	all above	

The cold storage of the bulbs lasted from 2nd of November until 12th of December. After this, the bulbs were transferred to shelf-life (ambient storage) from 13th of December until 15th of January in order to notice the effect of different environmental conditions on quality and weight loss during the storage and to detect the convenient method to store the sweet potato bulbs. For weight-loss determination laboratory scales and rulers were used in order to collect the individual weight (g) and length (cm) data of the bulbs.

Acoustic measurements: Nondestructive acoustic stiffness analysis was carried out at the Department of Postharvest Science and Sensory Evaluation at Szent Istvan University, Faculty of Food Science. The purpose-built measuring device (developed at the Department of Physics and Control, Szent Istvan University) consists of a data acquisition hardware and software in order to detect and analyze the characteristic sound response related stiffness of the bulbs. Measurements were carried out according to the measurement of carrots reported by Zsom-Muha and Felföldi (2007). The vertically located sample was excited for its sound response by a gentle hit on its top. The characteristic sound response was collected and recorded by a microphone located under the bulb in the sample holder. Then it was transformed and analyzed by a special software called Stiffness. All points were marked, in this case the second time exciting (knocking) point was the same. 10 sound samples were collected per every bulb, so 800 samples were evaluated. The acoustic stiffness coefficient of the bulbs (S, m^2s^{-2}) was calculated as $S = f^2 * l^2$, where the ‘f’ is the characteristic frequency of the sound response (Hz), and the ‘l’ is the length of the bulb (m) (Zsom-Muha and Felföldi, 2007).

Inner content parameters: Sweet potatoes Brix (%) was measured by Hanna HI 96801 type refractometer. Quality of vegetables relates to the quantity of dissolved solids in plant sap (fresh juice to detect the sugar contents as well).

β-carotene content was measured by spectrophotometric analysis using color absorption levels, while Anthocyanin content of purple sweet potatoes was measured by spectrophotometric analysis based on method of Jungmin et al. (2005).

Statistical Analysis: The results were expressed according to basic statistic rules, average ± st. deviation with significance level 5% (α=0.05). Basically, Microsoft 365 ProPlus Excel with Statistic ToolPak and IBM SPSS Statistics v25 software were used for Analysis of Variances (ANOVA).

Results and Discussion

From weekly measurements we calculated the ratio of bulb weight loss (in percentage compared to initial weight). Table 2 includes that from 2nd of November until 15th of January. According to our results, the weight loss increase speeded up especially after the bulbs’ removal from cold to ambient storage conditions (note the change between 13th Dec. and 15th

Jan.). There was a difference between the varieties ('O' - orange and 'P' - purple colored variety). Additionally, difference was also found between washed (marked with C, D) and unwashed (marked with A and B) bulbs. Unwashed bulbs lost their weight earlier with higher intensity. All of 6 °C samples (marked with A and C) suffered faster reduction of weight than samples stored at 10 °C (marked with B and D) especially after removal to shelf-life at ambient conditions due to its susceptibility to too low storage temperature caused physiological disorder under 12 °C (chilling sensitivity and injury), to prove statements of Cantwel an Suslow (2001).

From the 13th of December until the 15th of January, the environmental conditions of storage changed from cold to ambient storage conditions (shelf-life) providing a clear effect on the percentage of weight-loss as (Fig. 2 and Fig. 3). These results are in close connection to the results of mass loss change vs. storage time and temperature as mentioned earlier.
In our figures, connection could be observed as the bulbs lost their weight, the textural change as acoustic stiffness follows the decrease, however the difference of decrease is not linear, and because of the high standard deviations of weight values, significance cannot be stated.
In case of water-soluble dry material content (Brix %), the connection could be observed as well (Figure 4), as a connection between the Brix value decreasing and the change in carotene and anthocyanin content (mg l^{-1}). Unfortunately, data is missing in case of orange variety (O) from January measurement.
The applied storage method affects the quality and the inner content of the bulbs. It has an influence on shelf-life properties also, and additionally, on the postharvest susceptibility of the bulbs to physiological disorders and/or infections caused by many pathogens related rotting diseases.

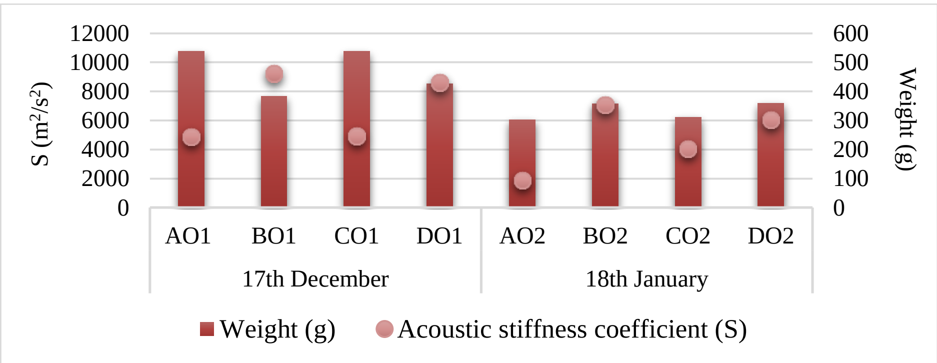

Figure 2. The connection between the orange bulbs weight loss and acoustic stiffness during ambient storage.

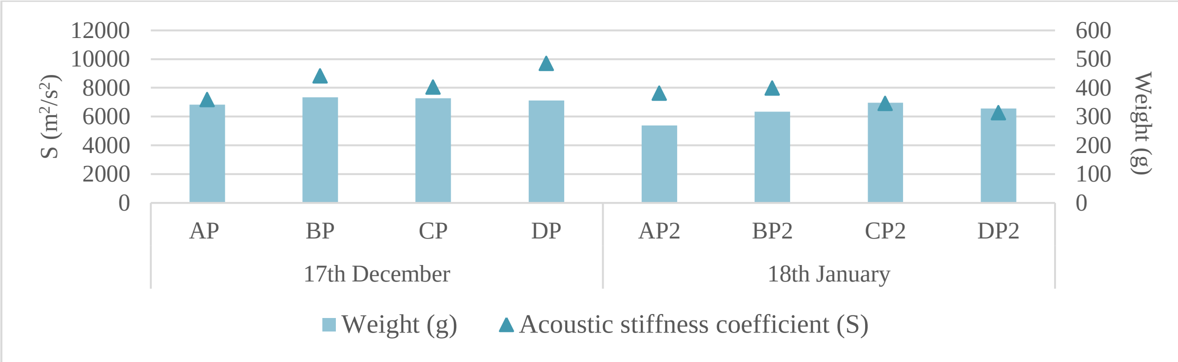

Figure 3. The connection between the purple bulbs weight loss and acoustic hardness factor in ambient storage time.

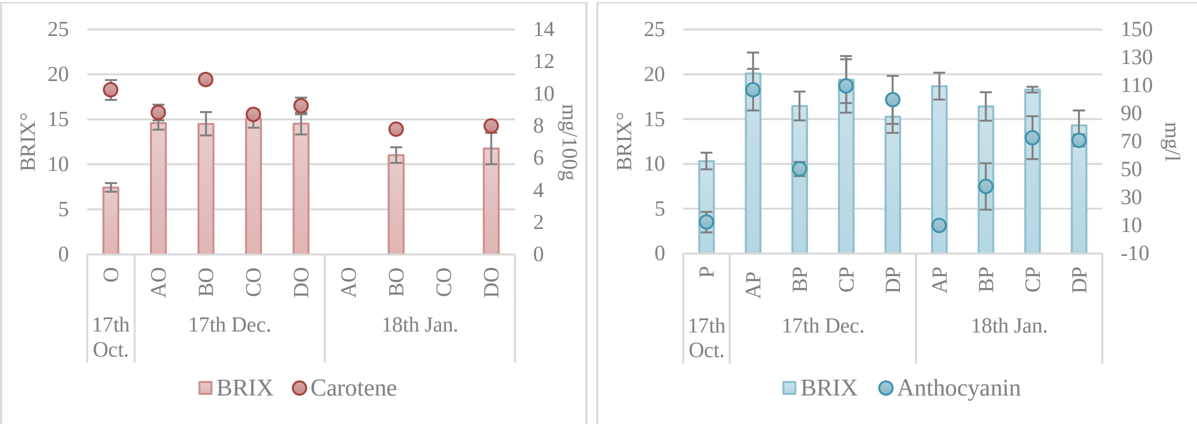

Figure 4. Change of Brix (%) and color contents (carotene and anthocyanin) of flesh in case of Orange (left) and Purple (right) type of sweet potato.

Conclusion

Several important facts were gained during cold storage time and ambient storage time. Effect of different storage environments caused different weight loss. During the cold storage the percentage of the weight loss increased faster in case unwashed orange bulbs on 10 °C, unwashed purple bulbs on 10 °C and washed purple variety on 6 °C. After ambient storage weight loss increased faster in all treatments. While in case of orange variety (O) the weight loss speed seemed independent on the washing treatment, in case of washed purple bulbs the weight loss was slower. Also, the weight loss was slower in every cases of treatments of purple variety, where the water-soluble dry material content was higher. In this case we can state that dry material content has higher effect to weight loss like storage temperature or washing of bulbs during storage time. Moreover, our results agree with Zainalabidin et al. (2019), where reported as the minimum safe temperature to store the sweet potato at low temperature is 13 °C and the chilling injury symptoms occur as the bulbs decline between 0 °C and the safe temperature of storage. However according to Cantwel and Suslow (2001) the recommended environment is dry air humidity and 12,5-15 °C temperature for long term (6-10 mths) storage, in short exposure the 10 °C temperature may not cause damage (Thompson and Scheuerman, 1993).

The non-destructive acoustic stiffness measurement showed interesting results, providing the possibility to follow the weight loss related overall quality and textural changes. Further experiments are needed to be carried out in order to get more information concerning any connections between some of the inner contents' change and textural changes, and with use destructive and non-destructive methods parallel to gain more accurate results.

Abstract

Drying is one of the oldest methods of preserving fruit. In the course of drying process, there is a change in some components of chemical composition to a degree depending on food type, its composition, and drying process itself. The testing was performed in three replications using plum fruits of the 'Čačanska Lepotica', 'Mildora', 'Čačanska Rodna' and 'Stanley' cultivars, at the optimum ripening stage required for drying, based on soluble solid contents. Drying was performed at the experimental dryer using the convective (streaming) drying process, at two constant air temperatures, 90 °C and 70 °C, until attaining 75% of total dry matter in the prunes. In addition to the control, the fruits were subjected to a pretreatment consisting of dipping in boiling water. This paper reviews the values of total sugars, invert sugars and sucrose in fruits of fresh and dried plums (calculated in grams per 100 grams of total dry matter), as well as the change of these parameters in prunes in relation to the fresh fruits (expressed in percentages). Drying temperature affected the change of total sugars, invert sugars and sucrose content in fruit of the tested plum cultivars. On the other side, dipping as an applied pretreatment had no effect on the change of these parameters except in the cultivar 'Čačanska Rodna', which dipped fruits are found to have higher decrease of sucrose compared with non-treated fruits. During drying, hydrolysis of sucrose occurred, manifesting in a dramatic decrease of its content in dried fruits, in relation to the starting raw material in all of the tested cultivars. Intensity of changes was conditioned by varietal characteristics.

Key words: *prune, drying temperature, dipping, invert sugar, sucrose.*

Introduction

Plum (*Prunus domestica* L.) is considered a national fruit species ranking first in the fruit growing of Serbia by both number of trees and by its annual production. Although a major part of plum yield in Serbia is processed into brandy (Popović et al., 2006), the most significant product coming from plum, in terms of nutritional value, is prune. Prune represents significant energy source for human body though is more commonly classified in high nutritional food with special dietetic and physiological importance, primarily due to its protective and therapeutic effect on digestive tract of consumers (Zlatković, 2000; Piga et al., 2003).

Drying is defined as a process of moisture loss resulting from simultaneous existence of the heat and mass transfer phenomena. Plum drying is a slow and long-term process because whole fruits are dried, hence, there are real conditions for various chemical transformations, primarily carbons, since they make up over 90% of the total dry matter of fruit (Friedman, 1996). In plum fruit, the most predominant are sugars, i.e. fermentable sugars (fructose, glucose and sucrose). During plum drying, in addition to oxidation reaction and acid hydrolysis (Dikerman et al., 2004), non-enzymatic browning reactions with sugars participating, such as caramelization and Maillard reaction (Manzocco et al., 2001; Kim end Lee, 2008), can be conducted too. Depending on the intensity of these reactions, characteristic colour and flavour of prune appears but on the other hand, they may lead to degradation of

product aroma and appearance (Dikerman et al., 2004; Sanz et al., 2001). Appropriate drying technology and raw material can affect the flow of these reactions in order to minimize the change of product quality, which is an ultimate goal of each processing.
The aim of the work was to examine the effect of drying temperature and dipping on the change of sugar content, both total and invert sugars as well as sucrose content in fruits of the plum cultivars 'Čačanska Lepotica', 'Mildora', 'Čačanska Rodna' and 'Stanley'.

Material and Methods

For the purpose of testing, plum fruits of the cultivars 'Čačanska Lepotica', 'Mildora', 'Čačanska Rodna' and 'Stanley' were obtained from the plantations of the Fruit Research Institute Čačak, in which standard agro- and pomotechnical practices were performed. Fruits for drying were selectively picked at full maturity stage for the appropriate cultivar, with the total dry mass content 15.77%, 25.50%, 22.67% and 19.59%, with average mass of about 41 g, 23 g, 36 g and 42g, respectively.
Drying of fruits was carried out in an experimental dryer for testing convective drying process (Kandić et al., 2006). An air streaming drying procedure was used at two constant air temperatures, 90 °C and 70 °C. Control fruits (without pretreatment) and dipped fruits (plum fruits which are, in laboratory conditions, immersed into boiling water for 20 seconds) were dried. Fresh plum fruits were placed in a single layer on an inox tray and 6 trays were placed in a drying chamber. Dipped and control fruits were dried simultaneously in the same experiment on the trays symmetrically placed in the drying chamber (3 trays with the control and 3 trays with dipped fruits). Through the trays with plum fruits, vertical heated air stream with predefined characteristics (temperature, flow) was introduced. Direction of vertical streaming during the process of drying was changed alternately and periodically for 60 minutes, thus achieving the same drying conditions on all of the trays. Fruit drying was completed once the fruits achieve 75% of total dry mater.
Fresh fruits have been kept in plastic bags until chemical analyses at –18 °C, while the dried fruits have been kept in plastic bags at room/ambient temperature (20 °C) until chemical analyses, for conditioning. By testing of fruit chemical composition of the investigated cultivars, the following was determined: content of dry matter (DM), obtained by drying at the laboratory dryer "Sutjeska" (Srbija) at 105 °C until constant mass, and the content of total and invert sugars and sucrose (by Luff-Schoorl's method). Results were expressed in grams per 100 gram of total dry matter (g/100 g DM).
Results were shown as arithmetical mean of three replications ± standard deviation and were processed statistically using analysis of variance (ANOVA). For testing of the difference significance of mean values of the tested parameters, Dunkan's multiple grading test for significance threshold was used $P \leq 0,05$.

Results and Discussion

Table 1 shows the content of total sugars, sucrose, invert sugars in the fresh and dried fruits of the plum cultivars, expressed in g/100 g DM for more accurate and clearer comparison. Percentage of the total sugars, invert sugars and sucrose in dried fruits compared to fresh fruit is shown in Graphs 1, 2 and 3, respectively, with the content of these parameters in fresh fruit shown by a line representing 100% of its content. Percentage of contents of the tested parameters depending on the drying temperature (a) and pretreatment influence (b) are shown separately on Graphs.
Analyzing the contents of total sugars in fresh fruit of the tested cultivars (Table 1), leads to an interesting information that the cultivar 'Čačanska Lepotica' had the highest value of this parameter (68.44 g/100 g DM). This could be explained with the fact that this cultivar, due to the lowest contents of total dry matter (15.77%), compared to the other tested plum cultivars,

has a greatest share of total sugars. In 'Mildora', the content of total sugars was 67.48 g/100 g DM, which was higher in comparison with the cultivars 'Čačanska Rodna' and Stanley, as expected, having in mind that this cultivar is known for the high content of total dry matter (Ogašanović and Ranković, 1996) and the total sugars (Mitrović et al., 2006).

Tab.1. Content of total sugars, invert sugars and sucrose (g/100 g DM) in fresh and dried fruit of cultivars

Cultivar	Sample		Total sugars	Invert sugars	Sucrose
Čačanska Lepotica	Fresh plum		68.44 ± 3.17 a	47.11 ± 2.84	20.26 ± 1.55 a
	Prune

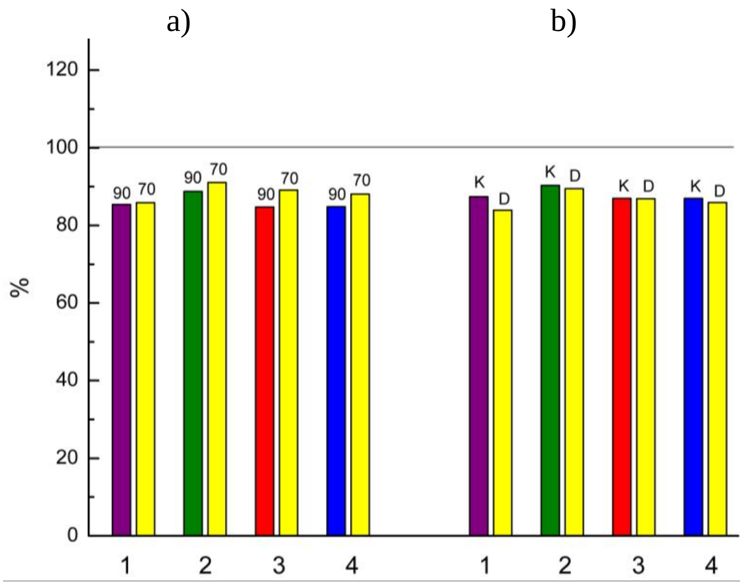
Data followed by different letters within each column and cultivar are significantly diferent according to Duncan's multiple range test at P ≤ 0.05

In dried fruits of all tested cultivars, except in 'Mildora', a lower content of total sugars was found, compared to initial fresh fruit regardless of the applied drying temperature and dipping procedure (Table 1, Graph 1). That loss is about 10-15%, although there was no juice leakage during the drying process. This was probably because of the participation of sugars in non-enzymatic browning reactions. Wilford et al. (1997), investigating the kinetics of sugar change during the drying of the plum cultivar d'Agen at three drying temperatures using convective drying, concluded that the Maillard reaction starts at about 45-50% of moisture loss, and the proof for that is profile change in the presence of some sugars.

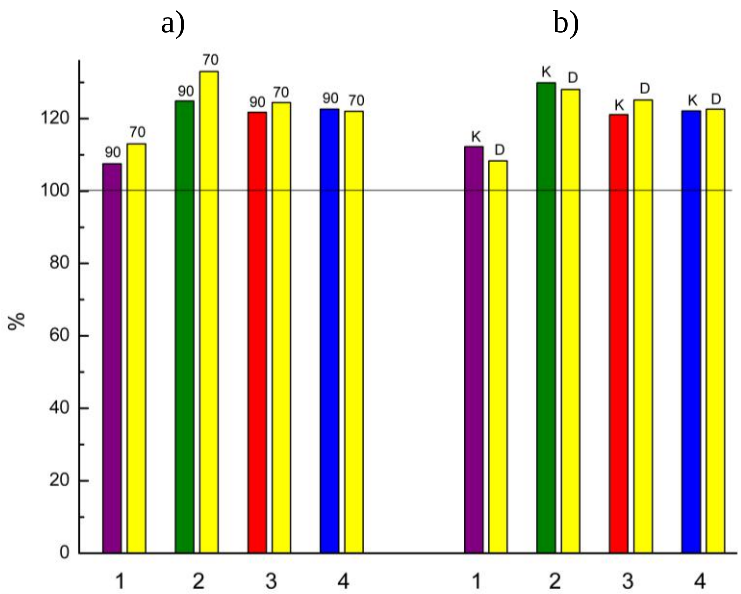
During the drying process, there comes to the hydrolysis of sucrose in plum fruit and the increase in the contents of invert sugars. Analyzing Graph 2, dried fruit of all tested cultivars were found to act similarly regardless of the drying temperatures and dipping procedure applied, i.e. the increase is about 25-30%. Exception is the plum cultivar 'Čačanska Lepotica', in which a minimum increase in the content of invert sugars was observed, of no statistical importance, and which was lower in fruits dried at higher temperatures (7.5% in total) than in dipped fruits where the increase is only 8.3%.



Graph. 1. Total sugars content in prunes compared to the frush plums, expressed as percentages

Legend:

- Cultivar: 1- Čačanska Lepotica; 2- Mildora; 3- Čačanska Rodna; 4- Stanley
- Influence of the drying temperature: 90 °C; 70 °C
- Influence of the dipping pretreatment: K- control; D - dipping



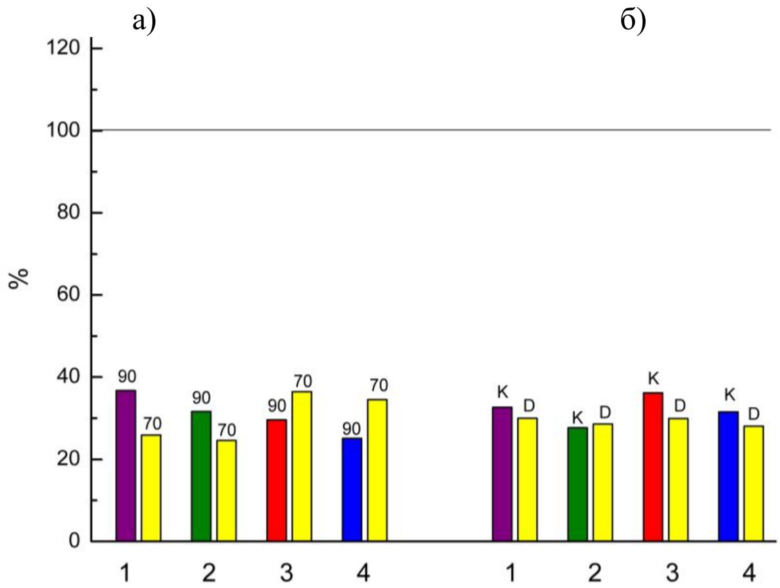
Graph. 2. Invert sugars content in prunes compared to the fresh plums, expressed as percentages

Legend:

- Cultivar: 1- Čačanska Lepotica; 2- Mildora; 3- Čačanska Rodna; 4- Stanley
- Influence of the drying temperature: 90 °C; 70 °C
- Influence of the dipping pretreatment: K- control; D - dipping

Examining the carbohydrate content of prunes and their products, Dikeman et al. (2004) reported a significant increase in the content of glucose and fructose, the two most important monosaccharides in plums, in relation to fresh fruit as a starting material. Cinquanta et al.

(2002) found the increased content of glucose and fructose in dried fruits of all the plum cultivars, whereas in the cultivar 'Stanley' differences in the increased content of these simple sugars among fruits dipped in different manners were noted to be of no statistical significance, compared with non-treated fruits.
As formerly stated, results of the sucrose content in fresh and dried fruit of the investigated plum cultivars are shown in Table 1. In all tested cultivars, dramatically lower sucrose content in dried plum was found compared to fresh fruit.
Analyzing Graph 3, drying temperature is found to have greater impact on the reduced sucrose content in dried fruit of all tested cultivars in comparison with the applied pretreatments. Dried fruits of the cultivars 'Čačanska Lepotica' and 'Mildora' acted in similar way, sucrose content in fruits dried at 90 °C was about 3 times lower than in fresh fruits, while in fruits dried at 70 °C, the content was 4 times lower. In cultivars, 'Čačanska Rodna' and 'Stanley' the opposite was found, and a lower sucrose loss was observed by a lower drying temperature.



Graph. 3. Sucrose content in prunes compared to the frush plums, expressed as percentages
Legend:
- Cultivar: 1- Čačanska Lepotica; 2- Mildora; 3- Čačanska Rodna; 4- Stanley
- Influence of the drying temperature: 90 °C; 70 °C
- Influence of the dipping pretreatment: K- control; D - dipping

Dipping as an applied pretreatment, had much less effect on the reduced sucrose content in dried fruit compared with non-treated fruits, i.e. control. A slight difference was observed between dipped and control fruits in decreased sucrose content in the cultivars 'Čačanska Lepotica' and 'Stanley', whereas in 'Mildora', which dried fruits contain about 3.5 times less sucrose compared to the starting raw material, sucrose loss is the same regardless of whether the fruits are dipped or not. Only in the plum cultivar 'Čačanska Rodna', effect of dipping on reduced sucrose content was recorded so that the dipped fruits contain 3.3 times less sucrose than the fresh fruits and in non-treated fruits, representing control, sucrose amount was reduced 2.7 times.
During the process of plum drying, the hydrolysis of sucrose occurs, thereby generating glucose and fructose. Analyzing the kinetics of carbon hydrate change during drying of the plum cultivar d'Agen, Wilford et al. (1997) found that, during the drying process, sucrose is completely hydrolysed. According to them, low pH value and high moisture of fruit in early stages of drying favour the hydrolysis of sucrose generating glucose and fructose. In their

investigations, at the drying temperature of 70 °C, sucrose was completely vanished in 6-7 hours, while at 90 °C, sucrose loss was noted after 2 hours of drying. Authors Di Matteo et al. (2003) also noted a complete loss of sucrose in dried fruit of the plum cultivar Angeleno. Cinquanta et al. (2002) recorded the complete sucrose loss in dried fruit of the cultivars Angeleno and Empress too, while on the other side in the cultivar 'Stanley' only reduced content of sucrose in dried fruit compared with fresh fruit was noted, thus emphasizing that 'Stanley' is an excellent cultivar for drying. Decrease in sucrose content in the course of drying is not a plum characteristic only as a fruit species. Moreover, in the course of banana drying, the hydrolysis of sucrose occurs, i.e. there is a decrease in content of sucrose in comparison with the starting raw material. (Leite et al., 2007).

Conclusion

Based on the investigation results of the drying temperature and dipping effect on the change of total sugars, invert sugars and sucrose content in fruit of the plum cultivars 'Čačanska Lepotica', 'Mildora', 'Čačanska Rodna' and 'Stanley', the following conclusions can be drawn:

- Drying temperature affected the change of total sugars, invert sugars and sucrose content in fruit of the investigated plum cultivars. Change intensity was conditioned by varietal characteristics.
- Dipping, as a pretreatment applied, had no effect on the change of these parameters content, except in the cultivar 'Čačanska Rodna' in which greater decrease of sucrose compared to non-treated fruits was noted.
- In dried plum fruits of the cultivars 'Čačanska Lepotica', 'Čačanska Rodna' and 'Stanley', a lower content of total sugars was noted, based on the calculation of the total dry matter in relation to initial fresh fruit, regardless of the drying temperatures and dipping procedure applied. The only exception was the cultivar 'Mildora' in which there were no statistical differences in the total sugar content in dried fruit compared to fresh fruit.
- During the drying process, an increase of invert sugars content occurred in all tested cultivars, except in 'Čačanska Lepotica', in which there was no statistically significant increase in the content.
- In the course of plum drying, the hydrolysis of sucrose occurred, which was manifested in a dramatic decrease of its content in dried fruits compared to starting raw material in all tested cultivars.

Abstract

This research involved analyses of six genotypes of the winter bread wheat (Toplica, Takovčanka, Perfekta, Vizija, KG-56S, and Aleksandra) on the experimental field of Centre for Small Grains in Kragujevac during two growing seasons (2011/2012 and 2012/2013). The most important parameters of bread-making quality were analysed (wet gluten content and rheological flour and dough properties). Grain samples were milled using a Brabender Quadrumat Junior laboratory mill. The gluten content was determined by the standard method and rheological flour and dough properties by Brabender Farinograph. Wet gluten content of analyzed wheat genotypes varied depending on the genotype and the year. The cultivar Aleksandra had the highest value of wet gluten content in both years of investigation (35.48% and 39.03%). The analyses of variance showed highly significant differences of wet gluten content between cultivars, investigated years as well as their interaction. The lowest water absorption in the first year of study was found in Takovčanka cultivar (59.2%), while in the second year in KG-56S (63.8%). The cultivar Vizija showed the highest water absorption in both years of studying (62.13% and 67.3%). According to the analysis of variance, highly significant differences for the water absorption were determined between genotypes, examined years and their interaction. Farinograph properties showed that flour of analyzed cultivars belonged to B_1 and C_1 quality groups in the first year, and B_1 and B_2 in the second year. The analysis of phenotypic variance indicated that the highest impact of variance for wet gluten content belonged to year, while for water absorption belonged to cultivar × year interaction.

Keywords: *wheat, quality, gluten, rheological properties.*

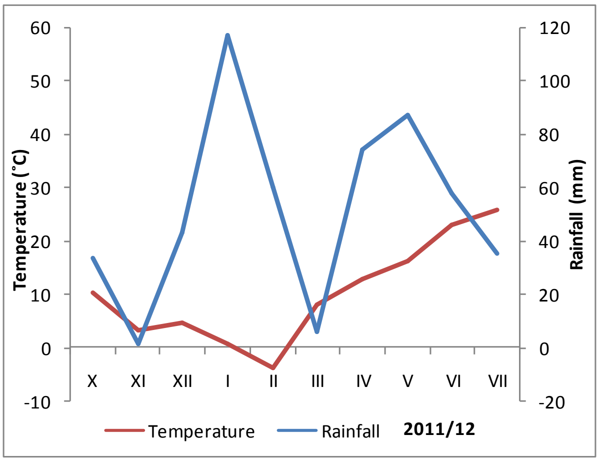
Introduction

The technological quality of wheat is primarily determined by the genetic potential of the variety, which is realized to a greater or lesser extent, depending on the agroecological conditions. The grain quality of wheat mostly depends on the quantity and quality of gluten. Gluten is formed in the early stages of ripening (milk) but its quality changes during maturity to the final characteristics (Lookhart et al., 2001). Temperature and precipitation in the filling phase and grain maturation has a great influence on the quality and content of the protein as well as on the rheological properties of the test (Đurićet al., 2010; Hurkman and Wood, 2011; Torbica et al., 2011). Water absorption is an important indicator of the quality of the flour, which is in a positive correlation with the protein content (Koppel and Ingver, 2010; Abbasi et al., 2011; Al-Saleh and Brennan, 2012). It represents one of the most important parameters in assessment of flour strength and it is directly related to the yield of finished bakery product (Dapčević et al., 2011). The quality properties associated with protein content are found under much greater influence of ecological factors and interaction of the genotype x environment, in contrast to the properties associated with the quality of the protein, the rheological characteristics of the test and the characteristics of the starch, where the influence genotype is significantly higher (Williams et al., 2008). It is known that one and the same genotype

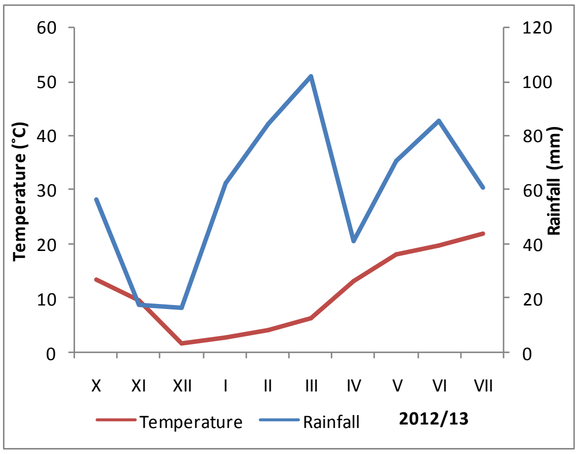
cultivated in different environmental conditions can belong to different quality classes and quality groups (Zečević et al., 2007). The cause of the variation in quality traits wheat is the consequence of genetic differences in cultivars, ecological factors, as well as their interactions, that are determined in research by a large number of authors (Zhang et al., 2004; Finlay et al., 2007; Vázquez et al., 2012; Zečević et al., 2013; Laidiget al., 2017).
The goal of this research is to investigate the influence of the ecological factors, genotypes and their interactions on some quality and rheological properties in winter wheat.

Material and Methods

In these studies, six wheat varieties (Toplica, Takovčaka, Perfekta, Vizija, KG-56S and Aleksandra) were analyzed. Varieties were grown in the experimental field of the Center for Small Grains Kragujevac (Serbia) during two vegetation season (2011/12 and 2012/13).
The rheological properties of grain quality were analyzed: wet gluten content, water absorption, quality number and quality group. Grain samples were milled using a Brabender Quadrumat Junior laboratory mill. The gluten content was determined by standard method (ICC standard methods 106/2, 1992). Farinograph was used to determine rheological properties of flour and dough. The results of the research were studied by Analysis of Variance (ANOVA) according to completely randomized block design with two main factors (genotype and year) using SPSS Statistics 22 statistical program. Evaluation of the importance of difference between average values of studied characteristics was tested by *Duncan* test. Components of variance (genetic, environment and interaction) were calculated by FALCONER (1981).
The average values of mean monthly air temperatures and precipitation amounts per month are shown on the graph1 and 2 (Republic Hydrometeorological Service of Serbia).



Graph. 1. Average monthly air temperatures and total amount of precipitation in production 2011/12 year



Graph. 2. Average monthly air temperatures and total amount of precipitation in production 2012/13 year

The first year of research, in November, was characterized by a dry period with extremely low precipitation. The average air temperature as well as total precipitation during October and November in the second year, was higher compared to the same months in the first year, which had a more favorable effect on seed germination and plant growing. Winter was mild with significantly lower precipitation in December and January in the second year compared to the first (78.8 mm compared to 160.5 mm). The stem elongation period and heading of wheat, during April and May, took place in both vegetation season in similar temperature conditions, with the amount of rainfall being higher in 2011/12 (74.5 mm, 87.3 mm compared to 41.2mm, 70.8 mm). However, in June, the filling phase of the grain was carried out at a higher air temperature (23 ˚C compared to 19.8 ˚C) and a lower amount of precipitation in 2012 compared to 2013 (85.4 mm compared to 66.9 mm), which affected the accelerated maturation of cereals.

Results and Discussion

In the first year of the research, the highest value of wet gluten content had the cultivar Aleksandra (35.48%) and KG-56S (34.6%), and in the second year the cultivar KG-56S variety (45.2%). On average, the wet gluten content was higher in 2012/2013 (39.14%) compared to 2011/12 year (31.56%), Table 1.

Table 1. Mean values for wet gluten content of wheat cultivars

Genotype	**Wet gluten content (%)**		
	2011/12	2012/13	Average
Toplica	31.75ab	38.28b	35.02
Takovčanka	29.49a	33.96a	31.72
Perfekta	29.05a	38.76b	33.91
Vizija	28.99a	39.59b	34.29
KG-56S	34.6bc	45.2c	39.9
Aleksandra	35.48c	39.03b	37.26
Average	31.56	39.14	35.35

Distinct letters in the row indicate significant differences according to Duncan test ($P \leq 0.05$).

Analysis of variance showed highly significant differences among investigated genotypes ($F=18.337$; $p<0.01$), years ($F=193.563$; $p<0.01$) and their interactions G × Y ($F=5.606$; $p<0.01$). Components of variance for wet gluten content have shown that the most variability belonged to year (69.16%), and a significantly smaller genotype (14.05%) and interactions genotype x year (10.17%), Table 2.

Table 2. Analysis of variance for wet gluten content of wheat cultivars

Source	**DF**	**MS**	**F**	**Components of variance**

** Significant at P = 0.01 level; ^{ns} Non significant

The results of these studies are consistent with the results of Kaya et al. (2014) and Luković et al. (2017) who found that quality traits were largely dependent on environmental factors while the impact of the genotype was lower, suggesting that breeders' quality objectives should be adapted to the targeted environments.
Water absorption is the amount of water that needs to be added to the flour to obtain the dough with optimum consistency. This indicator depends primarily on the content of damaged starch grains, the content of protein and non-polysaccharide arabinoxylane (Rakszegiet al., 2014). In both years of research, the highest water absorption was established at cultivar Vizija (62.3%, 67.3%, respectively), with all varieties on average having a higher water absorption capacity in the second year compared to the first year of testing. Using the Farinograph the quality number and quality group for analyzed cultivars was determined. In 2011/2012, the best quality, expressed through a quality number, showed Aleksandra (61.3/B_1). The analyzed genotypes, in 2012/2013, showed the quality of the flour at the level of the B_1 quality group, except for the cultivar Vizija (B_2), Table 3.

Table 3.Mean values for water absorption (%), quality number and quality group of wheat cultivars

Genotype	Water absorption (%)			Quality number/ quality group	
	2011/12	2012/13	Average	2011/12	2012/13
Toplica	60.33b	65.47bc	62.9	47.6/B2	66.2/B1
Takovčanka	59.2a	66.2c	62.7	21.5/C1	62.2/B1
Perfekta	60b	64.33a	62.17	21.8/C1	63.3/B1

Total	**35**	**-**	**-**	**5.422**	**100**

** Significant at P = 0.01 level, ^{ns} Non significant

By performing analysis of variance it was determined that the most significant contirbution of variance belongs to the interaciton G × Y (34.32%) as well as the year of (32.66%), while substanitally lower for the genotype (12.01%), Table 4. The results of these investigations agree with the results of Zečević et al. (2007) and Rozbicki et al. (2014) who emphasize that water absorption was more affected by the environment than by the genotype. Also, Laiding et al. (2017), studying the genetic improvement in quality of winter wheat varieties in the last

32 years in Germany, found that traits influencing baking quality (protein sedimentation, water absorption and bread volume), most impact of genetic factors (more than 60% of total variability belongs to the genotype), emphasizing that the years are more important than locations to explain variation.

Conclusion

In these studies, a significant influence of ecological factors on the quality of analyzed wheat varieties was established. The analysis of phenotypic variance indicated that the highest impact of variance for wet gluten content belonged to year, while for water absorption belonged to cultivar × year interaction. The year of 2012/2013 was a milder winter with more accurate rainfall during the wheat growing season. The period of heading and blooming in the month of May lasted with enough rainfall in both years. However, the grain filling phase in the second year of study was carried out at a slightly lower air temperature and higher precipitation compared to the first year, which caused the wheat varieties to be studied to achieve better quality of grain and flour.

Abstract

Watermelon is an annual vegetable crop from *Cucurbitaceae* family. Five mini watermelon cultivars (red-fleshed ′Faerie′ F1, ′Golden crown′ F1, ′Bonanza′ F1 and yellow-fleshed ′Sureness′ F1, ′Yellow baby′ F1) were grown in open field experiment from May to July 2018. Plants were grown on a fertile soil, covered with black mulch film, on a distance 75x120 cm. During vegetation period regular agricultural practices were applied (fertirrigation, weeding and preventive protection against diseases and pests). Fruits were harvested after 60 days from planting. The aim of this study was to examine morphological traits of five cultivars in full physiological maturity. Fruit weight ranged between 1.57-2.65 kg with the highest value in cultivar ′Sureness′. Number of fruits ranged from 20 (′Yellow baby′, ′Sureness′) to 35 (′Faerie′). Rind thickness ranged between 5.22-11.91 mm with the highest value in ′Yellow baby′. Total soluble solids ranged from 9.5-10.95 °Brix and randman between 37-49%. Among all cultivars, red-fleshed ′Bonanza′ showed the highest randman and total soluble solids (49% and 10.95 °Brix, respectively). Opposite to that, the lowest total soluble solids showed yellow-fleshed cultivars ′Sureness′ and ′Yellow baby′. Generally, yellow cultivars showed higher fruit weight and rind thickness, whereas red cultivars showed higher number of fruits per plant, total soluble solids and randman. The present study outlines that ′Bonanza′ and ′Faerie′ showed the highest quality (soluble solids content) among tested varieties.

Keywords: *Watermelon, Fruit weight, Rind thickness, Randman, Total soluble solids.*

Introduction

Watermelon is an annual vegetable crop from *Cucurbitaceae* family. Nutrition quality of watermelon fruits originate from lycopene, flavonoids, phenolics, vitamin C, citrulline and fibers. According to FAO (2017) total production in European Union was 3.216.037 t with the highest production in Spain (1.112.192 t), Greece (647.000 t) and Italy (570.762 t).

Watermelon production depends on genotype selection, environmental conditions, growing practices and consumer habits. Breeding programs allowed accomplishing different market demands for fruit size, shape and colour, flesh colour, rind thickness and taste. Fruit size of 4-6 kg, round or oval fruits, the maximum rind thickness 1.5 cm, high randman and total soluble solids 8-10% (Gvozdanovic-Varga et al., 2011). Guner and Wehner (2003) reported the existence of genes responsible for flesh colour (red, orange, white and yellow). The same authors emphasized importance of rind colour in breeding programs. Rind thickness is a quantitative trait (*Sharma* and Choudhury, *1988*) with preference in thick rind and higher randman. Total soluble solids can describe sweetness degree and level of ripening (Sabeetha et al., 2017). Watermelon studies confirmed positive correlation between total soluble solid and sugar content (Soteriou et al., 2014).

New type of watermelons with reduced fruit size, mini watermelon, came to market in 2003 with round fruit shape, thin rind and average fruit weight 1.5-4 kg (Gusmini and Wehner, 2007). Mini watermelons are *characterized* as sweet, crisp, juicy, seed or seedless, from pink to red flesh colour. According to Magda (2016) they have more lycopene and beta-carotene (6.700-9.600 μg per 100 grams) compared to large watermelons (3.700-6.900 μg per 100 grams).

The objective of this study was to investigate five different mini watermelon cultivars, their morphological and chemical properties in conventional agriculture practice.

Material and Methods

Five mini watermelon cultivars were examined (′Faerie′ F1, ′Golden crown′ F1, ′Sureness′ F1, ′Yellow baby′ F1- Known-You Seed Co., Ltd and ′Bonanza′ F1- Syngenta). ′Faerie′ has a globe shaped fruit, average size 3 kg with light yellow rind and pinkish flesh. ′Golden crown′ is an early watermelon, average size 2.5 kg, oblong, icebox-sized with golden yellow rind and red flesh. ′Bonanza′ has a round fruit, average weight 1.5-3 kg, with thick light green rind and red flesh. ′Sureness′ has oval fruit with green rind and yellow flesh, sized 4-5 kg. ′Yellow baby′ has a globe shaped fruits, sized 3.5-4.5 kg with thin dark green rind and bright yellow flesh. An open field experiment was conducted during April-July 2018 at the company Iceberg Salat Centar, Surcin, Serbia. Before experiment chemical analysis of the soil showed sufficient levels of major nutrients and humus (nitrogen-0.18 %; phosphorus-66.6 mg/100g; potassium-27.2 mg/100g and humus-2.9 %).

Watermelon seedlings were grown in a peat cubes, size 6 cm, from the substrate Potgrond H (Klasmann-Deilmann) in a controlled glasshouse conditions. Seedlings were sown on April 28 and their production lasted for 30 days. Watermelon plants were transplanted on May 29, in a black marsh soil, covered with black mulch film. During growing cycle regular cultivation practices were carried out (fertirrigation, protection against diseases and pests, weeding). Soluble commercial fertilizers were applied with drip irrigation system, 7 times, during growing cycle. During vegetation period air temperature, air relative humidity and precipitation were collected from meteo station in Surcin. Average air temperature, air relative humidity and total precipitation are presented in Table 1.

Table 1. Climate conditions during watermelon growing cycle

	Average temperature (°C)	Average humidity (%)	Minimum temperature (°C)	Maximum temperature (°C)	Total precipitation (mm)
April 2018	16.6	63.1	5.0	29.0	14.4
May 2018	19.9	64.4	10.1	30.3	13.4
June 2018	21.4	71.9	10.2	34.5	57.8
July 2018	21.9	73.5	10.7	31.1	138.3

The experiment was organized in a complete block design. Each plot consisted of 13 plants and distance was 75x120 cm. Fruits were harvested 60 days after planting, at full physiological maturity. For morphological and chemical analysis, we used 5 plants. All morphological traits were measured using scale, digital caliper and ruler. Total soluble solids were measured using refractometer (Brix/Specific Gravity Refractometer w/ATC, Vee Gee Scientific, USA) and results are presented in degrees Brix (°Brix).

Statistical analysis was performed using DSAA STAT (2011) and Microsoft Office Excel 2007. One-way ANOVA was used to examine the effect of genotype with LSD test for comparation. All tests were performed at a significance level α of 0.05.

Results and Discussion

Fruit weight, rind thickness, randman and total soluble solids were statistically affected by genotype.

Table 2. Different watermelon parameters affected by genotype

Cultivar	Fruit weight (kg)	Rind thickness (mm)	Randman (%)	Total soluble solids (°Brix)
Faerie	1.62	5.22	49	10.95
Bonanza	2.12	7.56	49	10.95
Golden crown	1.57	11.00	37	10.50
Sureness	2.65	10.67	47	9.50
Yellow baby	2.25	11.91	46	10.15
Min	1.57	5.22	37	9.50
Max	2.65	11.91	49	10.95
Average	2.04	9.27	46	10.41
CV (%)	13.59	15.51	8.12	5.39
LSD 0.05	0.3664	1.8977	4.9083	0.7404
LSD 0.01	0.4998	2.5885	6.6952	1.0099

Fruit weight ranged between 1.57-2.65 kg and the average weight was 2.04 kg (Table 2). Cultivar ′Sureness′ showed the highest fruit weight (2.65 kg) and the lowest ′Golden crown′ (1.57 kg). Among red-fleshed cultivars, the highest fruit weight showed ′Bonanza′. Generally, yellow-fleshed cultivars showed higher fruit weight and there was significant difference between yellow-fleshed and red-fleshed cultivars with exception between cultivars ′Yellow baby′ and ′Bonanza′. Our results were similar to those found by Proietti et al. (2008) on ungrafted mini watermelon plants (2.27 kg). Experiments with black mulch film showed the highest watermelon yield and fruit weight (White, 2003) and it is recommended to cultivate watermelon on mulch film to decrease water and fertilizer loss from the soil, prevent weeds and contact between fruit and soil.

Total number of fruits ranged between 20-35. Yellow-fleshed cultivars, ′Sureness′, ′Yellow baby′, showed the lowest total number of fruits (20) compared to red. The highest total number of fruits showed cultivar ′Faerie′ (35). Fruit number per plant was similar to results Proietti et al. (2008) with 74.7%, 49.4% and 54.5% increased fruit number per plant in red (′Faerie′, ′Golden crown′ and ′Bonanza′, respectively) compared to yellow (data not presented in Table 2).

Rind thickness ranged between 5.22-11.91 mm and the average rind thickness was 9.27 mm (Table 2). Cultivar ′Yellow baby′ showed the highest rind thickness (11.91 mm) and the lowest cultivar ′Faerie′ (5.22 mm). Yellow-fleshed cultivars showed thicker rind compared to red-fleshed. Significant difference was found between yellow and red-fleshed cultivars with exception between two yellow fleshed cultivars ′Yellow baby′ and ′Sureness′ with ′Golden crown′. Gusmini et al. (2004) separated watermelon fruits into 3 groups according to rind thickness (higher than 19 mm, 10-19 mm, less than 10 mm). According to this classification cultivars ′Faerie′ and ′Bonanza′ belong to first group (less than 10 mm) and ′Golden crown′, ′Sureness′ and ′Yellow baby′ belong to second group (10-19 mm). Our results are in agreement with Proietti et al. (2008) on ungrafted mini watermelon plants (8.9 mm). On contrary, results of White (2003) showed higher values of rind thickness (16.7-22.3 mm).

Watermelon randman ranged between 37-49 % and the average randman was 46 % (Table 2). Cultivar ′Bonanza′ showed the highest randman (49 %) and the lowest cultivar ′Golden crown′ (37%). Cervenski et al. (2008) studied randman of two watermelon genotypes and showed higher randman compared to our results (′Danka′ 62.74 %, ′Crimson Sweet′ 53.38 %).

Mainly, red-fleshed cultivars showed higher randman compared to yellow but this difference wasn't significant. Cultivar ′Golden crown′ showed statistically lower randman compared to all cultivars.
Total soluble solids ranged between 9.5-10.95 °Brix and the average total soluble solids were 10.41 °Brix (Table 2). Cultivars ′Bonanza′ and ′Faerie′ showed the highest total soluble solids (10.95 °Brix) and the lowest ′Sureness′ (9.50 °Brix). Red-fleshed cultivars showed significant higher total soluble solids compared to yellow with exception between ′Golden crown′ and ′Yellow baby′. Within cultivars in red-fleshed group and yellow-fleshed there wasn't significant difference. Our results were in the range for red and yellow-fleshed watermelons (Pardo et al., 1997; Sabeetha et al., 2017) or even higher (Proietti et al., 2008). Sabbetha et al. (2017) reported lacking information of total soluble solids in yellow-fleshed watermelons. Their research showed no significant difference between red and yellow-fleshed watermelons (10.46 and 9.91 °Brix). Results of Davis et al. (2008) showed positive correlation between flesh colour (orange, yellow, red, pink) and total soluble solids. Their results indicated lower total soluble solids in yellow-fleshed compared to red (8.8 and 11.5 °Brix, respectively). According to Vasquez et al. (2005) 8-10 °Brix is a market tolerable value. All our results are in this range and compared to previous results are in agreement with lower total soluble solids in yellow compared to red-fleshed cultivars. Total soluble solids depend on environmental factors and maturity (harvest). Watermelon requires temperature 23-28 °C, relatively low air humidity, long day (Costa and Leite, 2007). During vegetation period average air temperature (16.6-21.9 °C) and air relative humidity (63.1-73.5 %) were almost optimal for watermelon production. During last month of their production total precipitation was higher and that could influence on lower total soluble solids. Even though it was a rainy period (especially July) we obtained satisfactory value of total soluble solids.

Conclusions

Mini watermelons have a round fruit shape, thin rind and average fruit weight 1.5-4 kg. The present study indicated that genotype (cultivar) affected fruit fresh weight, rind thickness, randman and total soluble solids. Yellow-fleshed cultivar ′Sureness′ showed the highest fruit weight. The highest rind thickness showed yellow cultivar ′Yellow baby′. Mainly, yellow-fleshed cultivars showed higher fruit weight and rind thickness compared to red-fleshed. Red-fleshed cultivars showed higher total number of fruits, fruit number per plant, randman and total soluble solids. Among tested cultivars, we can recommend ′Faerie′ and ′Bonanza′ as a source of sweetness and for the highest quality parameter (total soluble solids), as well as the highest randman.

Abstract

Lettuce belongs to a group of leafy vegetable crops with special importance in human nutrition. Along with healthy compounds lettuce can accumulate nitrate in leaves. The purpose of this study was to examine the effects of genotype, microbiological fertilizers and season on plant weight and nitrate content in outer and inner leaves. Green cultivars (′Kiribati′, ′Aquino′, ′Aleppo′) were cultivated in a fertile soil, in a greenhouse trial at the company Iceberg Salat Centar, during three successive seasons (autumn, winter and spring). Microbiological fertilizers (EM Aktiv, Vital Tricho and combination of EM Aktiv and Vital Tricho) were applied in the soil before trials and foliar. In spring cultivar ′Aquino′ showed the highest head fresh weight (360.3 g). All microbiological fertilizers led to increased head fresh weight in ′Aquino′ during autumn trial. Mainly fresh weight was higher in spring and winter compared to autumn. Cultivar ′Aquino′ showed the highest nitrate content (985.4 mg/kg, autumn) in outer leaves with application of Vital Tricho. Opposite to that, the lowest nitrate content was found in inner leaves of cultivar ′Aleppo′ (35.4 mg/kg, spring) with combination of fertilizers. Generally, microbiological fertilizers significantly increased nitrate content in outer and decreased in inner leaves. In both leaves the lowest nitrate level was measured in spring season. During all trials nitrate content remained under allowed level of European Commission Regulation (563/2002) for protected lettuce.

Keywords: *Lettuce, Microbiological fertilizers, Season, Plant weight, Nitrate.*

Introduction

Lettuce is an annual, cool weather vegetable crop from *Asteraceae* family. Generally, lettuce has short vegetation period and in temperate climate it is feasible to accomplish multiple harvests all year-round. According to Food and Agriculture Organization (FAO) in 2017, total area harvested in European Union was 118.508 ha with leading countries Spain (34.508 ha), Italy (34.069 ha) and Germany (15.096 ha). Lettuce is consumed as a fresh vegetable and it is a component of fourth range products which are processed and packaged in modified atmosphere and come to market as ready for consumption (Borghi, 2003). It is rich is beneficial phytochemicals important in human diet (minerals, fiber, antioxidative compounds).

Leafy vegetables, including lettuce, tend to accumulate nitrate. Various factors like genetic, environmental (photoperiod, irradiance, humidity) and growing practice (use of fertilizers and pesticides) influence on nitrate accumulation in plants (Maynard et al., 1976; Reinink and Eenink, 1988). Major sources of human nitrate intake are from vegetables, drinking water and meat products (Wolff and Wasserman, 1972). Excessive use of nitrate in agriculture can have a negative effect on human health (transformation of nitrate into nitrite and its interaction with haemoglobin to form methaemoglobin). European Commission regulated maximum levels of nitrate that can be found in vegetables. It is allowed for lettuce grown under cover (excluding

'iceberg' type) harvested between 1 October to 31 March, 4500 mg/kg nitrates and between 1 April to 30 September 2500 mg/kg nitrates (EC regulation No 563/2002).
Effective microorganisms are a group of naturally found beneficial and compatible microorganisms that can be used as microbial inoculants in different preparations (fungi, lactic acid bacteria, photosynthetic bacteria, yeasts and actinomycetes). Application of effective microorganisms can have a positive effect on soil physical and chemical properties, improve plant growth, yield and quality (Babalola, 2010). Fungus genus *Trichoderma* spp. includes avirulent, cosmopolite, opportunistic species that can be used as biofertilizer, biopesticide and soil improver. They can colonize plant roots without evoking defense response in plants, ameliorate root growth and enhance nutrient uptake, improve plant growth and yield, enhance quality of vegetables and alleviate impact of different stresses (Lopez-Bucio et al., 2015). Effective microorganisms and *Trichoderma* preparations can be used in conventional, organic and integrated agriculture. With their application we can decrease the usage of inorganic fertilizers and synthetic pesticides and preserve natural environment (soil, water and air) from further pollution.
The aim of this study was to investigate the effect of genotype, microbiological fertilizers and season on plant weight and nitrate content in outer and inner lettuce leaves.

Material and Methods

Three green lettuce cultivars (oak ′Kiribati′, multi-leaf butterhead ′Aquino′ and lollo ′Aleppo′-Rijk Zwaan) were studied. Seedlings were grown in peat cubes, made from substrate Potgrond H (Klasmann - Deilmann) in a controlled glasshouse conditions. After transplanting plants were cultivated in the greenhouse without additional heating, in a fertile soil, covered with black mulch film. The experiments were conducted during three consecutive growing seasons autumn (11 October-7 December 2016), winter (27 December 2016-5 April 2017) and spring (27 April-3 June 2017) at the company Iceberg Salat Centar, Surcin.
Before experiments chemical analysis showed sufficient level of macronutrients and humus (nitrogen-0.22 %; phosphorus-58.35 mg/100g; potassium-32.45 mg/100g and humus-5.02 %) and all experiments were carried out without application of inorganic fertilizers. Two different microbiological fertilizers and their combination were examined. EM Aktiv (EMA; Candor) is a liquid preparation of different groups of beneficial microorganisms isolated from natural surroundings: *Aspergillus oryzae, Azotobacter chroccooum, Bacillus subtilis, Bacillus megaterium, Lactobacillus plantarum, Lactobacillus casei, Rhodopseudomonas palustris, Rodobacter sphaeroides, Saccharomyces carevisiae, Streptomyces albus, Streptococcus lactis, Streptomyces griseus*. Vital Tricho (VT; Candor) is a powder preparation of two *Trichoderma* species (*Trichoderma* ***asperellum*** and *Trichoderma viride*). The experiments were organized in a complete block design with four treatments (control - without fertilization (C), EM Aktiv (EMA), Vital Tricho (VT) and combination of EM Aktiv and Vital Tricho (EMA+VT)) and 3 replications. Each plot consisted of 32 plants with 25x25 cm density. Microbiological fertilizers were applied in the soil before planting (150 ml/10 l H_2O EMA, 21 g/10 l H_2O VT and 150 ml + 21 g/10 l H_2O EMA+VT) and four times foliar during vegetation period (30 ml/6 l H_2O EMA, 12 g/6 l H_2O VT and 30 ml + 12 g/6 l H_2O EMA+VT). Regular agricultural practices were applied for lettuce greenhouse production (ventilation, irrigation, weeding and preventive protection against diseases and pests).
During vegetation period air temperature and air relative humidity were measured for 24 hours using RC-4HC Data Logger. Monthly reviews of average air temperature and air relative humidity with minimum and maximum temperatures are represented in Table 1.

Table 1. Climate conditions during three growing seasons

	Average temperature (°C)	Average humidity (%)	Minimum temperature (°C)	Maximum temperature (°C)
October 2016	12.4	85.4	1.2	26.2
November 2016	8.0	87.7	-6.2	26.1
December 2016	2.3	89.3	-7.9	26.4
January 2017	-1.7	85.2	-16.6	20.8
February 2017	6.5	82.0	-9.8	38.0
March 2017	13.4	78.4	-2.1	38.8
April 2017	15.8	67.5	3.1	34.6
May 2017	21.1	74.5	5.0	40.4
June 2017	26.0	70.1	15.9	40.3

Plants were harvested when they achieved marketable size, by hand, same day. Rosette fresh weight was measured on scale. After that lettuce leaves were divided into two groups, outer and inner. Fresh leaves were dried for 72 h at 70 °C to constant weight to obtain dry weight, results are represented in grams (g). Nitrate content was determined colorimetrically by nitration of salicylic-acid described by Cataldo et al. (1975) with modifications (Jana and Moktan, 2013). Absorbance was recorded at 410 to 420 nm. Nitrate content in outer and inner leaves is represented in ppm FW. Three-way ANOVA with Tukey's test for post-hoc comparation was used in order to test effects of genotype, treatment and season. All tests were performed at a significance level α of 0.05. Statistical analysis was performed using software SPSS Statistics for Windows (Version 22.0. Armonk, NY: IBM Corp) and Microsoft Office Excel 2007.

Results and Discussion

Results of rosette (head) fresh weight are represented in Table 2. Rosette (head) fresh weight varied between 90.7-171.7 g in autumn, 188.7-324 g in winter and 229-360.3 g in spring.

Values followed by the same letter aren't significantly different at the 0.05% level of probability according to Tuckey's test. Symbols are a,b - differences between cultivars; A,B - differences between treatments; x,y,z - differences between seasons

Cultivar ′Aquino′ showed the highest head fresh weight in spring (control treatment, 360.3 g) and with application of VT in winter (324 g). In all treatments cultivar ′Aleppo′ showed the lowest rosette fresh weight in autumn (control, 90.7 g; EMA, 104 g). Literature data indicate positive impact of different effective microorganisms and *Trichoderma* preparations on yield, fresh and dry weight of different vegetables (Björkman et al., 1998; Tošić et al., 2016). Effective microorganisms can synthesize vitamins, hormones, organic acids, enzymes, siderophores and other compounds that can stimulate plant growth. They contribute to enhanced nutrient availability and uptake, improve plant growth and yield, ameliorate soil structure, contribute to microbial diversity in the soil and suppress plant pathogens. In our study, all microbiological fertilizers significantly increased head fresh weight in cultivar ′Aquino′ in autumn. On contrary, in spring combination of microbiological fertilizers led to significantly decreased head fresh weight in aforementioned cultivar. Some experiments didn't show positive effect on yield of different crops with application of microbiological fertilizers (Poldma et al., 2001; Van Vliet et al., 2006). The effectiveness of microbiological fertilizers, including *Trichoderma*, depends on genotype, potential root colonization by different *Trichoderma* strains, soil characteristics, method and frequency of application. Our results showed that in autumn and winter season microbiological fertilizers led to increased rosette fresh weight in different cultivars but this wasn't statistically significant. This can be probably explained with particular interaction of genotype and effective microorganisms (*Trichoderma*) or inadequate quantity of applied fertilizers. Season significantly affected rosette (head) fresh weight in all cultivars and treatments. The present study pointed out to increased rosette (head) fresh weight in spring and winter compared to autumn season. This can be probably linked to influence of day length (autumn-short day 11-9 h, winter-growing day 9-13 h, spring-long day 14-15 h) and temperature. Optimal temperature for lettuce planting is 21-23 °C (day) and 15-18 °C (night). Our study confirmed previous reports in lettuce (Pavlou et al., 2007; Konstantopoulou et al., 2012) regarding to reduced plant weight and yield in autumn compared to spring and winter production.

Results of nitrate content in outer and inner leaves are represented in Table 3. Results of nitrate content varied between 202.7-985.4 ppm in autumn, 210.0-932.0 ppm in winter and 35.4-316.0 ppm in spring. In control treatment, the highest nitrate content in outer and inner leaves showed cultivars ′Aquino′ and ′Aleppo′ (autumn 908.2 ppm, winter 701.5 ppm). Siomos et al. (2002) found higher nitrate content in butterhead type compared to leaf lettuce. In both leaves, the lowest nitrate content was found in spring in cultivars ′Kiribati′ and ′Aleppo′ (control 62.4 ppm, 35.4 ppm with combination of fertilizers). According to Sorensen et al. (1994) nitrate accumulation in lettuce depends on genotype (variety) and environmental factors. Application of EMA and combination of fertilizers led to significantly enhanced nitrate content in outer leaves of cultivar ′Kiribati′ in autumn and spring, VT in cultivar ′Aquino′ in spring and EMA in cultivar ′Aleppo′ in spring. On contrary, combination of fertilizers led to significantly decreased nitrate content in cultivar ′Aquino′ in winter. In spring, application of all microbiological fertilizers led to significantly increased nitrate content in inner leaves in cultivar ′Kiribati′ and application of EMA in cultivar ′Aleppo′. In autumn fertilizer VT significantly decreased nitrate content in cultivars ′Kiribati′ and ′Aquino′ and in winter in cultivar ′Aleppo′. Generally, in outer leaves application of microbiological fertilizers led to increased nitrate content as well in spring in inner leaves. These results probably indicate contribution of effective microorganisms to increased nutrient availability. Experiments with lettuce and rocket showed enhanced nitrogen uptake from the soil using *Trichoderma* fertilizers (Fiorentino et al., 2018). Season significantly affected nitrate content in both leaves of all cultivars and treatments with exception of cultivar ′Aquino′ with application of VT in inner leaves. The lowest nitrate content in both leaves was measured in spring. Short day and low light intensity can influence on increased nitrate content

(Govedarica-Lučić and Perković, 2013). In all seasons nitrate content varied 35.4-985.4 ppm and remained under allowed level for protected lettuce (EC regulation No 563/2002).

Values followed by the same letter aren't significantly different at the 0.05% level of probability according to Tuckey's test. Symbols are a,b,c - differences between cultivars; A,B,C - differences between treatments; x,y,z - differences between seasons

Conclusions

The study showed that genotype, microbiological fertilizers and season significantly affected rosette (head) fresh weight and nitrate content in both leaves. Cultivar ′Aquino′ showed the highest head fresh weight in spring. In autumn season, all microbiological fertilizers significantly enhanced head fresh weight in cultivar ′Aquino′. The lowest nitrate content was measured in cultivar ′Aleppo′, in spring, using combination of fertilizers. Mainly, in outer leaves microbiological fertilizers led to increased nitrate content whereas in inner leaves microbiological fertilizers led to significantly decreased nitrate content. Application of VT and combination of fertilizers had a great influence on tested parameters. In all seasons nitrate content stayed bellow maximum allowed level for protected lettuce. Authors can recommend spring season to obtain the highest rosette fresh weight and the lowest nitrate content.

Abstract

Originating from Iran and the surrounding area, pomegranates have been cultivated for thousands of years yet are still considered emerging crops although well noted for ancient uses and cultural importance. Pomegranates contain a number of functional compounds that are responsible for beneficial health properties. Polyphenolic compounds are primarily responsible for these benefits and include phenolic acids, flavonoids (e.g. anthocyanins), and tannins. These compounds have shown effects in many studies including those related to cardiovascular, anti-inflammatory, anticancer, and antidiabetic conditions. The object of our study was to investigate the impact of pasteurization on the quality of pomegranate juice from "Hicaz" variety from the region of North Macedonia. The pH value and total acidity of the juice were not affected by pasteurization. There were no significant differences between those two parameters in fresh and pasteurized juice. However, all other parameters were significantly affected. The level of citric acid was almost double in fresh juice from "Hicaz" variety of pomegranate (781 mg/L) in comparison with pasteurized juice (402 mg/L). The amount of total anthocyanins was higher in fresh juice (598 mg/L) in comparison to pasteurized juice (537 mg/L). In addition, total phenols were higher in fresh then pasteurized juice (3367 mg/L and 3196 mg/L respectively). Opposite to this tendency, the total catechins were higher in pasteurized (50.1 mg/L) than fresh juice (44.9 mg/L). The pasteurization strongly affected the color of juice. The intensity of the color, the hue and the yellow color were higher in fresh juice. Opposite, the red and blue colors were more intense in pasteurized juice. The results from our study lead us to conclusion that pasteurization influenced significantly the quality of pomegranate juices from "Hicaz" variety.

Key words: *pasteurization, organic acid, total phenolic compounds, anthocyanins, catechins.*

Introduction

Pomegranate (*Punica granatum* L.) is one of the major sources of polyphenolic phytochemicals, such as anthocyanins and catechins (Mphahlele *et al*., 2014; Jaiswal et al., 2010). However, the processing and storage of pomegranate juice had a decisive impact on the degradation of anthocyanin compounds and the consequent formation of brown pigments (Vegara et al., 2013). Total anthocyanin content and antioxidant capacity were substantially and significantly influenced by the heat treatment applied according to the working group of Mena (Mena et al., 2013). The results from study of Tezcan *et al*. showed that commercial pomegranate juices had markedly high total phenolic contents and antioxidant capacity. In the six commercial pomegranate juices studied in their work, in comparison to fruit juices reported in the literature, much higher total phenolic content and antioxidant capacities were observed, with increased health benefits for the consumers (Di Nunzio *et al*., 2013). The antioxidant activity of pomegranate aril juice, attributed to a great extent to total phenols and anthocyanins by cyanidin-3,5-diglucoside was the major antocyanin in pomegranates. (Cassano *et al*., 2011; Turfan *et al*., 2011). Furthermore, excellent review of Kalaycıoğlu and Erim quantitatively established the antioxidant activity, total phenolic content, anthocyanins,

organic acids, sugars and other important ingredients in pomegranate juices obtained from cultivars from different regions (Kalaycıoğlu and Erim, 2017). The late-pomegranate fruits were rich in phytochemicals and could be of great interest to the juice industry (Galindo *et al.*, 2014; Nag and Sit, 2018). In the work of Mena et al., 15 pomegranate cultivars was studied in order to demonstrate the wide diversity among the quality of Spanish pomegranates. According to their findings, "Wonderful" juices displayed large antioxidant activity and a polyphenol content with very high acidity. In contrast, 'Mollar de Elche' showed fewer anthocyanins although it had very superior organoleptic properties. In addition to a high content in ellagitannins, 'Valenciana' juices had exclusive colour parameters (Mena *et al.*, 2011). Regarding total phenol content, rutin was predominant flavonoid from the pomegranates peel (Mphahlele *et al.*, 2017).
To the best of our knowledge, there is no published results for the impact of the pasteurization on the quality of pomegranate juices from the region of North Macedonia. Therefore, the objects of this study was impact of pasteurization on freshly squeezed juice from "Hicaz" pomegranate variety as well as determination of chemical parameters such total polyphenolics, total anthocyanins, the level of organic acids as well and intensity of color and hue.

Materials and Methods

Sample preparation

The sampled fruits were harvested from the region of Kavadarci and Valandovo (East region of North Macedonia in October 2018. The samples were selected randomly in order to separate three replicates for analysis, using 10 kg per replicate and cultivar. Pomegranates were weighed, cut in halves, and arils were handseparated from thepith avoiding contamination by components in membranous walls (septum). Juices of each cultivar were obtained by pressure of arils and were weighed to determine the juice yield. Samples of freshly prepared juice were stored frozen (−20 ◦C) until analyzed (O'Grady *et al.,* 2014). The process of pasteurization was performed on 65◦C for 20 min.

Determination of titratable acidity, total soluble solids, pH

All analyses for the quality of pomegranate juices as well as the process of pasteurization were performed at the department of food control at UNILAB, Faculty of Agriculture, University "Goce Delčev"-Štip.
For determination of titratable acidity (TA), 2 ml of fresh juice was diluted with 70 mL of distilled water and titrating with 0.1 M NaOH to an end point of pH 8.2 using a Metrohm 862 compact titrosampler (Herisua, Switzerland). The results were expressed as percentage of citric acid (% CA). Total soluble solids (TSS, °Brix) was measured using a digital refractometer (Atago, Tokyo, Japan) calibrated with distilled water. The pH values were determined at room temperature using a calibrated pH meter (Crison, Model 00924, Barcelona, Spain). All measurements were made on triplicate.

Determination of organic acids

For determination of organic acids, A Chromatograph Agilent technologies 1200 series, with Jasco AS-950 sampler, an auto injector (10 μl injection volume) and refractive index detector was used for analyses of organic acids. Separation of organic acid was performed on AMINEX HOX-87 (H 300 x 7.8) column. The eluent was prepared by mixing of 75μl H_2SO_4 in 250 mL H_2O. The mobile phase flow rate was 0.6 mL/min and the temperature was 55°C.

The percentages of organic acids were measured by following calculation:

$$mg\ organic\ ac./100ml = \frac{At}{As}\ x\frac{Cs}{Ct}x100$$

where:

- **At** is the area of test sample
- **As** is the area of standard
- **Cs** is the concentration of standard in mg/mL and
- **Ct** is the concentration of test in mg/mL

*1.1.*Determination of total phenolic compounds (TPC), colour, total catechins and total antocynanins

The total phenolic content of pomegranate juices was determined with Folin–Ciocalteau reagent (O'Grady et al., 2014). Determination of total phenolics was performed by the colorimetric method of Singleton and Rossi (Singleton and Rossi, 1965). For determination of total catechins, the modified method of Atamossa and Gholap was used. In brief, the pomegranate juices from both varieties were dissolved in water (1:5) and measurements of total catechins was performed using UV-VIS spectrometer in the spectral range of 200 to 500 nm (Atamossa and Gholap, 2015). The measurements were performed in triplicate.

1.2.Statistical analyses

The level of significance in differences between anthocyanin content and total phenolic content was determined by 5% by a one-way ANOVA using Tukey's test. The results from statistical analyses were classified using letters (different letters means significant differences among results). The letters are a,b,c,d,e and f according to the decrease of the result values. SPSS v.16.0 software, IBM corporation, USA was used for the applied statistical treatment.

Results and Discussion

The chemical parameters of the samples of fresh and pasteurized pomegranate juice from "Hicaz" variety are presented in table 1.

Table 1. Chemical parameters of pomegranate fresh and pasteurized juice

Samples of "Hicaz" juice	Brix	pH	Total acids g/L	Malic acid g/L	Citric acid g/L	Total phenolics	Total catechines	Total antocynains
Fresh	16.0±1.1[a]	3.04±0.0[a]	29.9±2.3[a]	0.18±0.10[b]	0.28±0.03[b]	2422±211[b]	25.5±4.3[b]	362.2±28.2[b]
Pasteurized	16.8±0.8[a]	3.04±0.1[a]	24.3±1.1[b]	0.36±0.52[a]	0.78±0.09[a]	3196±207[a]	50.1±5.0[a]	537.6±31.8[a]
	IC	**Hue**	**A_{420}**	**A_{520}**	**A_{620}**			
Fresh	2.87±0.12[b]	0.23±0.07[a]	15.7±0.12[b]	72.9±5.98[a]	9.9±0.5[a]			
Pasteurized	4.14±0.27[a]	0.26±0.05[a]	19.6±0.22[a]	70.5±4.77[a]	9.8±1.4[a]			

*Source: Author s' elaboration based on the obtained results.

As results show, there is significant difference between all measured parameters with exception of pH of the juices and brix. The level of malic and citric acid was significantly lower in comparison to commercial pomegranate juices from Turkey. However, the amounts of total phenolic compounds for fresh "Hicaz" juice was very similar to the same samples (Di Nunzio *et al*., 2013). The level of monomeric anthocyanins were almost double for pasteurized in comparison to fresh juice. Furthermore, the amount of monomeric anthocynains for fresh juice was very similar to the results published for pomegranate juices from the working group of Jaiswal (Jaiswal *et al*., 2010). The intensity of the color was higher for pasteurized juice, which was expected, due to the higher level of total phenolic compounds and monomeric anthocyanins (Table 1). Moreover, the higher intensity of red color can be linked to the dominance of cyanidin-3-glucoside as the major anthocyanin in pomegranate juice (Turfan *et al*., 2011; Cassano *et al*., 2011; Varasteh *et al*., 2012). Furthermore, citric and malic acids were the predominant organic acids in the sample of pasteurized juice. The acids attributed to the formation of ester upon the reaction of predominant citric acid with some juice compounds (Gundogdua and Yilmaz, 2012).

The results for amounts of total phenolic compounds obtained from Macedonian variety of "Hicaz" are similar to some varieties published by working group of Mena. (Mena *et al*., 2011). According to their findings, total phenolic content in WSN sample had similar value as Macedonian "Hicaz" variety. He stated that Folin–Ciocalteu values were not the sum of polyphenols which can be detected by HPLC (EA derivatives, punicalagins and anthocyanins) as other compounds, such as flavanols, flavonols, phenolic acids, proanthocyanidins, and hydrolysable tannins that are different to punicalagins, also contribute to the phenolic profile (Mena *et al*., 2011). The pomegranate juice from Macedonian "Hicaz" variety had higher value for total phenolic components than Valencia variety but significantly lower value than Akko, Hershkovitz and Wonderful varieties (Jaiswal *et al*., 2010). The amount of total phenolic component for fresh juice is similar to total phenolic content in Spanish pomegranate juice which was in range from 170-270 mg/mL gallic acid equivalent (Galindo *et al*., 2014).

Generally speaking, we assumed that higher level of anthocyianins, catehines, total phenolic compounds and intensity of the color in pasteurized juice can be results of enzymes inactivation and microbial destruction (Reddy *et al*., 2007). Results from our study showed that pH 3 is insufficient to inactivate enzymes and microbiota in degradation of phenolic compounds in fresh juice. However, changes of the color can be linked by the degradation of anthocyanin compounds and the consequent formation of brown pigments (Vegara *et al*., 2013).

Conclusion

The purpose of the present study was to evaluate the overall quality of freshly squeezed and pasteurized juice from "Hicaz" pomegranate variety from the region of North Macedonia. Based on the explanation above, it can summarize that pasteurized pomegranate juice from "Hicaz" variety is richer source with polyphenolic compounds in particular monomeric anthocyanins and total phenolic compounds. The effect of pasteurization gives improvement in terms of the enzymes inactivation and microbial destruction, which affects to the chemical parameters and quality of the juice.

Abstract

Amaranth (*Amaranthus sp.,* Amaranthaceae), quinoa (*Chenopodium quinoa,* Amaranthaceae) and canihua (*Chenopodium pallidicaule,* Amaranthaceae) are pseudograins originating from South America. They are widely used in the diet as well as chia seeds (*Salvia hispanica,* Lamiaceae) from South America and wheat (*Triticum aestivum*, Poaceae) and millet (*Panicum miliaceum,* Poaceae), characteristic for our climate. The aim of the study was to determine the nutritive characteristics, phenolic content and antioxidant activity of commercial samples of pseudograins (amaranth, quinoa and canihua) from our market, as well as a comparative analysis to chia seeds, common and khorasan wheat and millet. Basic nutritive value parameters and mineral contents were assessed for pseudograins and chia seeds. The content of total phenolic compounds (TPC) and total flavonoid compounds (TFC), antioxidant activity by DPPH and FRAP tests were determined for all samples. The results of the nutrient composition indicates that analyzed pseudograins are good sources of proteins (13.39%) and unlike chia seeds are characterized by relatively low fat content (5.97%). Analyzed pseudograins contain calcium, magnesium, zinc and iron in a significant amount. The highest TPC content was observed in chia seeds (395.7 mg GAE/100 g), following canihua (327.4 mg GAE/100 g), quinoa (161.9 mg GAE/100 g), common wheat (61.8 mg GAE/100 g), Khorasan wheat (51.1 mg GAE/100 g), while the lowest content was identified in millet (32.9 mg GAE/100 mg). TFC content was in a range from 0.001 % (common wheat, khorasan wheat) to 0.099 % (canihua). Antioxidant properties of pseudograins were lower compared to chia seeds, but similar to common wheat and khorasan wheat while even higher comparing to millet.

Keywords: *pseudograins, chia, millet, wheat, phenolic compounds, antioxidant activity.*

Introduction

Amaranth (*Amaranthus sp.*), quinoa (*Chenopodium quinoa* Willd.) and canihua (*Chenopodium pallidicaule* Aellen) from Amaranthaceae are usually called pseudograins (pseudocereals) because they belong to the different family than the usual cereals like wheat, oat or rise (Poaceae). They are native to South America and have been used for thousands of years (Repo-Carasc-Valencia et al., 2010). Chia presents edible seeds of *Salvia hispanica* L., (Lamiaceae), annual plant from Central America (Da Silva et al., 2017). Pseudocereals as gluten-free grains, and chia seeds, contain various biologically active compounds like polyphenols of growing interest regarding their potential health benefits (Vollmannova et al., 2013; Valdivia-López and Tecante, 2015; Tang and Tsao, 2017).
Millet (*Panicum miliaceum* L., Poaceae) originates from India and represents one of the oldest cereals. It is traditionally used in European and Asian countries and just like pseudocereals,

millet is also gluten-free and is convenient for patients suffering from celiac disease (Alverez-Jubete et al., 2010). Moreover, the proteins in millet grains have higher biological values compared to wheat grain, due to the higher content of essential amino acids (leucine, isoleucine, methionine) (Kalinova and Moudry, 2006).
Another nutritionally valuable grain is an ancient khorasan wheat, kamut or oriental wheat (*Triticum turanicum* Jakubz.). Whole grain consumption can have the significant role in the prevention of cardiovascular disease, diabetes and other metabolic diseases. It has also been found that khorasan wheat products promotes the growth of probiotic strains in the gastrointestinal tract and improves metabolic, lipid and antioxidant status in healthy subjects and in patients with acute coronary syndrome (Sofi et al., 2013; Whittaker et al., 2015)
The aim of the study was to evaluate the nutritive characteristics, phenolic content and antioxidant activity of commercial samples of pseudograins (amaranth, quinoa and canihua) from our market, as well as a comparative analysis to chia seeds, common and Khorasan wheat and millet.

Material and methods

Commercial samples of amaranth, quinoa, canihua, chia, millet, khorasan and common wheat were purchased from the market in Belgrade, Serbia. Three independent samples from different suppliers were used for the research. All samples were grounded, homogenized and stored at room temperature until the analyses.

Nutritional analysis

Determination of moisture (water, loss on drying), ash and crude fiber in the samples was performed by the recommended methods by the Association of Official Analytical Chemists (AOAC 930.04; AOAC 930.05; AOAC 930.09; AOAC 977.02). Proteins were estimated from the nitrogen content by multiplying by factor 6.25. The analysis of fat content was done by Soxhlet extraction after acid hydrolysis and carbohydrates were calculated by subtracting the total sum of proteins, lipids, crude fiber and ash from 100% sample. The contents of nutrients was expressed in percentages. Total energy values were calculated in kcal multiplying the amount of fat by factor 9 and protein and carbohydrate by factor 4.
After dry ashing mineralization (AOAC method 999.11 B), the content of sodium, calcium, magnesium, phosphorus, iron, zinc and manganese were determined by the ICP-OES, Vista-PRO Simultaneous ICP-OES (Varian Inc.). The mineral content was expressed as miligrams per 100 g.

Total phenolic content (TPC)

The total phenolics were determined in methanol (80% *V/V*) extracts of investigated samples spectrophotometrically by *Folin–Ciocalteu* method. Gallic acid was used for construction of calibration curve and the results were expressed as mg of galic acid equivalents/100 g of sample (Singleton et al., 1999).

Total flavonoid content (TFC)

The content of the total flavonoids in methanol extracts was determined according to the procedure given in the monograph of Ph. Eur. 7.0. (Ph. Eur. 7,0)

Antioxidant activity determination by DPPH scavenging activity

For the DPPH scavenging activity determination the solution of DPPH (0.0147 g DPPH in 20 ml of ethanol) was prepared *ex tempore*. The standard solution was Trolox in ethanol (2 mM/l) in the range 0.2-0.7 mM/l. The colour change was measured spectrophotometrically at 525 nm after 1 hour of incubation at the dark place. The results are presented as mM Trolox equivalents/100 g of sample (Brand-Williams et al., 1995).

Antioxidant activity determination by FRAP test

Ferric reducing antioxidant power (FRAP) assay is a method for determination of total reduction ability. During analysis the antioxidant donates electrone to the [Fe^{3+}-*TPTZ*] complex (Fe^{3+}-2,4,6-tris(2-pyridyl)-*s*-triazine), that is subsequently reduced to blue [Fe^{2+}-*TPTZ*] at low pH values. After the incubation at 37˚C for 40 minutes, the absorbance is measured at 593 nm. The Trolox was used for the construction of the calibration curve (0.1-0.8 mM/l). The results are presented as mM Trolox equivalents/100 g of sample (Benzie IFF, Strain, 1999).

HPLC analysis

HPLC analysis of flavonoids was performed on the Agilent 1100, using the Zorbax Eclipse XDB-C18 analytical column (4.6 × 250 mm, 5 μm particle size), with the photodiode array detector set to 370 nm. Dried methanol extracts were dissolved in methanol (10 mg/ml). The samples were gradiently eluted with a two phase system: phase A = water/phosphoric acid (99.97:0.03), pH=2.75; and phase B = 10% A in acetonitrile, flow rate of 0.8 ml/min, at 25ºC. The identification of components was performed by comparing the spectra with reference standards and quantification of rutin by constructing the calibration curve.

All analyses were done in triplicate and results were expressed as average mean.

Results and discussion

The results of nutritional analysis of commercial samples of pseudograins, chia seeds, millet and khorasan wheat are given in Table 2. The amount of water was in the range 7.89-12.03% that was in accordance with the previous data (Repo-Carrasco-Valencia et al., 2010; Da Silva et al., 2017). The highest content of total ash was determined in the chia seeds (4.16%) and the lowest in the millet (0.7%). The results of total ash were also in agreement with former investigations (Repo-Carrasco-Valencia et al., 2010; Da Silva et al., 2017).

Pseudograins are important source of valuable proteins (Repo-Carrasco-Valencia et al., 2010; Da Silva et al., 2017; Kalinova and Moudry, 2006; Villa et al., 2014). Amaranth (19.91%) and chia (18.38%) contained the highest content of proteins, while lower contents were obtained in quinoa (8.31%) and millet (9.63%). However, obtained protein contents for quinoa (8.31%) and canihua (10.5%) were lower, while the amaranth (19.91%) protein content was higher than previously published data (Repo-Carrasco-Valencia et al., 2010).

Relatively low content of total lipids is one of the main nutritive characteristics of pseudograins. As expected, the obtained lipid content was 3.89-9.59%. On the contrary, chia seeds are characterised with high lipid content. So, obtained average content (30.09%) of total lipids in chia seeds is in accordance with literature data (Da Silva et al., 2017; Coates and Ayerza, 2009). Importantly, chia seed lipids contain very high amounts of polyunsaturated fatty acids, especially essential omega-3 alpha-linolenic acid (Coates and Ayerza, 2009). Observed higher total lipid content in chia seeds compared to other samples, corresponded the higher energy value than in other analysed samples.

Table 1. Nutritional values of commercial samples of pseudograins, chia seeds, millet and khorasan wheat

Sample	Water [a]	Ash	Proteins	Lipids	Available carbohydrates	Crude fiber	Energy value kcal/100 g
	Content, %						
Amaranth	10.06	1.94	19.91	3.89	63.63	0.57	369.17
Quinoa	12.03	2.15	8.31	6.29	70.92	0.3	373.53
Canihua	11.76	2.13	10.5	9.59	65.84	0.27	390.86
Chia	7.89	4.16	18.38	30.09	38.53	0.95	498.45
Millet	11.27	0.7	9.63	4.11	74.18	0.11	372.23
Khorasan	10.94	2.12	14.4	2.21	67.13	3.2	346,01

[a] loss on drying;

The mineral content of analyzed samples is given in Table 2. The highest average content of calcium was observed for chia seeds (597.15 mg/100g). The obtained value was about three to four times higher than in amaranth (166.71 mg/100 g), about ten times higher than in quinoa (60.52 mg/100g), and even one hundred times more than in millet (5.25 mg/100g). Also, noticed variations in phosphorus contents were in the range 37.26 mg/100 g (millet) to 820.61 mg/100 g (chia seeds). Similarly, the lowest (51.73 mg/100 g) and the highest (337.06 mg/100 g) magnesium contents were recorded in the millet and chia seeds, respectively. Opposite to other samples, the quinoa had a relatively higher concentration of sodium (average 47.11 mg/100 g). Variations in iron content were in the range 0.93-4.04 mg/100g. The highest levels of iron were noticed for amaranth and chia, while the quinoa had the highest average content of manganese.

Table 2. The content of minerals in commercial samples of pseudograins, chia seeds and millet

Sample	Calcium	Phosphorus	Magnesium	Sodium	Iron	Manganese	Zinc
	mg/100g						
Amaranth	166.71	499.20	256.91	2.00	4.04	3.92	4.24
Quinoa	60.52	378.98	193.42	47.11	2.33	5.39	2.74
Canihua	41.23	184.37	117.59	8.53	1.47	3.67	2.29
Chia	597.15	820.61	337.06	5.70	3.85	3.61	3.89
Millet	5.25	37.26	51.73	2.38	0.93	0.21	2.79

The total phenolic content (TPC) in investigated samples was in the range 32.90-395.75 mg GAE/100 g and total flavonoid content (TFC) 0.91-98.90 mg/100 g (Table 3). The highest content of phenolic compounds was in chia (395.75 mg GAE/100 g) and in canihua (327.36 mg GAE/100 g) samples, while the lowest in millet (32.90 mg GAE/100 g). Although the chia seed contained the highest value of phenolic compounds the obtained results were lower than previously described (757 mg GAE/100 g) (Hirose et al., 2010). The total phenolic content in amaranth (65.55 mg GAE/100 g) was similar to the Khorasan (51.05 mg GAE/100 g) and common wheat (61.82 mg GAE/100 g) samples. The highest amounts of total flavonoids were measured in canihua (98.90 mg/100 g) and quinoa (86.41 mg/100 g) samples.

Additionally HPLC method was used to identify the phenolic compounds in ethyl acetate extracts obtained after the hydrolysis of bounded phenolics and glycosides. Identified compound was present in very small amounts. In the ethyl acetate extracts of canihua and quinoa seeds quercetin aglycone was identified at 370 nm.

Table 3. Total phenolic and flavonoid content and antioxidant activity of commercial samples of pseudograins, chia seeds, millet, khorasan and common wheat

Sample	TPC [a]	TFC [b]	FRAP	DPPH
	mg GAE/100g	mg/100 g	mM TE/100g	
Amaranth	65.55	2.06	5.8	2.55
Quinoa	161.92	86.41	3.0	0.85
Canihua	327.36	98.90	5.5	1.70
Chia	395.75	4.14	13.7	3.65
Millet	32.90	2.48	1.7	- [c]
Khorasan	51.05	0.91	6.4	9.06
Wheat	61.82	1.08	5.2	10.38

[a] total phenolic content; [b] total flavonoids content; c no antioxidant effect

The antioxidant activity of pseudograins, chia seeds, millet, khorasan and common wheat was not pronounced (Table 3). The total reduction ability measured by FRAP assay was in the range 1.7-13.7 mM TE/100 g and the DPPH radical scavenging activity 0-10.38 mM TE/100 g. The highest antioxidant activity in FRAP assay was obtained with chia seed (13.7 mM TE/100 g) and the lowest with millet sample. On the contrary khorasan and common wheat samples showed the highest scavenging activity in DPPH test (9.06 and 10.38 mM TE/100 g).

Conclusion

Despite its growing popularity, this study is one of the scarce that offers insight in nutritive value of commercial samples of pseudograins on our market. Opposite to nutritional composition, there are observed differences in total polyphenol content and consequently in antioxidant activities among amaranth, quinoa and canihua samples. Also, there are prominent differences in all analyzed parameters among pseudograins and chia seeds, compared to millet. No differences were observed between khorasan and common wheat. In conclusion, obtained results of favorable nutritive value support the importance of pseudograins and chia seeds intake as part of our variety and balanced diet.

BIODIVERSITY OF CHICKPEA: BLACK CHICKPEA

Ali KAHRAMAN*

Department of Field Crops, Faculty of Agriculture, Selcuk University, Konya, Turkey

Abstract
Sustainability of agriculture includes; conservation of natural resources in long term besides using agricultural technologies that are non-destructive to environment and living creatures. Providing diversity of products supplies protection of soil, using local seeds, decreasing of pesticide usage, information transfer to farmers about chemical fertilizers etc. components. Local plant species are developed by selection method in traditional agriculture that are well adapted to ecology, provides the cultural demands and traditions. Local seeds are one of the main sources for conventional agriculture and a great effort for social, environment, economic output amongst farmers over the World. Otherwise, expansion of industrial agriculture caused to pressure on conventional methods under narrow area and difficulty on product sales. Therefore, farmers prefer growing the seeds which are desired by markets which causes a serious danger of distinction of the local genetic resources. Black chickpea is a type of chickpea which has a rich content of nutritional value and taste, contains more protein ratio and some other minerals than common chickpeas. Ideal for losing weight due to higher fiber content, a good vegetable energy source, health care statues especially for diabetes and cholesterol, a well iron source, provides oxygen demand for body, higher antioxidant content. The present paper describes some features of the less known legume – black chickpea and offers some proposals about farming systems depending on biological diversity which could provide more employment, more food production, better quality, effective usage of the local facilities, food security, controlling of production costs, more income to families and prevention of migration.

Keywords: *Biosecurity, Climate change, Conservation, Sustainable agriculture.*

Introduction
Plant genetic sources are the main sources which came up by development of historical process. Genetic materials are ancestral live material which are genetically protected, used for development of new plant varieties and called as modern varieties present day. Production of goods and services was increased after Second World War for almost all the sectors in addition to changes in technology, consumption and production molds. However, pressures on natural resources were increased more than 10% ratio between 1947 and 1970 years (Aruoba, 1997). During 1970s, the "ecological foot print" that means request of human for sources was more than yearly biological renovation capacity of world. By other words, human population consumed more than renovation capacity of source ecosystem (WWF, 2010). Today, legumes are essential plant species for both human health and soil features. Black chickpea; a species of legumes is a less known plant which is promising for various works especially for adaptation mechanism of plants and well balanced nutrition projects in plant breeding programs.

Applications of agricultural industry, agricultural policies that supporting the seed usage that are released by private sector, changes in legislation related with seed, increasing dominance of super markets instead of local production and consumption, pesticides and their relative seed production activities by companies that are providing higher yield but unhealthy production methods, asymmetric knowledge of farmers and customers about those products etc. main factors caused to concern about protection and production of local seeds.

The present paper reviews the importance of biodiversity by means of plants and introduces "black chickpea" that is a less known edible legume species by view of its nutritional value, health care statues in addition to potentials by mean of sustainable agriculture.

Agricultural Sustainability and Biodiversity of Local Genotypes

The term of agricultural sustainability means that; protection of natural resources in long term as well as application of agricultural technologies that are not harmful for environment and other living organisms. There are many applications together with sustainable agriculture. Providing of product diversity and hence protection of soil, using of local seeds, decreasing of chemical usage and giving information to producers and extension works, preservation of natural areas and forests etc. factors are all components of the subject. As human invited the power of seed; agriculture was started on earth. Since that time, a lot of effort had been made about seed, plant growing, yield, taste, nutritional and other quality components.
Importance of plant genetic resources by view of sustainability may be summarized as following; possess various characteristics belong to different ecologies, high level of allele, developing of new varieties by agricultural activities, preserving of rich genetic characteristics by generations. From this perspective, determination and defining of plant varieties is an essential topic for various plant species that will provide to main data about plant biotechnology and agricultural breeding works. Increasing population and so demand for food, climatic changes, urbanization and industrialization, deforestation etc. events caused to serious problems for sustainability of life. In this point, evaluation of genetic resources – especially local plant genetic resources are quite important.
Industrial agriculture is increasing over the world in addition to migration from village to city. Most of the populations in villages are consisted from old people. These factors cause ton increasing of extinction on local seeds. The best way to protection of seeds is; production and preservation. Day by day, human being is more sensible for importance of the situation especially for sustainability of environment and human health.
Local ecotypes of plant seeds which are also called as "ecotype" also called as "landrace" are developed by traditional agricultural production systems that are including selection method, well adapted to the ecology, providing cultural demands and tradition. Present day, agricultural production depends on less species (Schmidt et al., 2010; Padulosi, 2011). According to the FAO reports, only 120 of plant species are produced for human food while 75% of plant based energy is realized by only 9 plant species while more than half is provided by wheat, rice and corn (Padulosi, 2011). The spread of industrial agriculture limited traditional agriculture to narrow areas, causing many difficulties especially in the marketing of those products. Therefore, farmers are obliged to higher valued commercial species instead of traditional species leading to the extinction of plant biological richness. For all the above mentioned factors, existence of traditional agricultural systems and traditional seed species and their protection will provide to sustainability of life.

Black Chickpea

Common chickpea (*Cicer arietinum* L.) on the dinner table is consumed for a long time and usually yellow colored while its seed color changes from white to black and from green to brown. Black chickpea has less oil, sugar and starch while more fiber than yellow chickpeas (Anonymous, 2019a). Three natural benefits of black cihckpeas may summarized by; clean digestive tract, cure bloating and belching, threat diarrhea naturally (Koradia, 2019) On the other hand, white and yellow chickpeas have more calories, potassium, calcium and iron than black chickpea (Quora, 2019). As the most important components of protein, amino acid compositions of yellow and black chickpea genotypes are presented on Table 1 (Rossi et al., 1984). Black chickpea is called by various local names; "gara nohut, siyah nohut, kara nohut, mukaşer" depending on local accents. Due to its dark color, it is not usually preferred by customers while it has better nutrition and health statues. In general, black chickpea is a kind of anti-oxidant store, seed coat is a little thicker than yellow types, so it should be wait in water around 24-36 hours.

Nutritional value and taste of black chickpea is better than the common chickpeas. Both protein concentration and the other nutritional components are quite higher. Higher ratio of fiber is ideal for the person who wants to diet. Additionally, it is a good plant energy source besides a wonderful legume crop for diabetes and cholesterol. Black chickpea is also an excellent source of iron. It helps to meeting of body oxygen need. On the other hand, it has more anti-oxidant matters (total phenolic components) than other legumes. It provides to avoid from cancer. It also has skin beautifying effects in case of regular consumption. Due to containing vitamin B6 and zinc, it is also quite effective on hair loss (Anonymous, 2019b).

Try	54	54	54	54	54	54	54	54	54	54	54	54	54	54	54	54	54	54	54	54

Some of the other benefits of black chickpea is summarized as it following; it is good for back pain, increases virility and so it is used on camels, resolves to congestion on spleen and hepatic, makes the bowels soften, fixes the toothache, complementary for cereals (Anonymous, 2018).

Conclusions

Farming systems depends on biological diversity provides more employment, foods as better quality, assurance for product quality that are desired by various consumers. Additionally, traditional production systems are realized by available local possibilities. Production costs are under control and so the farmer families will gain more. Protection of local seeds and transfer to the next generations is an urgent issue. Therefore, farmers should protect them as the first step for their own usage. As a member of legume crops, there is need for depth research on black chickpea by view of its features related with sustainability concept.

SUSTAINABLE SOIL USAGE: LEGUMES AND HEAVY METALS

Ali KAHRAMAN*

Department of Field Crops, Faculty of Agriculture, Selcuk University, Konya, Turkey
*Corresponding author: kahramanali@selcuk.edu.tr

Abstract

Industrialization and increasing of population caused effects on the whole ecosystem and environmental problems especially for heavy metal pollution of air, water and soil. There is not a distinct definition of heavy metals in literature but known as more than 20 for atom number (such as; Ag, As, Cd, Cu, Fe, Hg, Ni, Pb, Zn) and they have versatile damages particularly on soil. Some of the heavy metals in nature join to food chain and presenting toxic effects even very small amounts. Most of the heavy metals accumulate on biological systems. Some are necessary for plant growing but more quantities than requirement are toxic. Furthermore, some of the hyper accumulator plants are used for medical and aromatic purposes. So, those kinds of plants should be studied for negative and positive sides as well. Cleaning of soil from heavy metals is called as phytoremediation and the topic is quite essential in the world. Researches on hyper accumulator plants that are able to accumulation of metals reported 400 plant species in total. These plants are gathered from the following plant families; *Asteraceae*, *Brassicaceae*, *Caryophyllaceae*, *Cyperaceae*, *Lamiaceae*, *Violaceae*, *Euphobiaceae*, *Poaceae* and *Fabaceae*. It is fair that; legumes (*Fabaceae*) are the main protein sources for both animal and human. On the other hand, these crops are known as "absolute crops" for rotation programs. Present paper focused on; heavy metals in soil, their accumulation by legumes and statues in legume based foods.

Keywords: *Healthy food, Hyper accumulation, Phytoremediation, Pulses, Sustainable agriculture.*

Introduction

Industrialization and increasing of population brings many environmental problems by affecting the ecosystem wholly. Components such as air and water, soil are also an important creature. Because, soil is the first essential component to human survive which is including most of the minerals. Industrialization causes to an increasing heavy metal accumulation of soil. Some of the heavy metals especially mercury, cadmium and lead is threatening to food chain and all the world. Most of the metals are also spread to environment by industry (Urano, 2010). Content of heavy metal in soil ranges from 1 to 100.000 ppm (mg kg^{-1}) values. Higher content of them causes to deterioration of soil organic structure, decrease of yield and quality (Long et al., 2002) and so human and other living organisms are under the adverse effects (Blaylock and Huang, 2000).

Disposal of heavy metals from soil is realized by trenching, chemical stabilization, soil washing, bury etc. techniques. But, application of these techniques is hard and expensive so they are not practical. Some of the plants that are growing on the contaminated soils are accumulating the heavy metals by higher values on their tissues. Hyper accumulator plants are able to collection of heavy metals from 1000 ppm to 10.000 ppm values. Accumulation is realized on their roots, stem and leaves. Hyper accumulator plants are also used for organic pollutants and radioactive elements (Yalçuk et al., 2004).

Cleaning of heavy metal contaminated soils (phytoremediation) by hyper accumulator plants is quite important and so, determination of those plants is essential as well. Hyper accumulation defines that; collection of heavy metals in its own structure by higher values.

Present paper describes; heavy metal pollution, hyper accumulation and role of legumes by view of sustainable soil usage.

Heavy Metals

There is not a distinct definition of heavy metals in literature while their specific weight is 5 and atom number is more than 20 (Ag, As, Cd, Cu, Fe, Hg, Ni, Pb, Zn etc.) and they have versatile damage. In some cases, their quite less values are toxic that are take part of food chain in the nature. Most of the heavy metals are accumulated in biological systems and excessive values are cause to death in some cases (Kahvecioğlu et al., 2007). In general, zinc, copper and nickel include most of the heavy metals. Definiation of heavy metals and their structure is quite important (Paschke et al., 2005). Table 1 presents ecological classification of some heavy metals (Avcil, 2018).

Table 1. Ecological classification of some heavy metals (Avcil, 2018)

Element	**Spesific weight (g/cm^3)**	**Requirement (R) for plant and animal**	**Pollutant (P) or non- pollutant**
Copper (Cu)	8,9	R	P
Mercury (Hg)	13,6	-	P
Zinc (Zn)	7,1	R	P
Iron (Fe)	7,9	R	P
Silver (Ag)	10,5	-	P
Cadmium (Cd)	8,5	-	P
Stannous (Sn)	7,3	-	P
Cobalt (Co)	8,9	R	P
Chrome (Cr)	7,2	R	P
Lead (Pb)	11,3	-	P
Manganese (Mn)	7,4	R	-
Molybdenum (Mo)	10,2	R	P
Nickel (Ni)	8,9	R	P
Platinum (Pt)	21,5	-	-
Thallium (Tl)	11,9	-	P
Tungsten (W)	19,3	R	P
Uranium (U)	19,1	R	P
Vanadium (V)	6,1	R	P
Zircon (Zr)	6,5	-	-

Hyperaccumulation

Pollution of soil is emerged by human effects and causes to structural corruption. Main activities that are cause to soil pollution is summarized in the below (Karpuzcu, 2010):
- Garbage deposition areas,
- Transfer of solid wastes by many of the industrial establishments,
- Muds formed on refinement facilities,
- Unloading of sewer contents,
- Transfer of liquid wastes to soil,
- Accumulation of agricultural chemicals (pesticides),
- Fertilizer using in agriculture (chemical fertilizers),
- Accumulation of particles and aerosol air pollutant on soil,
- Increasing of salt content by irrigation.

Cleaning of the heavy metal contaminated soils is really hard, expensive, needs long time as in mentioned formerly. Plant are used both macro nutrients (N, P, K, Ca, Mg, S) and micro nutrients (Fe, Mn, Zn, Ni, Cu, Mo) while some of the plants are collecting As, Co, Cd, Se while they are not using them (Alford et al., 2010; Lasat, 2000). Those plants are called as hyperaccumulator. According to a former research, almost 400 plant species are able to metal accumulation. Some the plant families are; *Asteraceae*, *Brassicaceae*, *Caryophyllaceae*, *Cyperaceae*, *Lamiaceae*, *Violaceae*, *Euphobiaceae*, *Poaceae* and *Fabaceae*. Amongst these, *Brassicaceae* is the widest family by 7 genus and 72 species (Thompson, 1997).

Legumes and Sustainable Usage of Soil

Among angiosperms, some of the hyper accumulator families are: *Brassicaceae*, *Caryophyllaceae*, *Cunoniaceae*, *Cyperaceae*, *Fabaceae*, *Flacourtiaceae*, *Lamiaceae*, *Poaceae*, and *Violaceae* (Prasad, 2001). Legumes are reported as one of the common plant family which is presented on metal enriched soils on temperate zone that is located in tropics while it is not obviously evolved metal tolerance but infrequently formed naturally in metal enriched soils (Macnair and Baker, 1994; Wu, 1990). It is noticed that; *Fabales* contains homo-phytochelatins that are metal binding peptides of homo-glutathione (Grill et al., 1986). In another research, *Brassicaceae* and *Fabaceae* families are defined as generally including hyper-accumulator species. Nature of hyper accumulation is still not fully understood. The featured hypotheses may be summarized as following 3 titles: a) Hyper accumulation is related with hyper tolerance that is resulted by chelation and vacuolar classification. b) In some cases, metal content of shoots may be more than root content. a c) Hyper accumulator are tolerant to drought stress and competes with plants in the same area. d) Hyper accumulators are effective to combat with fungi and insect. Accumulation of Nickel showed protection against fungal and bacterial pathogens and insects as well. Similarly, zinc presented anti-herbivory effect (Martens and Boyd, 1994; Pollard and Baker, 1997).

In addition the those features, as the legumes have symbiotic living mechanism by *Rhizobium* sp. bacteria, they are the essential choice for crop rotation systems that are presenting natural nitrogen fixation mechanism that is an eco-friend type of nitrogen in addition to many advantages on soil reforming features.

Conclusions

Some of the hyper accumulator plants exist in same area with medical and aromatic plants. So, human have to take care about the risk. On the other hand, increasing human activities causes to metal pollution on the environment and its risk is rising rapidly. Therefore, there is need to more studies on the phytoremediation to find issues and providing sustainability concepts.

NITROGEN FIXATION IN LEGUMES AND CHANGES IN CLIMATE

Mustafa ONDER*, Ali KAHRAMAN

Department of Field Crops, Faculty of Agriculture, Selcuk University, Konya, Turkey
*Corresponding author: monder@selcuk.edu.tr

Abstract

Increase in the world population is directly related with requirement of fossil energy and production of fertilizer as well. The truth in this condition is economic difficulty and environmental damage. Intensive agriculture systems cause to huge amount of nitrogen fertilizer usage which led to concern on N cycle over the soil-water nitrate accumulation and nitrogen oxide in atmosphere. Change in climate over the world is an essential issue for humankind. Scientific researches on plant response to environmental factors are a topic which increasingly takes attention due to concern on resources of plants, biodiversity and global food security. Legume family known as eco-friend and health-care plants which are fundamental crops for sustainability besides presenting second major crop of agricultural importance over the world. Depending on environmental changes, response of legume nitrogen fixation varies by view of drought, salinity, heat stress, carbon dioxide concentration and soil acidity. Present paper describes the main environmental factors which are directly connected with climatic changes and their major effects on N_2 fixation and legume production worldwide. Additionally, suggestions for adaptation of symbiotic legumes to climatic variability on production quantity are given depending on recent studies by view of molecular and biotechnological efforts over the world. Therefore, aim of the paper is improvement of healthy food supply consider to sustainable agricultural system.

Keywords: *Eco friendly, Global warming, Grain legumes, Rhizobium, Sustainable agriculture.*

Introduction

According to NASA records for 137 years (from 1880 to 2016), 9 of 10 highest years was realized after 2001 year. Additionally, 2016 presented the highest temperature. Agriculture in the world is developing day by day in accordance with providing the personal and public requirements. Global competition is also increasing while trade of agricultural products are developing, agricultural supports showing a declining trend, profit margin is shrinking, China and India countries are important factors for global agricultural factors; increasing income causes to more consumption of meat, fish, vegetables and fruit, cereal production is decreasing as the advantage of vegetables and fruit, demands of China causes to increase in prices for raw materials.

Nitrogen based chemical fertilizer are the most used types over the world. One of the most important points in this is the negative effects of nitrogen to environment and climate as well. Legumes are the most valuable crops by mean of their symbiotic nitrogen fixation mechanism. Present paper describes climatic changes and its agricultural effects in addition to why we need to take a part to legumes in crop rotation programs.

Climate Change and Agricultural Production

Climate changes will also cause to; periods with warmer and less precipitation, increasing of extreme meteorological events such as flood, overflowing and vigorous storms, erosion, decrease in water sources, increase in drought intensity, corruption of soil and water quality, decrease in ecosystem and biological diversity, increase in disease and insects, decrease in agricultural productivity, narrowing and/or extinction of ecological habitat, problems in

sustainable food security. On the other hand, changes in climate will give rise to some other problems for agricultural activities such as; sowing-planting, harvest and thrash, soil tillage, fertilization, drainage, spraying, cultural practices (hoeing- pruning), yield and quality, providing of irrigation water, increasing of vegetation period, diversity of plants, increased CO_2 concentration will cause to increase in plant growing. Water consumption of several food sources are quite different from each other (Gleick, 2000, Guy et al., 2004; Hoekstra et al., 2011, Pegram et al., 2014).
There are some scenarios for climatic changes and its effects on agriculture. According to a considerable report (RPCC, 2016), the negatively affected places would be; Africa, South America, South Asia, Middle East and Australia while positively effects on; North America, Europa and North Asia. Some of the risk factors are summarized as following: In global scale, climatic fluctuations will cause to more than 30% loss of products (Lobell and Field, 2007). Only each 1^oC increase in temperature, CO_2 fertilization will cause to yield decrease almost 6.0% of wheat, 3.2% of rice, 7.4% of corn, 3.1% of soybean if an effective adaptation and genetic improvement will not be realized (Zhaove et al., 2017).

Legumes - Nitrogen Fixation and Global Climate Change

Legumes are the third plant group by mean of production that is following to cereals and oil seeds (Graham and Vance, 2013). Due to wonderful symbiotic nitrogen fixation mechanism with *Rhizoubium* bacteria species, they are minimizing the environment and socio-economic dangers of chemical nitrogen fertilizers. Increasing of CO_2 concentration is an expected result of increasing of temperature and drought (Feller, 2016). Global climate change present variable effects by increasing of decreasing of temperature in different regions (Bhandari et al., 2017). Higher temperature has more effects on nodule and bacterioid formation than other parts of the plants (Aranjuelo et al., 2014). Drought stress causes to deformation of cells, less nitrogenase activity, protein less nitrogen for biosynthesis of protein and decrease in seed yield (Farooq et al., 2016). Legumes are sensible to salinity while *Rhizobium* species are more tolerant. But as a consequence, salinity causes to decreasing of nodule formation in *Rhizobium* due to osmotic stress and/or ion toxicity besides decreasing of nitrogenase activity in legumes (Hanumantha Rao et al., 2016). Similarly, increasing of CO_2 will give rise to decreasing of nitrogen content in plants (Hikosaka et al., 2011) while some times increasing of root secretion and thus encouragement of microbial developing and activity (Haase et al., 2007).
It is fair that, changes in climate will cause to increasing of carbon dioxide and temperature in atmosphere and hence drought and salt. These changes will negatively effect to legumes that are grown in arid and semi-arid climates. Increase in CO_2 will increase nodule developing and biological nitrogen fixation. However, drought stress by 2-4^oC increasing of temperature will give rise to negative effects on; root hair infection, number of nodules, size – growing and activity of nodule and so fixation mechanism. Additionally, salinity problem will reduce to respiration of nodule and content of hemoglobin (Yavaş and Ünay, 2018).
Agriculture is an important sector for both economy and social concepts. On the other hand, fields are a kind of factory which has no roof, so; it has a very sensitive structure by view of main components such as; ecosystem, and also sensible and unprotected for climatic changes. Therefore, changes in climate are a topic which should be paid more attention, faster and accurate estimations. According to "Global Framework for Climate Services (World Meteorological Organization) - GFCS", agriculture and food security are within priority sectors. Similarly, "Sustainable Development Goals (SDGs)" identified the first two topics as "no-poverty" and "zero hungry" respectively. Increasing of atmospheric CO_2 and longer plant vegetation period are caused to positive effects while changes in climate have negative impacts on higher temperature and so changes in quantity and regime of precipitation, increased frequency and violence of excessive weather events, and hence many unfavorable

effects on agricultural activities. Agricultural systems are forced to provide increased demands for food and renewable energy. Change in climate, scarcity of water, pollution, erosion and corruption of soil are more than threats on food security and quantity. Velocity of climatic changes and its effects are estimated more and more in following years. Short term plans are not solution for the problem. Main goals should cover; energy projects, irrigation programs, consolidation of fields, developing of climatic adaptable plant species etc. climatic based projects. All the mentioned effects of climate will effect to; animal husbandry, fishery and agricultural production by main negative effects on; yield and quality reduction, increased demand for water-pesticide-fertilizer, changes in sowing and planting times. Therefore, there is need for pay more attention about effective usage and reservation of agricultural inputs that are mainly composed by water and fertilizers. Herein, legumes are essential plants for crop rotation programs that are promising for the following statues related to combat with global climate changes; effective production planning, diversity of agricultural production, protection of biological diversity – soil and water resources, increased yield and producer profit, balance of supply and demand, reduction of public finance welded by purchase, increasing of international competition power and production planning, healthy agriculture inventory, better producing plan, demand projection for future, supports will be rational – router – effective and so; natural resources will be protected and all the factors will provide sustainability.

Conclusions

Agricultural production of the world should be increased. World population is growing as much population of Turkey every year. For the sustainability of agriculture, we need to take care the following issues; usage efficiency should be increased by the least source and input consumption, increasing of yield by low cost, the least intervention to nature and minimum environment damage, possible least period and a small number of process, independent from climate as much possible. Nitrogen - as an important and essential component of agriculture is able to be fixed by legumes – bacteria symbiotic live mechanism, naturally. So, there is need for increased legumes production for sustainability of healthy nutrition, agriculture, ecosystem and food security.

SUSTAINABLE PESTICIDE USAGE IN FARMING LEGUMES

Mustafa ONDER*, Ali KAHRAMAN

Department of Field Crops, Faculty of Agriculture, Selcuk University, Konya, Turkey
*Corresponding author: monder@selcuk.edu.tr

Abstract

Pesticides are used in agriculture commonly including insecticides, fungicides and herbicides. Today, almost a total of 900 pesticide products and 600 active pesticide ingredients accessible in the markets. Millions of tons of pesticides are used in agriculture while only 5% of them are selective which means rest of it (95%) stored in soil, non-targeted systems, mix to water and atmosphere as well. Plants that are exposed by pesticides response in various amounts depending on physicochemical features, genotype, soil and environmental conditions. Pesticide application can realized by roots and other upper organs of the plants. A part of the pesticides are reasonably persistent and non-biodegradable. Pesticides which are taken by plants can change the locations through xylem or phloem while only by phloem in roots. Their mobility affected from water solubility characteristics. Therefore, oxidation of pesticides is important for their activity. For all that, many of pesticides have long half-life and remains in plants. Legumes are the secondary important food for human following to grains. Yield and quality of legumes reduces owing to pesticides (aldrin, chlorpyrifos, chlordane etc.). Additionally, pesticides also have negative effects on symbiotic nitrogen fixation by affecting the rhizobium bacteria. Nevertheless, bacteria which have pesticide tolerant strains may grow under pesticide stress. As the main principle of sustainable agricultural systems, legumes are essential crops in rotation. Present paper describes effects of the pesticides which effects growing, yield, photosynthetic activity, nitrogen fixation and tolerance in legumes.

Keywords: *Agricultural pollution, Biodegradation, Pesticide effect, Sustainable agriculture, Toxicity.*

Introduction

Legumes are valuable food sources due to higher nutritional statues, environment friend crops and have wide adaptation ability over the world. Farming legumes provides many advantages on economy, social life, husbandry, soil, sustainable agriculture, food safety, human health, environment and so it means a kind of essential investment for human and future. Additionally, increasing of legume farming in crop rotation programs is an important point in recent years by focus on agriculture and the future of food supply while the topic will be also important for many years in worldwide. Present paper reviews pest management system, farming legumes and common problems that are need for management by view of sustainability principles.

Sustainable Pest Management in Agriculture

Agricultural production systems are changed from conventional techniques to intensive applications that are including pesticides and fertilizers in the world. Discovery of chemical fertilizers was realized during the 18th century by super-phosphates and ammonia including types, respectively. Similarly, pesticides were invented almost end of 18th century (Horne and Page, 2008). According to archives (Faostat, 2015), using of nitrogen, phosphorus and potassium is realized around 69.3 kg ha^{-1}, 25.8 kg ha^{-1} and 14.8 kg ha^{-1}, respectively. On global scale, amount of pesticide using is approximately; for herbicides; US $35 billion, for insecticides; US $15 billion, for fungicides; US $5 billion and for other products; US $5

billion in 1999 (Agrios, 2005). Additionally, almost 3 billion tons of pesticides are applied every year over the world (Pimentel, 2009a). It is reported that; benefit/cost ratio 2/1 by many risks for pest resistance, limitations on specificity and many harmful side effects (Pimentel et al., 1980; Pimentel, 2009b; McDougal, 2010). Although many efforts to use less chemicals for the agriculture, it is fair that usage of chemicals are too much and cause to serious problems on health of public and environment (Pimentel et al., 2005). The potential risks may be shown in the long term by compaction and erosion of soil and decline in fertility, health problems and extinction of biodiversity (Stinner, 2007).
For the mentioned problems on pest management, one of the feasible solutions is; integrated pest management that depends on a well following system from soil tillage for cultivation to eat on the table. This solution may be realized by integration of; science, policy and business (Hokkanen, 2015). Crop rotation has a great importance on pest management and, legumes in a crop rotation program are an important source for nitrogen and availability of nitrogen for plant to management of pest management. Legume cover crops are also provides to breaking of pest or weed cycles welded by fixation mechanism (Daniel et al., 2018).

Legumes and Pesticide Using

Common problems on legumes are several weeds, diseases (*Phytophthora capsici*, *Xanthomonas axonopodis pv. Phaseoli*, *Colletotrichum lindemuthianum*, *Pseudomonas savastoni pv. Phaseolicola*, *Fusarium spp.*, *Rhizoctonia solani*, *Macrophomina phaseoli*, *Uromyces appendiculatus*, *Perenospora viciae*, *Mycospheralla pinodes*, *Ascochyta pinodella*, *Peronospora lentis*, *Fusarium oxysporum*, *Ascochyta rabiei*, *Uromyces ciceris-arietini*), virus (bean common mosaic virus, bean yellow mosaic potyvirus) and insect (*Amicta oberthuri*, *Apion arrogan*, *Bruchus*, *Deliaplatura*, *Epithrix hirtipennis*, *Etiella zinckenella*, *Gryllotalpa gryllotalpa*, *Lampides boeticu*, *Liriomyza bryoniae*, *Liriomyza cicerina*, *Liriomyza huidobrensis*, *Liriomyza trifolii*, *Phytomyza horticol*, *Phyllotreta spp.*, *Sitona crinitus*, *Tetranychidae*, leaf flea) welded troubles.
Prices of pesticides to combat with the problems are quite expensive, application is hard on the progressive developing periods, some of the active ingredients are not effective on the level of recommended dose and/or presenting toxic effects to legumes and at the most important point; all the pesticides have potential risk for health by direct or indirect ways. There are many researches on pesticide using on legumes that are supported by breeding studies. In general, main breeding techniques on legumes may summarized as; mass selection, single-seed descent, pure-line selection, bulk, pedigree selection, backcross method in addition to advanced methods likewise; tissue culture, gene transfer, mapping populations, selection by molecular markers etc. methods that are examined under biotechnology. For resistance to pesticides, disease-weed and insect control, there are studies on genetically modified organisms (GMO) as well. Studies on GMOs are; transgenesis, cisgenesis, intragenesis, targeted mutagenesis (zinc finger nuclease technology), oligonucleotide directed mutagenesis, grafting, agro-infiltration, synthetic genomics and other techniques (reverse breeding) may be summarized (Legume Forum, 2018). Similarly, it was highlighted that; as a part of positive effects on pest management, the level of habitat in the field may be improved to other functions of ecosystem like controlling weeds, relaxation of soil erosion, cycling of nutrients that are realized by atmospheric nitrogen fixation by legumes (Simpson et al., 2013).

Conclusions

Demand for increased yield and quality, tolerant and/or resistant for changing climate-disease and insect factors, increased health care statues, high level of competition in the trade of global scale and providing sustainability concepts has been a rising trend for all the agricultural systems. Therefore, protection of biodiversity, better and faster breeding techniques, supporting of farmers, new types of foods and industrial usage, widening of extension besides cooperation and new varieties should be developed for legumes.

Abstract

Pastures are main living area of many living organisms and hunting as well. Environmental pollutions, intensive farming systems, urbanization and excessive usage of natural resources caused to significant negative effects on ecosystem even distinction of many species which gave rise to decrease in biodiversity. Wild species of both animals and plants absolutely depend on pastures while these areas are in danger by corruption of balance which is welded by human eventually while natural disasters and epidemic diseases have just a very few ratio. On the other hand, senseless utilization of the pastures likewise out of purpose, excessively irrigation, fertilization, pesticide application, pasturage, illegal hunting and/or on forbidden period, misidentification, extreme and unconscious collection from nature etc. significant mistakes caused to great negative threats on biodiversity on the pasture areas that are quite important side or direct effects on sustainability of ecosystem. Hunters usually do the activity because of the sporting activity, friendship, food, hobby and habit. Some of the hunters do not have license and have a little knowledge about sustainability components such as; birth season, number of kids, average life time, diet, limitation and techniques. It is fair that most of the interviews with hunters showed that the hunters love the animals very much and their associations realize many activities to increase to animal population. Finally, remediation of destruction on nature is extremely limited and impossible in some cases. Therefore, present paper focused on threats on biodiversity of hunting animals in pastures, its socio-economic perspectives and to make suggestions.

Keywords: *Bioresource, Extinction, Hunter, Sustainable environment, Wild life.*

Introduction

History of hunting is as older as human. Purposes of hunting are; nutrition, controlling of population and balance, sport activity and tourism. Irregular and unconscious hunting caused to some laws to legality and sustainability of life. Additionally, intensive applications on agriculture also gave rise to some concerns about biodiversity of pastures and hunting as well.
Hunting laws are including not only hunting animals but also their environment, other living organisms (Çalışkan, 2003a, b). In many countries that have a higher culture pay attention for hunting animals. Species of these animals, quantity, their environment are defined very well (Çanakçıoğlu and Mol, 1996). According to the official laws, hunting means a verb that; hunting depending on laws that is guiding to exact date, species, places, limit and methods. Hunting animal explains; the animal which is caught by hunting activity. Main purposes of the laws are related with: protection of hunting animals in their natural places. If human focused on protection of only one species, the other organisms would be affected as well. So, the main principle should be focused on sustainability. Because, all of the matters in the environment are component of the ecosystem.
As the changing statues on life and industry over the world, there is an increasing concern about sustainability of life and so all the components of environment. Hunting and other effects of human on ecosystem are directly and/or indirectly effects to sustainability. In the present paper, hunting and socio-economic dimensions are reviewed by biodiversity frame.

From this perspective, main purposes of the review are; importance of biodiversity by view of sustainability, determination of basic factors which have negative impacts on environment and wild life welded by increasing of population – urbanization – industrialization and unconscious hunting activities.

Sustainability of Biodiversity on Pastures

All the living organisms in the ecosystem are under the negative effects and risks of adverse conditions (Aktan, 2006). People who are not related with life sciences and hunter that are not educated are an element of danger/risk for sustainability (Akbaba, 2001). Love for nature, animal and all the living organisms are components for environment consciousness (Türçek, 2006). Industrialization and environmental pollutants are often realized by lack of responsibility and sensitivity (Dinç, 2005).

The term of environmental sustainability includes; long term solutions of environment - that is including the pastures - problems and, examination of conditions for economic development that are suitable for environment, newly planned evaluations for future. In this perspective, biodiversity on pastures is an essential element for the purpose and so, sustainable development should take care about providing of the demands for next generations without risk and also for the present time. Using of the natural sources and also pastures has multiple effects on biodiversity in addition to ecology that are serving to human demands (Ankara, 2001).

Sustainable Hunting

Rapid increasing of human population, modern industry, un-planned urbanization, rashly usage of natural resources etc. welded environment problems are threating on global scale. These factors caused to the term of "sustainable development" including economy, ecology, social sustainability and seeking to find solution on many sectors and sciences (Şermet, 2017). The term of sustainability is explained in "First International Conference On Urban Regeneration and Sustainability" as; persistence of functions of life quality in urban areas that are demanded by public without limitation of present and future choices and as not cause to negative effects (Özden, 2008)

One of the components for protection of nature over the world is wild animals as conscious, providing the balance between environment and wild animals, possibility of access from wild animals in sustainability principles (Ege, 1998). Depending on this definition, sustainable hunting may be summarized as following (Alpat, 1989); protection of wild animals by view of their presence-living environment-nutrition evenly, avoid from destruction of living area including diversity of plant, precautions for extinction, whole time watching to balanced reproduction, precaution for forbidden hunting and disease management, pay attention about agricultural activities-applications and cultural practices as well. In the present day, most of the hunters are aware of; importance of wild life, knowing the rules, and efforts for the topic by authorities are admirable and effective (Çaya, 2010). An excellent project suggests an example of theory for wild meat and food security as it seen on Figure 1 (CBD, 2017).

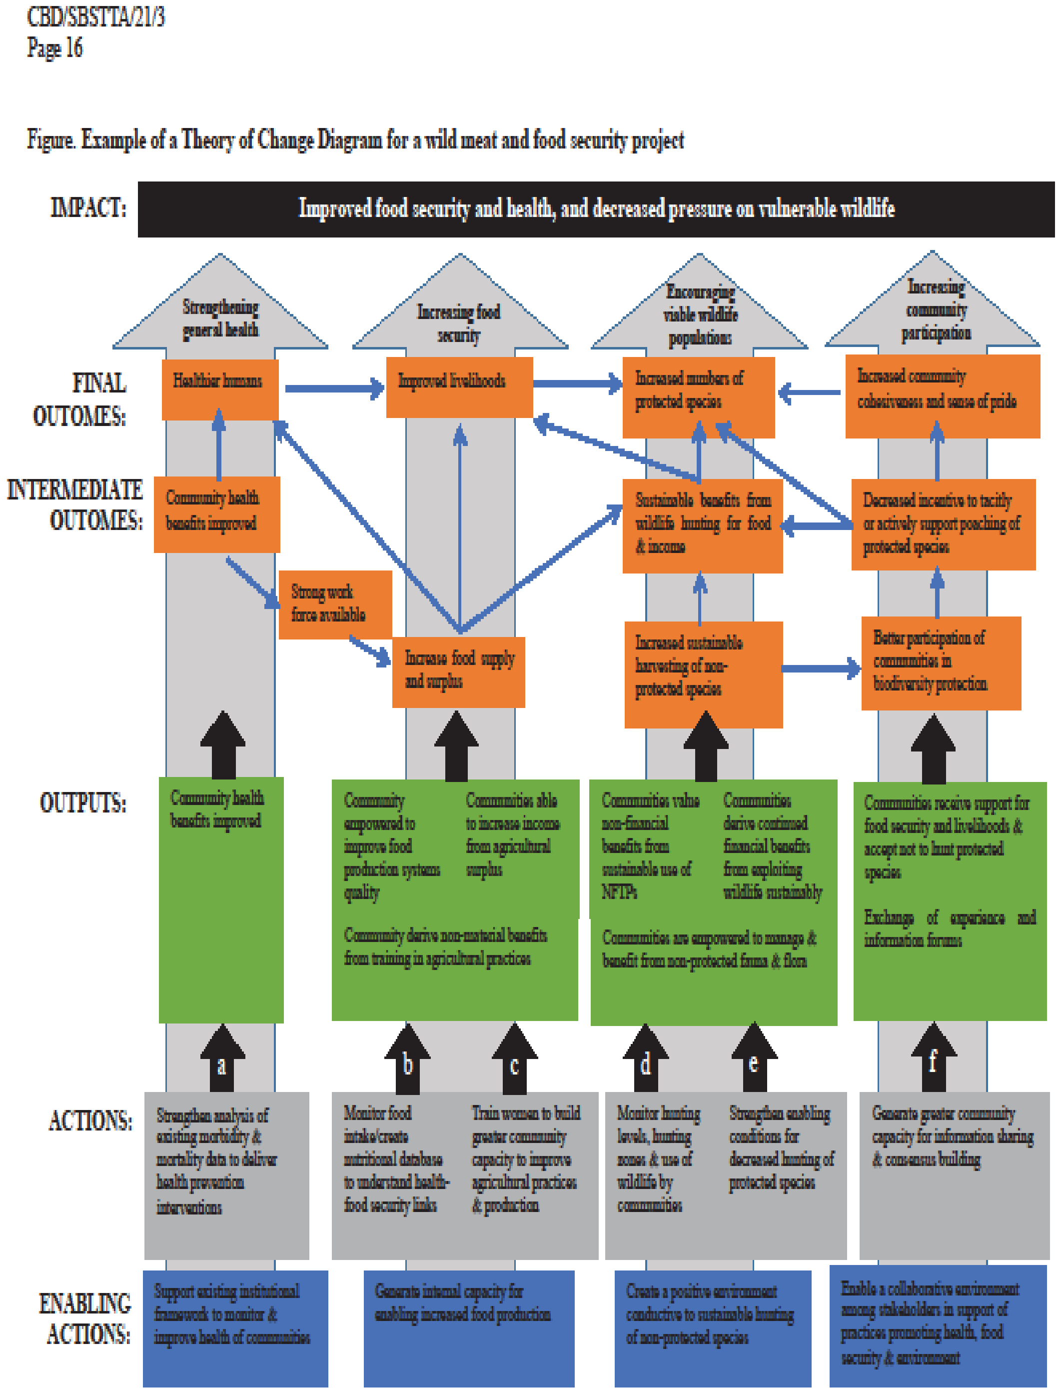

Figure 1. Change diagram for a wild meat and food security (CBD, 2017)

Hunting and Socio-Economic Dimensions

Hunting is an activity which was started by the first human and continues today. All the laws about hunting are focused on sustainability and balance of life. Some of the wrong and/or improper activities in addition to irregular actions give rise to misunderstanding or prejudice by many people who has insufficient knowledge about hunting or hunters. In some cases, wild animals suffers from human activities such as urbanization, mining, fire, industrialization, agricultural activities etc. factors for many times more than hunting and also some of the wild animal species are disappeared already. Therefore, there is need for more education and expansion works on hunters and the people who are strictly objecting to hunting as well. Similarly, all the human activities should be aware of sustainability principles. People has to take into account that; if somebody realizes something wrong, it does not mean all the people on that cite are going to do the same activity.

Conclusions

Some of the points in hunting should be revised such as; sustainability principles, participation, principle about; the person who benefits should contribute, regain, effective protection, honorary inspectorate, sources of income, documents and permission for hunting, hunting tourism, central hunting commission, employment and economy, educational publication and extension, management of ecology and environment, deterrent penalties. It is fair that; biodiversity of pastures, hunting and other human activities and economic development are very important factors for the future. Therefore, all the people who are strictly related with the mentioned topics should decide together.

Abstract

Seedling production and the quality of vegetable growing is a determining factor of subsequent yield. Transplant use has further advantages, e.g. earlier yield, improved efficiency of seed germination, increased growth safety, uniformity, etc. Non-profit orientated farmers can also consider using transplants because of these reasons. By applying substrate-improvement agents, farmers have a chance to enhance the seedling productivity in hobby gardens and in commercial production as well. These agents can improve the water capacity and nutrient content of substrates, and it can simplify the use of the media. Multiple type substrates can decrease the amount of chemical fertilizers necessary in production.
This research aimed to study the development of lettuce and tomato seedlings in organic substrate with an improvement agent (BRT® Evergreen – AE), and estimate the efficacy of different amounts of these additives in vegetable transplant growing.
AE is a lightweight substrate additive. It was developed by BRT Ltd., with the purpose of increasing the water holding capacity and nutrient absorption of the growing media.
Differences were found in the development of lettuce and tomato transplants. The additive in different doses increased the nitrogen, phosphorus and potassium uptake of the plants as well. Furthermore, the dry material, nitrogen and SPAD chlorophyll content showed expressive coherences too.

Introduction

Experiences of the past few years proved that seedling production has a particular importance. It can increase earliness, extend the growing period and provide crop safety. Moreover, it allows better utilization of the growing area, and it allows the growers to use the expensive seeds reasonably (used seeds per hectare may significantly reduce) (Pap, 2011). Because of controlled climate conditions, not only the productivity of the plants, but the quality of the yield will also be adequate (Montemurro and Maioranna, 2009). Disadvantages that should be mentioned are the costs of extra work and plant sustainment (Kappel, 2006).
Increase in temperature and decrease in rainfall are the current trends associated with climate change which are perceived to have huge impact in the production of different crops. Considering these conditions and its probable adverse implications, especially in terms of water availability for the growing plants, different interventions and technologies are developed. In addition to the utilization of good quality growing medium that are able to provide optimum growing conditions, different growing mixture additives were used such as superabsorbent (e.g. hydrogels or superabsorbent polymers) which are synthetic substances and water-insoluble polymers that have ability to retain water within its structure. It has been largely utilized during the last decades among different plant species including cotton, oat, onion, watermelon, potato, sage, corns, furthermore *Fagus sylvatica*, *Picea abies*, *Pinus*

sylvestris etc. (Ngoben et al., 2007; Viztiu et al., 2014; Savi et al., 2014; Faried et al., 2014). and was found to be beneficial in moisture conservation and economic reduction of irrigation for agricultural crops (Radó-Takács, 2016). By incorporating this in the growing media, the amount of irrigation needed in the cultivation is expected to be significantly reduced. Similarly, DCM Aquaperla® is a substrate additive developed to improve moisture and nutrient capacity. Aside from the water retention, it is also found to be advantageous in the development of string root, vigorous plant, and greener foliage (WEB 1). In the study conducted by Tilly-Mándy et al. (2016) where a recently developed plant growing media, namely BRT® GreenMoss and Uni-20 professional growing medium had been used in combination with the different levels of substrate improvement agents, specifically BRT® Evergreen and FAIN Bioactivator (FBA) in Tagetes patula "Csemő", it was found that moss can be a suitable growing medium for the plant which promotes significant increase in plant height and width and decline in the stress-enzyme activity of the plant. Another related study that was also done in an ornamental species, particularly Viola x wittrockiana 'Carrera' used BRT® Evergreen and FBA with coconut coir and peat as the growing media. Results indicated that taller and bigger plants have grown from the treatment groups with mix coconut coir, BRT® and FBA as compared to treatment groups with peat as the growing medium (Radó-Takács, 2016).
In this study the effect of additive agent was examined on some vegetable transplants, and tried to define the optimal use of additives with mixtures of black peat.

Material and Methods

The experiment was conducted in a forcing system, in a 50 m^2 type greenhouse at the Department of Vegetable and Mushroom Growing (Szent Istvan University, Faculty of Horticulture, Hungary, Budapest). 40 cell type plastic trays were used for tomato, and 66 cells type trays were used for lettuce seedling growing. The used tomato variety was 'Vilma', which is characteristically a dwarf type cocktail tomato. Sotalis F1 butter head lettuce variety was applied in our experiment. Lettuce transplants were grown from 27th of March 2018 to 24th of April 2018, while tomato transplants were grown from 12th of April 2018 until 24th of May 2018. All treatments had 6 replications, in case of tomato we used 20 transplants in one repeat, and in case of lettuce 30 plants. During the growing we used only clear tap-water for irrigation. The temperature and air humidity were measured by Voltrcraft DL 181THP data-logger. Table 1 shows the applied treatments with signs and important components.

Measurements

The following parameters were determined:

- Plant length to the tip of the longest leaf in case of lettuces
- Plant height to the tip of the plant in case of tomato
- Dry matter content of foliage (calculated from fresh and dry weights)
- Nitrogen and phosphorus in leaves and roots
  - ✓ Nitrogen – Kjeldahl method (Sáez-Plaza et al, 2013)
  - ✓ Phosphorus – spectrophotometric evaluation method (Thamné et al, 1968)
- Chlorophyll content from measured SPAD values with use of Konica-Minolta SPAD 502 Chlorophyll meter

Statistical analysis was evaluated with Microsoft Office Excel 2016 Analysis ToolPak.

Table 1: Marks of the treatments and type of substrate and additives.

Treatment	Marks	Notes
Control Florasca	**F**	55% Black peat 25% white peat and 20% Hungarian grey cattle manure
Florasca + 10% of BRT® Evergreen (WEB 2)	**F 10**	BRT (Biomass Refine Technologies) → Carbamide formaldehyde polymer, Formaldehyde, Carbamide, Clarified phosphorus acid, Alkylbenzole sulfur acid, Surfactant, Water
Florasca + 20% of BRT® Evergreen	**F 20**	
Florasca + 30% of BRT® Evergreen	**F 30**	
Florasca + Aqua Perla® additive (WEB 3)	**F AP**	Aqua perla → Potassium-poliacrilate

Table2: Physical evaluation of applied substrate (F).

Mineral content	Values
pH (KCl)	6,07
Total Salt (TS - m/m%)	0,05
Na (mg/kg)	835
Nitrogen (NO_2+NO_3-N mg/kg)	1040
Phosphorus (P_2O_5 - mg/kg)	6180
Potassium (K_2O - mg/kg)	7500
Mg (mg/kg)	1910
Cu (mg/kg)	13,4

Results and Discussion

According to physical evaluation of transplants a remarkable difference was observable in case of diameters of tomato seedlings (Table 3). In as much as F value is higher than F crit., and p-value does not reach 0,05, the H1 is acceptable. In this case significance is observable between treatments, where F 30 and F AP is presenting relevant difference from other groups.

Table 3. One-way ANOVA - Diameter of stem of tomatoes

SUMMARY

Groups	*Count*	*Sum*	*Average (mm)*	*Variance*	*St. Deviation*
F	30	100,74	3,36	0,11	0,33
F 10	30	99,24	3,31	0,07	0,26
F 20	30	103,62	3,45	0,08	0,28
F 30	30	114,79	3,83	0,20	0,45
F AP	30	106,69	3,56	0,11	0,33

ANOVA

Source of Variation	*SS*	*df*	*MS*	*F*	*p-value*	*F crit.*
Between groups	5,06	4	1,27	11,26	5,5332E-08	2,43
Within groups	16,30	145	0,11			
Total	21,369	149				

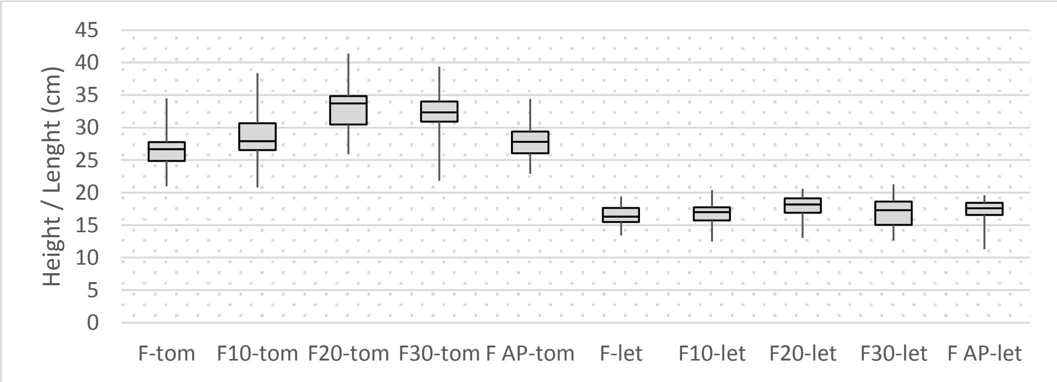

Figure 1. Plant length to the top of the longest leaf in case of lettuces and plant height to the top of the plant in case of tomato

Plant height of tomato and length of lettuce gave the similar results in Figure 1., because in case of F20-tom, F30-tom and F20-let the plants were higher or with longer leaves. In case of tomato they had thicker stems as well. They were well-developed, however transplants of F AP in case of tomato were stocky with thicker and shorter stem. Stem and height data can supplement each other correctly, however it was suitable only for tomato, because in the case of lettuce measurement of stem wasn't feasible.

Also, dry matter content in leaves can supplement the results of physical properties of transplants (Figure 2.). However, in case of lettuce the differences weren't significant, F30-let gave higher dry matter contents. Parallel in case of tomato, treatment of F30-tom gave a robust difference from two kind of plants, however because of high standard deviances we couldn't find significant variance.

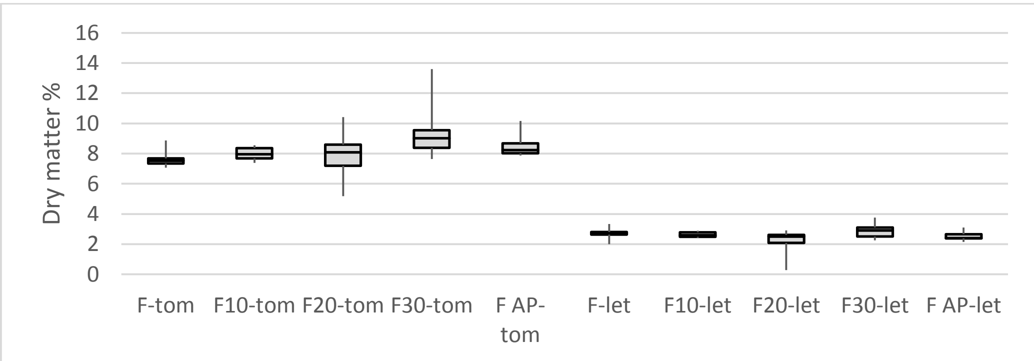

Figure 2. Dry matter content of foliage in case of tomato and lettuce transplants

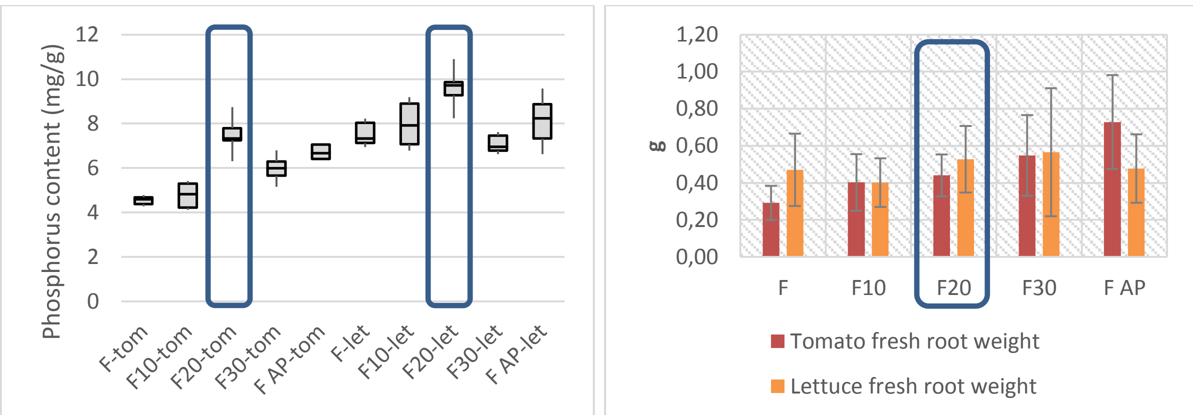

Figure 3. Phosphorus content of roots (left) and fresh root weight (right) in case of examined plants

Phosphorus is an important factor for stronger and powerful root development. Moreover, root system is determines the quality of transplants, and mostly in field growing the better survival and latter stress tolerance (Hopkins and Hüner, 2009). In the case of both plant the treatment F 20 affected higher phosphorus uptake and content. However, in Figure 3. the fresh root weight was not observed to follow this trend.
Also, another relationship was important in our investigation, to prove the earlier results about connection between nitrogen content and SPAD Chlorophyll value. Nevertheless, in our experiment the SPAD values did not follow the changing of data of Nitrogen (Figure 4.).

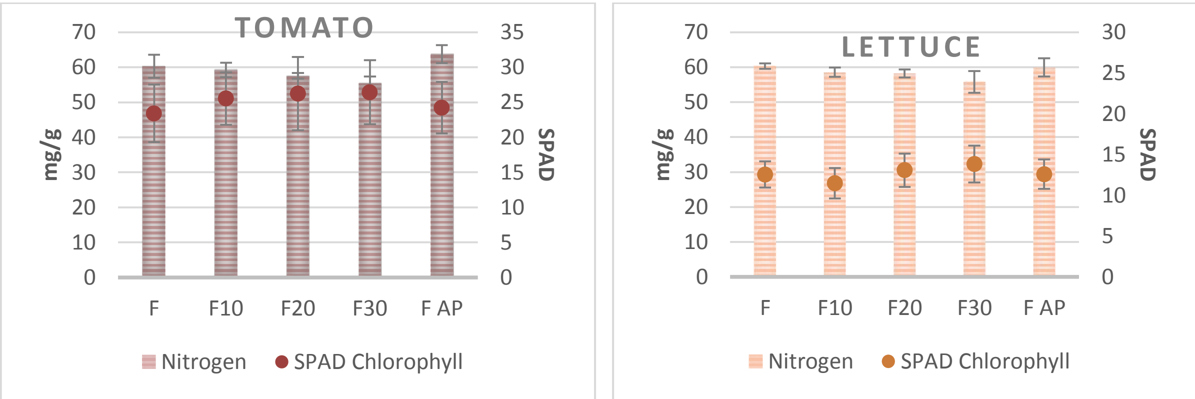

Figure 4. Correlation of Nitrogen content and SPAD in case of tomato (left side) and lettuce (right side) transplants.

Conclusion

During this experiment the development of plants was dependent on two factors in different substrate mixes: nutrient content of substrate and nutrient content of additive. How we increased the amount of additive, we gave more nutrients, however this quantity was moderated. All our additives were advantageous from side of increasing the water capacity of substrate, however in the first stage of our experiment we were curious for the effect of the additives for plant development and behavior. Growth of plants followed the opportunities of higher nutrient values of substrates. In this case, the higher amount of BRT has provoked higher height of tomato seedlings and longer leaves for lettuce. This result could be visible in leaf dry material content as well. At the same time fresh weight of root followed the results above, because of higher volume of nutrients, but the phosphorus value increased extremely higher in treatment of F 20 (in case of both plant). This result did not follow the changes of fresh weight of roots, however according to Hopkins and Hüner, (2009) Phosphorus is important for strong root development. Higher P uptake of treatment of F 20 can give chance for other questions that is recommendable for a latter experiment.
According to Sharaf et al (2015) the SPAD values follow the nitrogen content in leaves, because nitrogen has relevant effect to Chlorophyll synthesis. In our experiment we could not prove this, however amount of nitrogen was similar in different treatments and the differences between SPAD values were not high as well.

EFFICACY OF MULTILAYER CROPPING ON FIG PRODUCTION IN ARID CONDITIONS OF KUWAIT

Hani A. AL-ZALZALEH, Gladson DCRUZ

Desert Agriculture and Ecosystems Program, Environment and Life Sciences Research Center, Kuwait Institute for Scientific Research, Kuwait.
*Corresponding author: hzalzale@kisr.edu.kw

Abstract

This study examines the influence of intercropping on the growth and performance of figs in a multilayer system of planting was carried out under the arid climatic conditions of Kuwait. The experiment was laid out in Randomized Block Design comprising of two treatments with six replications in two sites. The two treatments were fig plants intercropped with or without vegetables. The main tree date palm was planted with a spacing of 7 X 7 m and the vegetables were planted in between the lines of fig trees. The results of the study revealed that date palm +fig +vegetables multitier system exhibited better performance, which has been reflected in the significant ($p<0.05$) increase of the soil nutrients, growth parameters and fruit quantity and quality than the fig plants without vegetables. Even though the trees were in initial orchard years and still young, fruit yield in terms of number of fruiting shoots, number of fruits, weight per fruits, and average yield per tree, the response to inter planting with vegetables was significant. Based on these results, it could be concluded that intercropping technique in date palm plantations along with figs and vegetables resulted in maximizing the use of unit land. Nevertheless, fruit quality of fig was influenced by the intercropping systems, which was considered to be a good sign for farmers in adapting and promoting inter-planting practices.

Keywords: *Inter-planting, date palm, microclimate, vegetables*

Introduction

Fig belongs to the *Moraceae* family (Vallejo *et al.*, 2012) and is among the earliest cultivated fruit trees in the world (Solomon *et al.*, 2006). Today, it is an imperative world crop and has been cultivated in Turkey, Egypt, Morocco, Spain, Greece, California, Italy, Brazil, and other places with typically mild winters and hot dry summers (Zohary and Hopf, 2000).
Kuwait's climatic conditions are harsh and are typical of an arid environment characterized by high temperature during summer, very low rainfalls, frequent winds, sand storms, and soil erosion. This limitation coupled with progressive buildup of salts in the soil hinders the growth of a wide range of plants. Hence, the State of Kuwait is making efforts to strengthen agricultural production and achieve partial food security in selected commodities. To achieve these goals, many types of figs has planted in home gardens and in designated areas in Kuwait. The suitability of land for fig production, combined with positive farmer perception, indicates that there is a potential for the development of this plant on a commercial basis.
The importance of the fig tree lies in the fact that it can withstand severe climatic conditions of arid regions such as low rainfall, high temperature and high soil calcium carbonate content. Due to its easy management properties, the crop is more acceptable in dry lands either as a monocrop or in mixed cropping. Its inclusion in agricultural land use system certainly helps achieve crop diversification

Materials and methods

The intercropping experiment was conducted during April to September of 2018 in an existing 10-year-old bearing date palm plantation site at Public Authority for Agriculture and

Fish Resources (PAAFR), located at Wafra. The experimental sites with enough plant-to-plant spacing were selected to assure a good shade. Out of the two areas, one area planted with Medjool date palms was selected as "Site 1" and the other with Barhi palms as "Site 2". The experiment was arranged in a randomized complete block design (RCBD) with two treatments and 6 replications in each sites. In both of the sites, the grafted seedlings of seven selected cultivars (Black Mission, Brown Turkey, Calimyrna Red, Calimyrna White, Sequoia, Sierra, and Tina) were planted in between the date palms at a spacing of 4 m, and the vegetables were planted in between the lines of fig trees. In short, there were two treatments, such as the interspacing area between date palms and figs planted with leafy vegetables and without vegetables. Similarly, there were two sites, and the vegetables were planted in two seasons.

In the first season, two leafy vegetables, parsley or garden parsley (*Petroselinum crispum*) and arugula or rocket (*Eruca sativa*), were planted on the inter rows of date palms as single strips, and each stripe were started 10 cm away from the basins of the fig plants. In intercropping, each row of fig was inserted between every rows of the parsley or arugula. In the second season, common purslane (*Portulaca oleracea*) and basil (*Ocimum basilicum*) were planted as interplant with fig plants. For the cultivation of these vegetables, the seedbed was prepared by ploughing the land twice at 30 cm depth. The ploughing was carried out perpendicular to the space in between the fig plants to prevent the runoff and improve water retention; basins were prepared around this prepared land. The seeds of all the four vegetables were broadcasted in the prepared areas and irrigated using adjustable drippers. However, no organic or inorganic fertilizers were given to the fig plants until the end of the experiment.

The plant height of fig trees was estimated by measuring the length of the main stem at the beginning and at the termination of season. Stem thickness of each plant was measured using a caliper at the 10-cm height of the plant above the ground surface. Leaf area was calculated on selected four leaves from each plant and expressed as centimeter squared. In the first week of July, the number of fruiting shoots were counted and recorded. The fruits were harvested at the peak of the color development (second week of August), and recorded number of fruits, fruit weight (g) and yield/plant (g). The growth rate of each plant was calculated using the equation as follows:

$$\text{Growth rate} = [(\text{Final total growth} - \text{Initial total growth}) / \text{Initial total growth}] \times 100 \quad (1)$$

The soil samples were analyzed for soil physical and chemical variables at the PAAFR laboratories, Kuwait. The percentages of N, P, K and Mg in plant leaves were determined according to the procedures that outlined by USDA, 2004. Total phenolic compounds of each sample were extracted by the Folin–Ciocalteu's method as described by Fu *et al*. (2011), while total flavonoid content was measured by aluminum trichloride assay (Koolen *et al*., 2013).

Results and discussion

Nutrient Status of Fig Plants

From the data in Table 1, it is clear that the intercropping practices resulted in the improvement of physical conditions and nutrient status of the soil. Intercropping fig plants with vegetables caused a substantial reduction of EC from 5.21 to 3.80 mS/cm, thereby making the major nutrient contents available to the fig plants, which reflects in the vegetative growth of plants under intercropping than the other treatment. Similarly, the lowest values of pH were noticed under intercropped areas, which enables smooth retention and availability of the plant essential nutrients.

Soils of fig plants intercropped with vegetables had a high concentration of major nutrients compared to pure stand of figs. Even though there was an uptake of nutrients by the main and sub crops, a high content of nitrogen was observed in rhizosphere of intercropped plants. The increase in the available nitrogen content of soil might be due to the greater recycling of bio-mass in the inter space with higher percentage of nitrogen in the vegetable based inter cropping system as compared to sole cropping systems (Manna and Singh, 2001). According to Thorup-Kristensen and Sorensen (1999), the planting of shallow rooted crops as intercrop with deep rooted crops where available N is present in deeper soil layers, nitrogen availability can be increased. This increase in available nitrogen content of the soil can be because of the in situ incorporation of intercrops biomass and increased the enzymatic activity of the effective microorganisms, which leads to the release of nutrients in the soil. Swain and Patro (2007) also reported an increased available nitrogen content of the soil through intercropping in mango intercropping systems. The available phosphorus content of soil under intercropping systems might be due to increase in the phosphorus solubulizers due to the incorporation of vegetable biomass. Also, Swain and Patro (2007) observed similar findings on beneficial effect of intercropping in increasing the availability of phosphorus in the soil. The intercropping of vegetables also increased the K levels in soil, which in turn provided resistance to plants to thrive prevailing drought conditions. The results also indicated that the intercropping system were advantageous in increasing the available potassium contents of soil, which corroborates with the findings of Swain and Patro (2007). This recycling of biomass had increased the content of humus in the soil and there by increased the available potassium content. Previous studies of Maheswarappa *et al.* (1998) also supported these findings by their results of improvement in major nutrient status of soil due to intercropping.

Plant Growth of Fig

Results of intercropping of fig plants with vegetables and sole croppingof figs on some vegetative parameters displayed that there was statistical difference between the intercropping and sole cropping ($p<0.05$) on relative growth rate and leaf area, while there was no difference on plant height, stem thickness in both the sites. Nevertheless no significant variation was found between the two sites in any of the vegetative parameters studied. The highest plant height, stem thickness, relative growth rate and leaf area were obtained from intercropped areas. While the highest relative growth (27.9) was obtained from fig plants interplanted with vegetables in Site 2, sole cropping of fig plants (26.6) from Site 1 followed it. The fig plants with vegetables intercropped surpasses the sole cropped plants in the leaf area in both sites. The sites and intercropping interactions had a statistically significant effect ($p<0.05$) on the leaf area only. The maximum leaf area was obtained from the leaves of fig plants planted in intercropped areas in both the sites. In general, the intercropping of fig plants with vegetables significantly higher than the sole cropping of figs in some of the primary growth characteristics. These results are in accordance with the findings of Aksoy *et al.*(1987).

The results of the studies showed that the vegetative growth characteristics of fig plants were positively influenced by intercropping. The reason for increase in growth parameters of fig plants might be due to this input utilization. According to Panda *et al.* (2003), adoption of suitable intercropping systems in fruit crops aids in efficient utilization of available natural resources and improves the input use efficiency in the system. Intercropping with nitrophilous crops particularly with purslane was helpful in the positive effective increase in nitrogen that results in higher vegetative growth in fig plants. More research findings supporting the observations on increase in tree height, girth, and canopy area of fruit crops due to intercropping were reported by Singh *et al.* (1996).

Fruit Weight and Yield of Fig Plants

Even though the fig trees were in initial orchard years and still yielded young fruit in terms of number of fruiting shoots, number of fruits, weight per fruits, and average yield per tree in response to interplanting with vegetables was significant. Plants represented the intercropped area produced more fruiting shoots, fruits, fruit weight, and yield per tree than in areas where vegetables were not planted as intercrops in both the sites. However, statistical variation among the sites and the interaction of sites and treatments were observed in the fruit characteristics of number of fruits per plant and yield per tree. Intercropping practices with vegetables in Site 1 had a significantly higher number of fruits per plant (12.4) and yield per tree (466.7 g) compared to those in Site 2. Regarding the interaction effect of sites and treatments, intercropping vegetables with fig plants in site 1 produced significantly more number of fruits per plant (12.8) and yield per tree (484.2 g) than the other studied interaction treatments under study.

The data showed that the intercropping of date palm, figs, and vegetables significantly increased all the fruit characteristics under study. This result may be because the palm tree provided enough space for the filler crop (figs) and the interplants (vegetables) to get favorable conditions for growth. Akyurt *et al.*(2002) found that date palm supply enough space for intercropping even if they are fully grown as they do not cover much area being a very tall tree. Aksoy (1998) reported that competition for resources between component crops and efficient utilization of natural resources such as solar radiation, soil moisture, and nutrients may be the reasons for higher yield parameters particularly fruit weight and fruit yield under intercropping systems. Moreover, cultural practices followed for the intercropped areas contributed to the higher production of fruits (Ghosh, 2001; Rath and Swain, 2006). According to Ali *et al*. (1998), the date palms could be intercropped with citrus and are possible to be grown as a mixed fruit orchard. Previous studies by different researchers concluded that intercropping those trees that are cultivated with various intercrops had no considerable adverse effects on the yield and fruit quality of main crops (Ashour *et al.,* 1994; Abouziena *et al.,* 2010).

Fig Fruit Quality

Results of total phenolic and flavanoid contents are shown in Table 2. The methanolic extracts of fig leaves from vegetable intercropped areas contained significantly the highest amounts of total phenolic and flavanoid compounds than the other treatments. A higher amounts of phenolic compounds with a value of 46.270 (mg GAE/g DE) were obtained from the intercropped with vegetable areas in site 1 and 43.194 (mg GAE/g DE) from the intercropped areas in Site 2. Similarly in this study, the highest amounts of flavonoids were noted in leaves of fig and vegetables intercropping areas with 16.393 and 15.932 mg QE/g DE in Site 1 and Site 2, respectively.

The analysis of quality parameters of fig plants in Table 2 revealed that there was no appreciable influence on fruit quality by intercropping practices. The fruit quality aspects such as total phenolic acids showed significant differences while there was no difference in total flavonoids between the treatments. Previous studies in fig showed that fruit quality parameters were unaffected by planting distances (Kumar *et al.,* 2014; Hosomi *et al.,* 2013). Similar results were obtained from the researches of Kanwar *et al.* (1993), and Ghosh (2001), where the quality of fruits were not affected due to growing of intercrops, in mango, citrus, and guava orchards.

Leaf Macronutrient Contents

Results clearly revealed that the different nutrients in the fig leaves were significantly varied in the main effects of nitrogen, potassium, and calcium contents. Regarding the interaction effect of sites and treatments significant variation was found in the content of Magnesium. Intercropping of fig plants with vegetables significantly increased the contents of four macronutrients compared to figs without intercropping. A gradual and significant increase in nitrogen, potassium, calcium and magnesium contents were recorded with growing figs with vegetables. These trends of nutrient increment were true in both sites.

The leaf analysis results indicated that the N, K, Mg and Cacontents of fig plant leaves were maximum under fig and vegetable intercropping system. The availability of nutrients in the soil is increased due to the *in situ* incorporation of vegetable residues might be the reason for the increase in the major plant nutrient status of fig leaves when compared to fig plants without intercropping. Maheswarappa *et al.* (1998) concluded that the incorporation of intercrops residues might be helpful in improving the soil physical, chemical, and biological environments, which in turn favors the higher uptake from the nutrient pool in the soil.

Conclusions

Multilayer cropping is becoming a sustainable crop production technique by utilizing a number of environmental beneficial effects and effective utilization of available land for diversifying agricultural outcome. High, medium, and low plants were integrated in a most sustainable manner in this production model. From the results of the study, it was revealed that intercropping was the ideal practice in increasing plant growth and fruit yield of fig plants. The plant growth, fruit weight and fruit yield of fig were found significantly higher in intercropping with vegetables under the canopy of date palms. Nevertheless, fruit quality of fig was influenced by the intercropping systems, which was considered a good sign for farmers in adapting and promoting interplanting practices. The introduction of intercropping technique in date palm plantations along with figs and vegetables resulted in maximizing the use of unit land. The results of the study also conclude that intercropping of fig plants and vegetables with date palm indicated that these techniques of intercropping could be used for combating desertification in the arable sandy soils of Kuwait.

Abstract

The Douro Demarcated Region, NE of Portugal is characterized climatically by low precipitation and high water losses due to evapotranspiration during the summer. In this sense, experiments were carried out to evaluate the effect of different water availability on the water status of grapevines and soils. In commercial vineyards, the 'Granier' thermal dissipation technique ('Moscatel-Galego-Branco' variety over 2008-09 growing seasons) and the 'compensated heat-pulse' method ('Boal' variety in 2012) were used to continuously monitor sap flow within the xylem of mature vines. Weather variables, soil moisture and leaf water potentials were also measured. Clear relationships between sap flow and increased water availability, after rainfall and irrigation events, were shown. Additionally, relationships between stress indicators, such as predawn leaf water potential, were examined. Furthermore, variations of trunk and root sap flow (using 'compensated heat-pulse' method) were observed during nocturnal periods, and were associated with high vapour pressure deficits. Relative transpiration (calculated as the relationship between the sap flows of water stressed plants and irrigated vines) showed a closer relationship with predawn water potential compared to soil moisture, suggesting being a potential indicator of automated water availability. However, the requirement for a (well-watered) control plot limits its practical applicability.

Keywords: *Grapevine, Survival strategies, Water dynamics, Predawn leaf water potential.*

Introduction

In northeast of Portugal, winegrapes are a major crop constituting an important source of income for local farmers. Located in deep valleys, protected by mountains, the climate in the Douro Demarcated Region is characterised by scarce rainfall and large evapotranspiration losses during the summer season. Thus, a deep root system is crucial for the survival of the vine during the driest period. Thus water redistribution within the plant, particularly between the roots, has been identified as a crucial survival strategy (Malheiro *et al.*, 2016). However, the mechanism generally considered most important for plant survival in a hot and dry environment is stomatal control to reduce transpiration (Dinis *et al.*, 2014). Plant transpiration can be determined indirectly by measuring evapotranspiration minus soil evaporation and/or directly by measuring sap flow, provided an adequate calibration is performed (Ferreira *et al.*, 2012). Sap flow determinations can be performed by methods such as the thermal dissipation technique (Granier, 1985), which stands out for its simplicity and low cost. However, the literature has shown that among the sap flow techniques, the compensation heat-pulse method is the most sensitive in detecting small flows. On the other hand, to evaluate the crop water status, the relative transpiration can be used, when the plants under water stress and in water comfort are available (Patakas *et al.*, 2005). Thus, the objectives of the present study were (i) to evaluate the water dynamics of mature vines using two sap flow methods and (ii) to evaluate the relationship between relative transpiration as an automated indicator and others water stress indicators.

Material and methods

The study was carried out in a commercial vineyard (41º15'N, 7º28'W, 600 m), located in the Douro Demarcated Region in Portugal, in two periods/experiments: 1) 2008 and 2009 with the Moscatel-Galego-Branco variety (syn. Muscat Blanc à Petits Grains) and 2) in 2012 with the Boal variety, in both cases grafted onto 196-17 Cl and planted in 1998 with spacing of 2.2x1.0 m. The climate of the region is of the Mediterranean type characterized by a sinusoidal pattern of precipitation with dry summer and wet winter. In the experimental area, the annual average long-term precipitation is about 630 mm. The average minimum and maximum annual temperatures are of 7.7ºC and 19.4ºC, respectively (www.ipma.pt). The soil, affected by human activity, is essentially of schist origin with a loam texture. Soil moisture was determined from the surface to a depth of 1.5 m by a portable TDR (Trime-FM, Imko). Predawn leaf water potential (Ψ_P) measurements were performed on 6 leaves per replicate of each treatment, with a pressure chamber (ELE International) on selected days during the summer. The data of an automatic weather station placed near the experimental plot were used to determine the reference evapotranspiration (ETo).

Experiment 1

The experimental design, with the Moscatel-Galego-Branco variety, consisted of four replications of irrigated plots and an equal number of irrigated plots. Water in the irrigated treatment was applied through a drip system from August to early September, with a total amount of 150 mm in 2008 and 190 mm in 2009. A Ψ_P threshold of -0.3 MPa was defined to start irrigation, in order to keep the plants in water comfort throughout the experimental period. Subsequently, irrigation was calculated through a simple water balance, so that the available water content varied around 60-70% in the 1.5 m of the soil profile. The thermal dissipation technique (Granier, 1985) was used to evaluate the sap flow of six vines in each treatment from July to September. Relative transpiration (RT) was calculated as the ratio between transpiration of plants under water stress (rainfed) and well-watered.

Experiment 2

The vines of the Boal variety were kept in a rainfed regime. Additional information on soil moisture conditions, physiological performance and yield components can be found in Dinis *et al.* (2014). The compensation heat-pulse method (Green *et al.*, 2003) was used to continuously measure sap flow in trunks and roots of eight vines. Thus, one set of probes (Tranzflo NZ Ltd, New Zealand) was placed on the vine trunk and another set on one of the larger diameter roots. The flow of sap ($L.h^{-1}$) was calculated using the methodology described by Green *et al.* (2003).

Results and discussion

Experiment 1

A decrease (that is, more negative) of Ψ_P was generally found in rainfed vines (-0.3 to -0.5 MPa) as soil moisture (SWC) decreased over the growing seasons (not shown). A close relationship was found between RT and Ψ_P. A similar approach was used for SWC, but with a weaker relationship (Figure 1). The higher dispersion pattern between RT and SWC for lower SWC values may be related to increasing deep-rooted activity, possibly beyond 1.5 m, towards the end of the vegetative cycle. In fact, together with the deep root system of mature grapevines, the typical stony soil characteristics are a major difficulty in monitoring soil water profile in the region. These results confirm a better performance of Ψ_P as a stress indicator in this crop. However, SWC is an estimation of water availability in upper soil layers and can be used to validate the amount of irrigation depth to apply, which can be of value when implementing an irrigation programme for this crop in the region. Close relationships between RT and Ψ_P were also reported in another wine region (Patakas *et al.*, 2005). These results indicate that RT is a potential indicator of water shortage. However, the requirement for a (well-watered) control plot and the need for careful data analysis (*e.g.* correction for natural thermal gradients) limit its practical applicability.

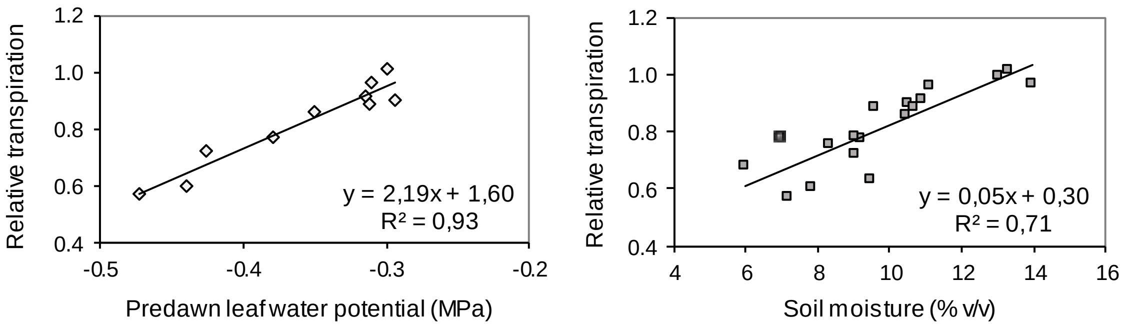

Figure 1. Relation between relative transpiration with predawn leaf water potential (left panel) and soil moisture (right panel): includes data from 2008 and 2009.

Experiment 2

The seasonal evolution of the (normalized) sap flow in the trunk (FSt/ETo) and roots (FSr/ETo) in the Boal variety was relatively stable throughout the growing season (Figure 2), suggesting an equally stable crop water status, despite the occurrence of "peaks" associated with the occurrence of precipitation and slight water recovery. This pattern is consistent with the moderate values of water stress from July to September, based on measurements of predawn leaf water potential (Ψ_P, -0.3/-0.5 MPa, Dinis *et al.*, 2014). The values observed for FSt/ETo (Figure 2) correspond to the basal crop coefficient (Kcb) multiplied by the stress coefficient (Ks). After significant precipitation events in September-October (when we can assume a Ks = 1), FSt/ETo reached values close to 0.4 corresponding to expected Kcb (Ferreira *et al.*, 2012). These results and the above comparison point out that the vines responded to moderate water stress with a reduction in sap flow (transpiration) compared to that at the beginning of the growing season. On the other hand, the fraction of available water in the upper 0.3 m of soil decreased to about 5% during summer (not shown). Such findings show that these grapevines are able to cope with a dry upper soil. The sap flow data showed that one of the plant survival strategies in such dry soil was to exhibit a midday stomatal depression, which tended to disappear after summer rains (not shown). In addition, there was a close relationship between ETo and FSr (Figure 2). Thus, it is possible that a significant amount of sap flow at the root has been converted to transpiration, rather than supporting the flow for rehydration of other roots. In fact, grapevine stomata are likely to remain slightly open during nights and, in conditions of elevated vapour pressure deficit, the resulting atmospheric demand being the main driver of water uptake. However, that response can be significantly reduced with increasing water stress conditions (Fuentes *et al.*, 2014).

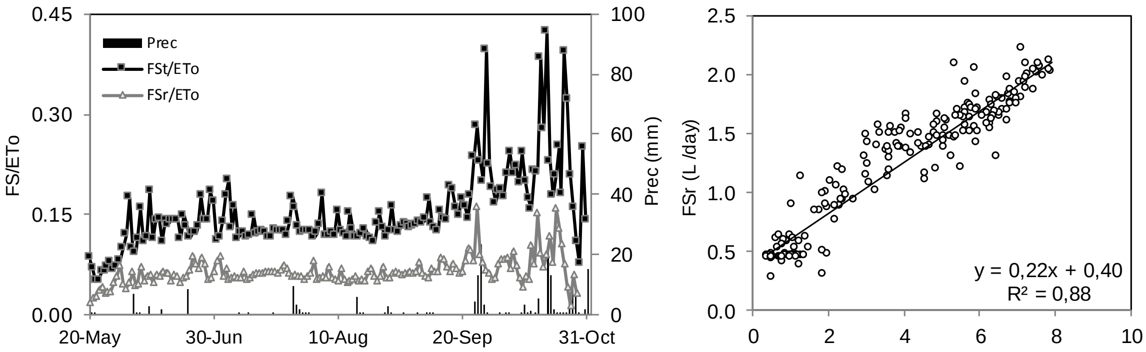

Figure 2. Seasonal evolution of precipitation (Prec) and sap flow in the trunk, FSt/ETo and roots, FSr/ETo (left panel) and the relation between ETo and FSr (right panel): 2012.

Conclusions

The "thermal heat dissipation" and "heat pulse" methods were used successfully in the measurement of sap flow in mature vines. The values found revealed the sensitivity to precipitation (or irrigation) events and conditions of significant atmospheric evaporative demand. A close relationship between relative transpiration and predawn water potential was found. The results suggest that relative transpiration is a potential automated indicator of water stress. However, the need of a well-watered plot limits its practical applicability.

Abstract

Durum wheat is one of the most common cereals which is widely grown and constitutes the cereal with the highest monetary yield. There are many studies where the different varieties are compared in case to find the better one with increased harvested yield and better seed quality. Therefore, it appears that the main objective of the investigation is to increase seed quality and seed yield. Furthermore, many chemical substances are sold stating that they can increase the final yield and the seed protein content. For the purposes of the study, a field experiment was established at the Experimental Farm of the Technological Educational Institute of Thessaly in Greece (TEI; Larissa plain) in 2018 (November), where the effects of three different foliar fertilizers in different dosages and their combination (10 different treatments in 3 replications) on final yield and seed quality characteristics were investigated. Few initial observations on the field resulted in more vivid plants with more intense colouring, which could lead to the expectation of higher harvested yield. There was not found any statistically significant difference on seed yield, where control reached almost the 4500 kg ha^{-1}and 6750 kg ha^{-1} for the 3rd treatment (highest). On the other hand, there was found statistically significant differences for the protein content with control reaching the 13.3% and the higher 17.37 reached at the 9th treatment. Due to the fact that the above results were found through the first year of experimentation, safer conclusions expected to arise after the repetition of the experiments in the same place for a second year.

Keywords: *Wheat, seed yield, protein, foliar fertilizers, cereals.*

Introduction

Durum wheat (*Triticum durum*) is one of the most important winter cereals, occupying more than 25 million hectares worldwide. The Mediterranean basin produces about 60% of the world production, and has the ideal growing conditions for producing quality grains (Nachit, 1998), while the Mediterranean countries (Italy, Greece and Spain) together account for 82% of total EU production, but grain yields are lower than those obtained in Northern European countries (European Commission, 2002). The rest is mainly produced in the USA and Canada (Belaid, 2000).

The Mediterranean agricultural region comprises the lands surrounding the Mediterranean Sea: the southern strip of Europe, northern lands of Africa and west Asia. This region is characterized by relatively cold and wet winters, dry and hot spring-summers (Aschmann, 1973) while the soils have typically low fertility (Ryan et al., 2009). Rainfall seasonality restricts agriculture to winter-spring crops and the amount and variation of rainfall drives relatively low and highly variable yield.

Quality of durum wheat is generally dependent on the protein content of the grain, at least in the range of protein percentages encountered in commercial wheat cultivars (Grant and Flaten, 1998; Anderson, 2000; Clarke, 2001). By carefully managing N fertilization, less N

may be needed while grain wheat yields and protein may be maintained or increased (Chaney, 1990; Alcoz et al., 1993; Gate, 1995; Grant and Flaten, 1998).
Matching N supply with crop demand is important to optimize fertilizer uptake, and utilization and retention in the cropping system. Adequate N fertilization is a prerequisite to produce high yields of wheat and to increase grain quality, though depending on the background fertility level. High levels of protein are important for superior durum wheat flour (Feil, 1997).
This study was conducted in the main agricultural plain (Thessaly) to evaluate the effects of three different foliar fertilizers in different dosages and their combination on final yield and seed quality characteristics in Greece.

Material and Methods

For the purpose of the study, a field experiment was established in a typical soil-climatic environment of Thessaly plain, in central Greece. The experimental site is located at the Experimental Farm of the General Department of the University of Thessaly, (ex Technological Educational Institute of Thessaly; Larissa plain, coordinates: latitude 39°62′69″ N, longitude 22°38′14″ E). The selected durum wheat variety was the "Meridiano", in order to assess the effect of different foliar fertilization scenarios in its performance, due to the fact that wheat is the most prevalent winter cereal in Greece.

Field management and experimental design.

Sowing was occurred using a modern cereal seeding machine (on November 2018), applying 225 kg ha^{-1} of seeds in a row-distance of 12.5 cm.
Basic fertilization applied one-two days before sowing using a dispenser and then the fertilizer was incorporated using a rotary cultivator. There was performed post-emergence herbicide application to control weeds.
The experimental design was a completely randomized design with ten foliar fertilization treatments and three replications (blocks), presented in Figure 1. Specifically:
Treatment 1: control, only basic fertilization (250 kg ha^{-1} of 20-10-0).
Treatment 2: basic fertilization (250 kg ha^{-1} of 22-10-0), and foliar fertilization with Tidal (2000cc/ha, in total) applied with one dose on 1st of April.
Treatment 3: basic fertilization (250 kg ha^{-1} of 22-10-0), and foliar fertilization with Zinctip plus (2000 cc/ha, in total) applied with one dose on 1st of April.
Treatment 4: basic fertilization (250 kg ha^{-1} of 22-10-0), and foliar fertilization with Miconic (2000 cc/ha, in total) applied with one dose on 1st of April.
Treatment 5: basic fertilization (250 kg ha^{-1} of 22-10-0), and foliar fertilization with Tidal (3000 cc/ha, in total) applied with two doses, half dose at the first on April 1st and the other half at the second on April 16th.
Treatment 6: basic fertilization (250 kg ha^{-1} of 22-10-0), and foliar fertilization with Zinctip plus (3000 cc/ha, in total) applied with two doses, half dose at the first on April 1st and the other half at the second on April 16th.
Treatment 7: basic fertilization (250 kg ha^{-1} of 22-10-0), and foliar fertilization with Miconic (3000 cc/ha, in total) applied with two doses, half dose at the first on April 1st and the other half at the second on April 16th.
Treatment 8: basic fertilization (250 kg ha^{-1} of 22-10-0), and foliar fertilization with Miconic (2000 cc/ha, in total) + Bumper (1000 cc/ha, in total) applied with two doses, half dose at the first on April 1st and the other half at the second on April 16th.
Treatment 9: basic fertilization (250 kg ha^{-1} of 22-10-0), and foliar fertilization with Zinctip plus (2000 cc/ha, in Total) + Bumper (1000 cc/ha, in total) applied with two doses, half dose at the first on April 1st and the other half at the second on April 16th.

Treatment 10: basic fertilization (250 kg ha^{-1} of 22-10-0), and foliar fertilization with Zinctip plus (2000 cc/ha, in total) + Miconic (2000 cc/ha, in Total) applied with two doses, half dose at the first on April 1st and the other half at the second on April 16th.

Figure 1. Field experimental design.

Laboratory measurements and data analyses
Soil analysis

Soil samples were analyzed using the following methods which are referred by Page et al. 1982.

Organic matter was analyzed by chemical oxidation with 1 mol L^{-1} $K_2Cr_2O_7$ and titration of the remaining reagent with 0.5 mol L^{-1} $FeSO_4$.

Inorganic forms of nitrogen were extracted with 0.5 mol L^{-1} $CaCl_2$ and estimated by distillation in the presence of MgO and Devarda's alloy, respectively. Available P forms (Olsen P) were extracted with 0.5 mol L^{-1} $NaHCO_3$ and measured by spectroscopy. Exchangeable forms of potassium were extracted with 1 mol L^{-1} $CH3COONH_4$ and measured by flame Photometer (Essex, UK).Available forms of Mn, Zn, and Cu were extracted with DTPA (diethylenetriaminepentaacetic acid 0.005 mol L^{-1} + $CaCl_2$ 0.01 mol L^{-1} + triethanolamine 0.1 mol L^{-1}) and measured by atomic absorption. In the case of the determination of total metals Mn, Cu and Zn, 1 g of wet material, was digested at 350 ^{o}C + 10 ml HNO_3 + 5 ml $HClO_4$. According to the method described by (Allen et al., 1974 and Varian, 1989), the samples were analyzed by Atomic Absorption (Spectroscopy Varian Spectra AA 10 plus, Victoria, Australia), with the use of flame and air-acetylene mixture.

Plant Measures

Total biomass and seed yield measured by a final sampling (final harvest; according to Zadocks scale: ripening stage 91-99). To avoid any border effect, 1 m^2 in the inner plot was harvested in each sampling above the ground. The samples were weighed at the field and then a sub-sample was taken for further laboratory measurements.

Protein, starch and gluten content was determined in dry seeds of each sample by near-infrared reflectance (NIR) spectroscopy technique using the DA 7250 NIR analyzer (Perten Instruments, Hägersten, Sweden).

The statistical package GenStat (7^{th} Edition) was used for the analysis of variance (ANOVA) within sample timings for all measured and derived data. The $LSD_{0.05}$ was used as the test criterion for assessing differences between means (Steel and Torrie, 1982).

Results and Discussion

Soil characteristics

The soil of the experimental site is characterized as a, calcareous (pH = 7.8), withlow organic matter content (0.9) and low salinity (0.11) at a depth of 30cm. Analytically, the soil properties/characteristics of the experimental field are shown in Table 1.

Table 1. Chemical properties of the field experiment.

Property	Soil depth (0-25) cm
Texture	Loam
pH (1part soil:5parts H_2O)	7.81 ± 0.16
Electrical conductivity, extract(dSm^{-1}) (1part soil:5parts H_2O)	0.11 ± 0.01
Organic matter (%)	0.93 ± 0.05
N-inorganic (mg kg^{-1})	44.8 ± 4.07
K-exchangeable (mg kg^{-1})	373.3 ± 7.45
P –Olsen (mg kg^{-1})	13.1 ± 1.87
$CaCO_3$ (%)	0.63 ± 0.07

Data represent average means and SE deviation. (n)=4

Yield

The results have shown none statistical significant differences between the tested foliar fertilization practices but only numerically superiority of few treatments (Table 2), especially in seed yield case which is the product of economic value.

Analytically, the treatments that treatments with the higher seed yield production were treatment 3 and 6 with seed yield of 4744 and 6048 kg ha^{-1}, respectively. This yield is 1500 – 2000 kg ha^{-1} higher in comparison with the control (treatment 1). The highlight of this is that both are Zinc tip plus treatments using different dosages. Therefore, even if there is not statistically significant difference the treatment 3 with the lower dosage and the use of only one spraying shows higher productivity.

Table 2. Biomass, hay and seed yield of *Triticum durum* under different foliar fertilization practices and its combinations.

Treatments\Characteristics	Biomass	Hay	Seed Yield
	kgha^{-1}	kg ha^{-1}	kg ha^{-1}
Treatment 1	11400	6920	4480
Treatment 2	8480	3885	4595
Treatment 3	12533	5789	6744
Treatment 4	11200	6487	4713
Treatment 5	11247	6837	4410
Treatment 6	10753	4705	6048
Treatment 7	11640	6328	5312
Treatment 8	9100	4808	4292
Treatment 9	10033	5622	4411
Treatment 10	11360	6392	4968
$LSD_{0.05}$	ns	ns	ns
CV (%)	13.2	19.4	23.8

Seed quality characteristics

Unlike the quantitative characteristics of wheat where there was no statistically significant difference, the quality characteristics are statistically significant different. Particularly there was found differences in protein and starch content, while in gluten content (dry and wet) there was not observed any statistically difference.

The results are presented in Table 3, where it is shown that the higher protein content was measured in treatment 9 reaching the 17.3 %. Other treatments with high protein content (> 15 %) were the 6th, 8th and 10th. The particular feature of these treatments is the fact of using double spraying with duration between the two sprays about fifteen days. Once again, it is noticed that the use of the commercial formulation Zinc tip plus (in this case, in combination with other commercial formulation) gives better results, where then protein content is higher compared with the control (which has the lower protein content) more than 2 %.

On the other hand, in case of starch content, the control is the treatment with the higher content indicating once again that seeds of higher protein content have lower starch content. It has been mentioned that proteins can have some obvious effects on enzymatic degradation of starch, such as by physically hindering access of degradation enzymes to starch (Zou et al. 2015). In a study for the barley by Wenwen et al. (2017), it was concluded that the protein content significantly and negatively correlated with starch molecular structures and therefore barley with lower protein content would have higher starch content and larger grain size, which is in agreement with our findings.

Finally, in gluten case, there was found none statistical significant differences between the tested foliar fertilization practices but only numerically superiority of few treatments (Table 3).

Analytically, the treatment with the higher gluten content was the treatment 9, which is the treatment that also gave seeds with higher protein content. In this case there was found that the wet and dry gluten content was 33.15 and 12.91 %, respectively. All treatments of lower protein content had also lower gluten content, indicating once again the effect of the commercial formulation Zinc tip plus to the quality seed characteristics (Table 3).

Table 3. Protein, starch and gluten % content of *Triticum durum* seeds under different foliar fertilization practices and its combinations.

Treatments\Characteristics	**Protein As is**	**Protein Dry basis**	**Starch Dry basis**	**Dry Gluten**	**Wet Gluten**
	%	**%**	**%**	**%**	**%**
Treatment 1	11.947	13.300	73.267	10.80	27.72
Treatment 2	12.553	13.907	72.433	10.51	26.41
Treatment 3	13.147	14.407	70.700	13.09	33.32
Treatment 4	12.213	13.507	70.633	11.32	28.64
Treatment 5	15.040	16.733	69.633	11.71	30.43
Treatment 6	14.263	15.800	70.867	12.41	31.67
Treatment 7	12.287	13.700	72.800	10.45	26.37
Treatment 8	13.783	15.367	71.433	12.71	32.37
Treatment 9	15.637	17.367	70.167	12.91	33.15
Treatment 10	14.167	15.767	71.333	12.41	31.73
$LSD_{0.05}$	0.1157	0.1972	0.3355	ns	ns
CV (%)	0.5	0.8	0.3	12.3	12.8

Conclusions

In all characteristics there was found an effect of the treatments using of the commercial formulation Zinc tip plus. In the quantity characteristics there were not found statistically significant differences but only numerically superiority. In case of the quality characteristics there found statistically significant differences with protein content achieving high values. Due to the fact that the above results were found through the first year of experimentation, safer conclusions expected to arise after the repetition of the experiments in the same place for a second and a third year. In case that the results of the third year will confirm the previous results then foliar fertilization practice with the commercial formulation Zinc tip plus should be proposed in future fertilization schemes, while an economic appraisal of interventions should be made to conduct safer conclusions.

Abstract

Numerous chemical factors limit normal growth of plants on acid soils. On soils with a pH ≤ 5.5, Al toxicity is a main stress factor for plants, and it is reflected through the inhibition of root growth, a numerous of damages above-ground plant organs, as well as on decreasing of solubility of important biogenic elements. Liming is one of the key measures that can maintain or increase the productivity of acidic soils. Research in the field trials, were conducted on soil type Dystric cambisol. The objective was to determine the reasonable amount of lime material required, in order to mobile Al content in the soil type Dystric cambisol to bring below the hazardous level. The aim was to determine the Al content in the roots of wheat plants, as well as plant's response to the reduction of content of this element in the soil. The three doses of hydrated lime (CaO x H_2O) have been applied in order to reduce acidity: the two were on the level of partial liming (1/3 Y_1 CaO and 1/2 Y_1 CaO), and the one as full liming (Y_1 CaO). Even in the partial liming, response of soil and wheat plants has been very strong. Compared to variants where no lime applied, by partial liming content of aluminum in the soil has been halved, and in the roots of wheat during the whole vegetation it has been multiply decreased.

Introduction

At acid soils with pH ≤ 5.5 Al-toxicity is the main stress factor for plants (Merino-Gergichevich et al., 2010), and in such conditions it is linked to the prevailing pressure for adaptation of cultivated plants (Ryan and Delhaize, 2010). First, its indirect impact by reduction of solubility is being noticed, as well as by availability of nutrients. Namely, aluminum ions, among other things, block the adsorption of phosphorus and potassium, and cause disturbing crop growth and development (Zheng, 2010). In addition there are indirect and direct effects, when Al ions act toxic to the plant. The acidic environment increases presence of trivalent aluminum cations - Al^{3+} (Lidon and Barreiro, 2002; Kochian et al., 2005), which is the most toxic of all types Al. The best recognized Al-toxicity effects, have been noticed and well described, in the roots (Barceló and Poschenrider, 2002, Ma, 2007; Panda and Matsumoto, 2007). A serious problem that appears at high concentrations of aluminum is the inhibition of root growth. It has been noticed that aluminum influences on the formation of immature and poor root systems, which have limited ability to adopt mineral nutrients and also increase the risk of stress caused by drought (Marschner, 1991). More precise, toxic effect is being caused by the inhibition of lateral roots and root hairs, interruption of feeding with P and Ca and inhibition of growth of shoots (Fageria et al., 1988). However, the upper parts of the plants may be damaged (Merino-Gergichevich et al., 2010), especially leaves, and about which is rarely known. Today, there are more evidences of the negative effects of aluminum on the light absorption, photosynthetic electron transport, gas exchange (Chen et al., 2005a, Chen et al., 2005b; Chen, 2006), photoprotective systems (Chen et al., 2005a; Ali et al., 2008), pigments (Chen et al., 2005a; Mihailovic et al., 2008;

Milivojević et al., 2000), as well as other elements associated with the structure or function of the photosynthetic apparatus. Aluminium toxicity in acid soils negatively impacts the production of staple food crops, particulary grain crops (Pineros et al., 2005). Calcination of acid soils is one of the key factors which can keep or even improve their productivity (Mao et al., 2008; Repšiene and Skuodiene, 2010). Therefore, this research aim is to investigate use of different levels of calcification in an acid soils, such as the Distric Cambisols, defines its effect on the degree of change on acidity and content of mobile Al in the soil and wheat roots.

Material and Methods

Studies were conducted on the soil type Dystric Cambisol near Leposavić municipality (43^0 16' N; 20^0 36' E) during two consecutive years (2010 and 2011). Leposavić belonging to the southern and central part of the Ibar-Kopaonik region, and located in southwestern Serbia and is located at an altitude of 545 m, and is characterized by a temperate continental climate.

Test crop was wheat cultivar Pobeda. For calcification has been used CaO with high degree of purity. The material is applied in both years in September, precisely before primary treatment, so it has been properly distributed over the surface and entered into the soil by plowing.

The quantities of CaO which have been applied, were calculated according to the value Y_1 in the soil and the size of the experimental plots (50 m^2). Three variants of calcification have been determined and applied: 1/3 Y_1 CaO (V-3), 1/2 Y_1 CaO (V-4) and Y_1 CaO (V-5), and two variants without calcification: variant with NPK (V-2) and the variant without liming and fertilization - control (V-1). Fertilizers were applied with the variant performed with calcification. In all cases, the dose of active nutrients: nitrogen, phosphorus and potassium were the 120 kg N/ha for P_2O_5 and K_2O, 90 kg/ha ($N_{120}P_{90}K_{90}$).

The experiment has been performed as a randomized complete block design (RCBD) with four replications. In both years, during the stage of wheat tillering (TL), 5 months after liming and after the harvest (AH), 10 months after liming, the pH was determined in 1M KCl using a pH meter, and exchangeable Al or cell by the method of Sokolov in soil extract with 1M KCl, so it has been firstly determined by the total substitutional acidity, and then precipitation of Al with NaF and influence of Al-ions in forming of substitutional acidity. The content of Aluminum has been determinate in the average samples of wheat roots during the phenophasis of tillering (TL) as well as the full maturity (FM) on the atomic absorption spectrophotometer (AAS). Data were analyzed using standard statistical methods of analysis of variance (ANOVA) using Microsoft Excel 2007 and Statistical Program 5.0. Data analysis has been used to interpret the results and draw conclusions.

Results and Discussion

The effect of three levels of liming on active, substitutional, and hydrolytic acidity has been in accordance with the applied dose of CaO (Table 1), the highest in the variants with complete liming (V-5), and the lowest in partial liming (V-3). The soil quickly reacted to entered CaO, and changes were obvious and complete already at the first check, 5 months after liming, i.e. in the stage of wheat tillering. The differences between the treatments where CaO has not been used (V-1 and V-2) and the treatments in which CaO has been used (V-3, V-4, and V-5) are highly significant. The differences between the variants in which liming has been performed can clearly be observed. All the differences are highly significant ($p < 0.01$), except for the changes in active acidity in the tillering stage (T) in 2010, when a difference in the level of statistical significance ($p < 0.05$) has been found between the first (V-3) and the second level (V-4) of partial liming.

Table 1. The change in pH (H_2O and KCl) and Y1 after liming

Variants	pH H_2O				pH KCl				Y1	
	2010		2011		2010		2011		2010	2011
	T	AH	T	AH	T	AH	T	AH		
V-1	5.45	5.43	5.42	5.50	4.83	4.83	4.84	4,83	16.32	14.12
V-2	5.50	5.51	5.41	5.47	4.75	4.79	4.79	4.82	14.32	14.56
V-3	5.92	5.89	5.90	5.84	5.23	5.30	5.29	5.24	7.76	7.66
V-4	6.17	6.15	6.18	6.14	5.57	5.56	5.60	5.58	5.21	5.38
V-5	6.79	6.77	6.87	6.73	6.24	6.20	6.24	6.19	3.00	3.45
Lsd 0.05	0.24	0.08	0.10	0.10	0.12	0.10	0.14	0.09	1.69	1.56
Lsd 0.01	0.35	0.12	0.14	0.14	0.17	0.14	0.20	0.12	2.43	2.25

The resulting changes, both in active and substitutional acidity, are in favor of the claims of the need for liming acid soils (Busari et al., 2008; Jelić et al., 2011; Mao et al., 2008), in order to perform the neutralization and create favorable conditions for smooth growth and development of plants. It particularly refers to a group of plants that are insufficiently tolerant to soil acidity.

The content of mobile Al^{3+}, in both years of research, was strongly changed in all the variants where CaO was applied (Table 2). Thus, trace aluminum content was found in the first measuring, in the stage of wheat tillering, in the complete liming variant. According to the results of other authors, liming had the same effect on other soil types, such as pseudogley (Jelić et al., 2011; Pivić et al., 2011).

Table 2. The changes in mobile Al content (mg · 100 g^{-1}) after liming

Variant	2010.		2011.	
	T	AH	T	AH
V-1	12.28	12.21	13.62	13.80
V-2	12.32	12.54	13.92	13.87
V-3	5.26	5.56	6.25	6.39
V-4	2.17	2.37	2.44	2.62
V-5	0.48	0.40	0.47	0.42
Lsd 0.05	0.35	0.28	0.35	0.07
Lsd 0,01	0.50	0.40	0.50	0.10

At the same time, also in the variants of partial (V-3) and particularly half-liming, the content of mobile aluminum was reduced to a level at which the risk of its toxic effect on the crops was significantly reduced. In V-3 and V-4 variants, a slight increase in the content of mobile Al was found during the growing season.

The reaction of the plant versus to lower content of Al in the soil in which liming has been applied, fully veryfy this measure. Namely, starting from partial and endin with full liming, it has been recorded constant decrease of Al content, in teh wheat roots (Table 3.).

Table 3. Changes of aluminium content in wheat roots (mg · 100 g^{-1}) after liming

Variant	2010.		2011.	
	T	AH	T	AH
V-1	54.00	64.50	55.00	66.75
V-2	55.50	64.00	55.00	65.00
V-3	43.50	42.00	44.50	44.50
V-4	26.00	25.75	24.00	25.25
V-5	21.25	21.25	20.75	21.25
Lsd 0.05	4.52	4.71	3.56	3.32
Lsd 0,01	6.25	6.51	4.92	4.60

By full liming, content of aluminum has been reduced at the normal level. The similar effect has been achieved at the variant with half-liming, what can completely recommend this level of the applied lime materials. A positive influence of liming materials on the Al content at other grains has been noted by other authors as well, like in the rotts and lieves of oats. (Djuric et al., 2011) and above land wheat mass (Pivić, et al, 2011).

Since the problem of acidity cannot be definitively resolved, it is completely acceptable regular application of lime material that would soil acidity maintain at an acceptable level (Garscho and Parker, 2001). In this way benefits would be multilateral. Smaller quantities calcification materials would be on one side, economically viable, and on the other side can ensure better availability of nutrients, as well as a more favorable environment for the growth and development of crops.

Conclusions

The degree of reduction in content of mobile Al with partial (1/3 Y_1) and in half calcification (1/2 Y_1) justify and affirm these levels in calcification of acid soil. Main benefits of lower levels of calcification were lower investments in calcification material, and reducing the content of mobile Al Tha plants response was in the reduction of Al content in the values which are usual in the lower level of calcification. By this it is appearing the imperative that further work should be targeted toward the defining of more precise, and economic reasonable quantities of lime materials lower than complete quantities for neutralization of acid soils, which can significantly improve soil conditions for unpended plant growth.

Abstract

In recent years, researchers are interested and focused on the identification of bioactive components in plants and food that affects the health, and may also reduce the risk of some diseases. The research of bioactive components, includes very extensive studies both in conventional breeding and biotechnological researches, with special reference to the possibility to increase their content. *Alchemilla vulgaris* L. is a plant from the *Rosaceae* family. Recent scientific research has shown that the source prevents the growth of many types of bacteria including staphylococci - a bacterium that has become resistant to many antibiotics. Within the experimental part of this final work, the following analyzes were performed: preparation of macerates, extraction of samples in the Soxlet apparatus, ultrasonic extraction and determining the content of vitamin C in the extracts obtained. In determining the content of vitamin C, we noticed that the highest content of this vitamin, determined in the extract obtained by maceration (9.75 mg / 100 g), was slightly lower in ultrasonic extraction (7.50 mg / 100 g), and the smallest content in Soxhlet- of this extract (3.45 mg / 100 g).

Keywords: *Alchemilla vulgaris* L, *maceration, ultrasonic extraction, extraction, vitamin C.*

Introduction

Vitamin C (ascorbic acid) is, by chemical structure,Figure 1., lactone close to L-glucose. It is technically obtained starting from D-glucose, which reduces to D-sorbitol by reduction, and by the action of enzymes of special microorganisms it passes into the L-Sorbose, which with HNO_3 produces 2-keto-L-gluconic acid, the methylester is treated with $NaOC_2H_5$ and then hydrolysed in Vitamin C is formed in the acidic environment. (Duh *et all.*, 1999).

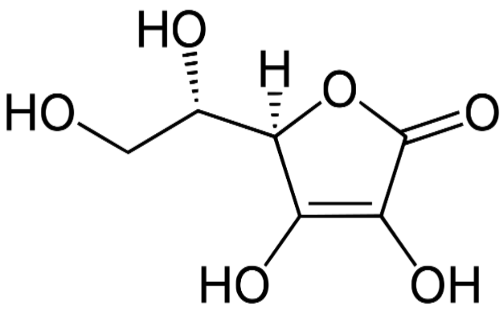

Figure 1. Vitamin C structure

Vitamin C is involved in the construction of cyclic amino acids, steroid hydroxylation, folic acid hydration in tetrahydrofuran, increases breathing intensity, activates many enzymes and improves the acquisition of microelements. Oxidation of L-ascorbic acid first produces monohydroascorbic acid, followed by dehydroascorbic acid. Both have vitamin activity, because they can be converted to ascorbic acid by reduction. L-ascorbic acid is of utmost importance in the metabolism of humans and animals (Tandon *et.*, 1995).

In vitamin C plants is 95% in reduced form, and only 5% is in the oxidized form as dehydroascorbic acid. It is important for the synthesis of collagen and carnitine. Also, the role of vitamin S in the creation of collagen is important for the regeneration of tissue, blood vessels, bones and teeth. The most important group of herbal preparations are extracts, which are obtained by applying different extraction methods, ranging from simpler technologies to advanced techniques. Extraction is the separation and concentration of certain constituents of plant and animal tissues by selective solvents using standard procedures. Depending on consistency, the extracts are divided into liquid, semi-solid and solid. Herbal extracts are obtained by crushing, mainly dry, parts of the plant into contact with the extraction solvent in the appropriate device, the extractor (Daker *et al*.,2008). Extraction material can be: plant, animal and mineral origin. The rate of extraction is influenced by: the size of the contact surface of the solvent and the particulate matter, the thickness of the boundary layer around the particle, and the temperature of the system. In organic laboratories, organic compounds are usually extracted from aqueous solutions using an organic solvent, which is not mixed with water or mixed in part, and two layers are formed. This technique is known as liquid-liquid extraction (Yan *et al.*, 2006).

Material and Methods

As a material in this final work, a virak plant (*Alchemilla vulgaris* L.) was used. The plant material originates from the locality of Cacak, Moravica District, acquired in November 2017. Extracts were obtained from dry plants. In Figure 4, the plant material used for the analysis is shown.All chemicals and reagents were of analytical grade and were purchased from Sigma Chemical Co. (St Louis, MQ, USA), Aldrich Chemical Co. (Steinheim, Germany) and Alfa Aesar (Karlsruhe, Germany). *Alchemilla vulgaris* L. is a plant from the Rosaceae family. This is a perennial herbaceous plant up to 50 cm high. Blooms from June to September. Ground leaves in the rosette from which the tree grows, more or less covered with hair. The rounded-kernel leaves, starched on the 7-11 lobes, along the entire periphery, are bent or chopped. The stem is upright, developing laterally on the rosette. The leaves on the stem are shaped like rosette leaves, but they are smaller. The flowers are small, yellow-green, naked, without crocheted leaves. The fruit of virka is nuts. The bloom is a wide broom. Three measurements of the fragmented sample were performed. Samples were dried in a drying oven at the prescribed temperature (at 105 ºC) under atmospheric pressure to constant mass. The height of the applied temperature depends on the type of sample whose water content is determined (Hsu *et al*.,2008). Before the samples are put on drying, it is necessary to dry the veggel with a lid in the dryer to a constant mass (at least 1 hour) at the prescribed temperature (105 ºC). The veggle is placed on the test sample and measured. Then it is put on drying in the dryer. During the drying of the vegeglas with the pattern, it must be opened, i.e. The lid is located next to it during drying. After drying, the vegeglas is cooled in a desiccator, and then measured.

Extraction by maceration

The extraction is the uniform separation of one or more constituents of a solid or liquid mixture (starting material) with another solvent which is not mixed or mixed with the solvent of the initial mixture, and the other ingredients are not soluble or less soluble in it.

The milled and homogenized sample (5 g), was poured with a solvent (200 mL 96% ethanol), then left in a closed, protected enamel mist. Maceration is done for five days, with shaking every day twice a day. After five days, the plant material from the maceration was cut through the gauze, and after and through the filter paper, black strip. The solvent is removed by evaporation on an aqueous bath, and the resulting extract is dried to a constant weight at a temperature of 50 ° C (Merken H. M. and Beecher G. R., 2000).

Extraction by Soxlet

The best-known apparatus for the continuous extraction of solids is the descendant of Soklet. Socklet extraction takes place by placing the starting material in the cauldron. The pattern with the sample is then inserted into the middle part of the extractor which is connected to the refrigerator and the balloon. The balloon was pre-dried for 1 hour at 105 ºC and measured on an analytical scale. Using a small funnel on the upper side of the condenser, so much solvent was poured into the apparatus that the extractor was filled and poured into the balloon. Further solvents (96% ethanol) are then added, ensuring that the total amount of solvent does not exceed more than ¾ of the volume of the balloon.

Ultrasonic extraction

Ultrasonic extraction is performed in an ultrasonic water bath (EUP540A, Euinstruments, France). The sample (5 g) was placed in a balloon and poured with 200 mL of 96% ethanol. The mixture was extracted for 30 minutes at a frequency of 40 kHz and ultrasound effect 90% (216 W), (Macheix, J.-J. and Fleuriet, A., 1998). For the quantitative determination of vitamin C, the Tillmans method (Tillmans), based on oxidimetric titration, is used in which L-ascorbic acid is oxidized to dehydroascorbic, while simultaneously reducing the reagent used. Titration with 2,6-dichlorophenolinophenol, i.e. The Tilmans Reagent (TR) is carried out in an acidic medium at pH 4-6. The oxidized form of the Tilmans reagent solution (which also has the role of the indicator) has a dark blue color (at pH 5,2), while in the presence of ascorbic acid, TR passes into its reduced, leuky form.

Calculation

The content of ascorbic acid (in mg / 10 g of extract) = ((V - Vsp) * s * 100) / Val,

V - mean value of the volume of TR solution used for the titration of the test probe (mL),

Vsp - the mean value of the volume of the TR solution consumed for the titration of the blank (mL),

c - titre of TR solution (mg $C_6H_8O_6$ / 1 mL TR solution)

Val - the volume of the aliquot part of the sample (mL).

Results and Discussion

Content of total extracted matter

After completed extractions, the extraction of the obtained herbal extracts to dryness was carried out, and then the measurement of the obtained residues was obtained. The yield of the extraction is calculated. From 5 g of plant material of virka (*Alchemilla vulgaris* L.)
The results obtained in percentages are shown in Table 1.

Table 1. Percentage yield extractions

Sample	Maceration	Soxhlet extraction	Ultrasonic extraction
herbal drug *Alchemilla vulgaris* L.	9.45%	4.72%	32.54%

Based on the results obtained, we can conclude that the smallest yield was obtained by Soxlet extraction, followed by maceration, and the highest yield was obtained by ultrasonic extraction. The method of ultrasonic extraction proved to be the most optimal method for this plant species, because it shortly lasts for maceration and takes place at a lower temperature, which is not the case with the Soxlet method, which occurs at high temperature, and it is assumed that there has been degradation of vitamins and other thermolable compounds.

Table 2. Vitamin C content

Type of extraction	Vitamin C mg / 100 g
Maceration	9.75
Soxhlet extraction	3.45
Ultrasonic extraction	7.50

In determining the content of vitamin C, Table 2, we concluded that the highest content of this vitamin is determined by maceration (9.75 mg / 100 g), followed by ultrasound (7.5 mg / 100 g) and the smallest in Soxhlet's extract (3.45 mg / 100g). We assume that maceration as an extraction method has proved to be the most optimal, with the highest yield of vitamin C, because the isolation was carried out at room temperature, and we know that vitamin C is thermolabile.

Conclusions

The smallest extraction yield was obtained by Soxlet extraction, slightly higher maceration, and the highest yield was obtained by ultrasonic extraction. In determining the content of vitamin C, we noticed that the highest content of this vitamin, determined in the extract obtained by maceration (9.75 mg / 100 g), is slightly lower in ultrasonic extraction (7.50 mg / 100 g), and the smallest content in Soxhlet extract (3.45 mg / 100 g). The maceration extraction method proved to be the most optimal and with the highest yield of vitamin C, since the isolation was carried out at room temperature, bearing in mind the fact that vitamin C is thermolabile.

GERMINATION OF CAPPARIS SPINOSA L. SEEDS UNDER DIFFERENT DORMANCY BREAKING TREATMENTS

Marija MARKOVIĆ*, Mihailo GRBIĆ, Dragana SKOČAJIĆ, Matilda ĐUKIĆ, Danijela ĐUNISIJEVIĆ-BOJOVIĆ

University of Belgrade, Faculty of Forestry, Kneza Viseslava 1, 11030 Belgrade, Serbia

Abstract

Capparis spinosa is a spiny, evergreen shrub, that grows to 1 m tall, spreading by semi-prostrate branching to 2 - 3 m wide. It is native mostly to Mediterranean coastal regions, growing on sandy or rocky soils, stone walls and rock crevices. Its unopened flower buds are edible and used as a flavouring in sauces or salads. Also, caper bush is an ornamental and drough tolerant species that is suitable for landscape use. Generative propagation of this species is difficult due to its seed coat dormancy, followed by embryo dormancy that develops after drying. The aim of this study was to investigate the effect of different seed treatments on dormancy breaking. The seeds collected in Perast, Montenegro at the end of summer, were stored for six months before setting the experiment. The treatments included: soaking seeds in sulfuric acid at 96 % for 15 or 30 minutes, mechanical scarification, hot water (40ºC) treatment, 3 months of cold stratification at 3-5^{o}C in perlite, treatment with 0.2% KNO_3. The obtained results showed that KNO_3 has negative impact on caper bush germination, and in all combined treatments, the germination rate was lower with the addition of KNO_3. The mechanical scarification showed the best germination rate (36%), but it is necessary to conduct the additional research in order to improve germination of dried caper bush seeds.

Key words: *Caper bush, stratification, sulfuric acid, embryo dormancy, scarification.*

Introduction

Capparis spinosa L. (caper bush) is a xerophilous, evergreen shrub that typically grows to 1 m tall. Its branches are semi-prostrate and the width of a shrub is 2 - 3 m. The native range is wide, including Mediterranean, southwestern Asia, Black Sea coast (Crimea and Armenia), east side of the Caspian Sea, Iran, Afghanistan, extending eastward to the Himalayas, Pacific Islands and northern Australia (Miras-Avalos and Baveye, 2018; Lansky et al. 2013; Chedraoui et al. 2017). The stems are spiny, with small, round, evergreen leaves, 5 cm long. The flowers develop from the leaf axils, with white petals and pale purple stamens. Diameter of flowers is 5 - 8 cm. *C. spinosa* blooms from spring to early autumn, but single flower lasts only one day. The fruits, known as the edible caperberries, are 1 - 2 cm long and they contain numerous and reddish-brown seeds (Lansky et al. 2013; Chedraoui et al. 2017).
Caper bush is grown as an ornamental species due to its decorative and sweet-scented flowers. It can endure drought, sun, and warm climate, and it can be grown on sandy and rocky soils, in a poor soils or even on stone walls and rock crevices (Miras-Avalos and Baveye, 2018). It is also valuable medicinal and edible species. The unopened flower buds are used as a spice, usually salted or pickled in vinegar (Lansky et al. 2013).
C. spinosa is an important plant for growing in the changing climate conditions due to its resistance to environmental stresses and it can be grown even on areas affected by hyper-aridity (Miras-Avalos and Baveye, 2018). Caper bush has an extensive root system which is very effective for water retention during rainfalls, additionally it has a very high root/stem ratio and capability for a high water use efficiency, absorbing water particularly in soil depths (Chedraoui et al. 2017). Also, it is used for the prevention and control of soil erosion in sloppy areas (Khalil et al. 2009). Caper bush tolerates salty or calcareous soils, low amount of

organic matter in soil and it successfully grows in saline and halophytic habitats (Chedraoui et al. 2017). It belongs to climate zones 8 - 10, but in accordance with the recent climate changes, many species belonging to zone 8 now are successfully grown in Serbia, in the warm and protected areas.

Caper bush can be propagated vegetatively, by hardwood, semi-hardwood or softwood cuttings, but rooting percentage is mostly low (Miras-Avalos and Baveye, 2018). Generative propagation of this species is difficult due to its seed coat dormancy, followed by embryo dormancy that develops after storage. Also, seed viability is low, about 2 years. For this reason, different combined seed pretreatments are used in order to overcome its dormancy, including mechanical scarification, the use of concentrated sulfuric acid (H_2SO_4), followed by KNO_3, gibberellins and different cold stratification pretreatments (Bahrani et al. 2008; Khalil et al. 2009; Labbafi et al. 2018; Miras-Avalos and Baveye 2018; Orphanos 1983; Basbag et al. 2009). However, the plants used in published studies of caper bush germination originated from different areas, and the obtained results varied considerably. For this reason, authors decided to evaluate the effect of different seed treatments on dormancy breaking of seeds collected from the elite genotype grown in neighbouring country Montenegro.

Material and Methods

The fruits were collected in Perast, Montenegro, at the end of summer, in 2016. Experiment was conducted in the Laboratory for seed testing at the Faculty of Forestry, University of Belgrade (Serbia). Dimensions and weight of fruits were measured as well as weight of seeds. This data was used for calculation of an extraction factor (the weight of cleaned seeds per given weight of fruits, expressed in percent), number of seeds in 1 kg and absolute weight of seeds (weight of 1000 seeds). The obtained seeds were kept in dry conditions, at room temperature, for 6 months.

The following treatment were used for a seed coat dormancy breaking:

- **chemical scarification treatment**

The seeds were soaked in a concentrated (95%) sulfuric acid (H_2SO_4) for 15 or 30 minutes, then carefully rinsed using a running water and disinfected by 0.8% solution of the fungicide benomyl *(*benlate).

- **mechanical scarification of seed coat**

The seed coat was cut on side opposite from micropyle so the radicle was not damaged, using a sharp scalpel blade.

- **soaking in a warm water**

The seeds were soaked in a warm water (40ºC) for 24 hours, followed by a disinfection using 0.8% solution of the fungicide benomyl.

The following treatment were used for embryo dormancy breaking:

- **treatment with potassium nitrate**

The seeds were treated with 0.2% KNO_3 (potassium nitrate) during germination test.

- **cold stratification**

The seeds were disinfected by 0.8% solution of the fungicide benomyl and stratified in perlite at the temperature 2 - 5ºC, for 3 months.

Each experiment consisted of four replicates with 50 seeds each. The seeds were placed on the top of two layers of filter paper in the petri dishes, humidity was controlled daily by adding the distilled water if necessary. Temperature during germination was 25°C. Germination was carried out in long day conditions (light/dark period 16/8h). The number of germinated seeds was recorded daily during the period of 21 day. After that, the seeds were cut in order to determine the percentage of viable seeds which is necessary to calculate the real germination rate, as a percentage of sound (viable) seeds that germinate (Grbić et al., 2010). The germination energy was recorded on 7th day. Obtained data were statistically analysed using the program Statgraphics Plus, Ver 2.1.

Results and Discussion

Morphometric analysis

The seed was relatively large compared to some available data where number of seeds per gram was 140 - 160 (Gorini, 1981; Bahrani et al. 2008; Miras-Avalos and Baveye, 2018) while in our research the average number of seeds 116.67 per 1g (Table 1). Due to its large native distribution, the morphological differences among different wild populations of *C. spinosa* from different geographical regions are expected which is proved by many research studies that conducted a morphometric analysis of caper bush seeds (Saadaoui et al., 2011; 2013; Chedraoui et al., 2017).

Table 1 Morphometric parameters of collected fruits and seeds

Parameter	Mean ± SE
weight of fruit (g)	9.75 ± 1.16
length of fruit (cm)	4.31 ± 0.17
width of fruit (cm)	2.01 ± 0.08
length of peduncle (cm)	4.35 ± 0.13
number of seeds per fruit	186.67 ± 36.27
the weight of seeds per fruit	1.68 ± 0.41
extraction factor (%)	16.61 ± 2.72
number of seeds per 1 kg	116671.50 ± 6853.51
weight of 1000 seeds (g)	8.71 ± 0.49

Effect of different seed treatments on dormancy breaking

In the control treatment there were no germinated seeds which was expected due to combined seed coat and embryo dormancy of this species (Table 2). Similarly poor results were obtained after 3 months of stratification, following the warm water treatment (40ºC) conducted for 24 hours. Bahrani et al. (2008) used warm water pretreatment for 30 minutes at the temperature of 50ºC, and obtained germination percentage was also very low.

The other treatments for breaking seed coat dormancy proved favorable for germination, and 30 minutes treatment with concentrated H_2SO_4 proved better than 15 minutes treatment (Table 2). Bahrani et al. (2008) use concentrated H_2SO_4 for 15, 30 and 40 minutes, and the best results were obtained after 30 minutes of treatment. Following the H_2SO_4 treatment, Bahrani et al. (2008) treated seeds by different concentration of gibberellic acid (GA_3) and it had favorable effect, increasing germination percentage at all applied concentrations, although the best result was obtained with 200 mg/L GA_3. Labbafi et al. (2018) also reported high germination rate of seeds treated with concentrated H_2SO_4 for 30 minutes followed by GA_3 treatment (75.%). However, Olmez et al. (2004) obtained the highest germination rate (49.7%) of caper bush treating a seed with concentrated H_2SO_4 for 20 minutes, followed by 0.2% KNO_3 application, while the same treatment with concentrated H_2SO_4 followed by GA application gave lower germination (27.4%).

In our research, the negative impact of 0.2% KNO_3 on *C. spinosa* seed germination was recorded (Table 2), and germination is lower after addition of KNO_3 (13% and 16.50%) than without it (17.50%, 22%, respectively). Similarly, Labbafi et al. (2018) also recorded the negative impact of KNO_3 on caper bush germination, obtaining lower results than a control treatment. Khalil et al. (2019) reported the highest germination rate of caper bush with combination of 20 minutes H_2SO_4 treatment, followed by 0.04% GA_3 treatment and then one week of cold stratification at 4ºC

In this research, the highest germination rate (36%) was obtained with mechanical scarification of a seed coat (Table 2), but some other researchers reported low germination rate with mechanical scarification pretreatment (only 20%) compared to treatment with concentrated H_2SO_4 (43% for 30 minutes duration of treatment) (Bahrani et al. 2008).

Table 2 Germination of collected seeds

Treatment	Germination rate	Germination energy	Real germination rate
Control	0.00^{d}	0.00^{c}	0.00^{d}
0.2% KNO_3	0.00^{d}	0.00^{c}	0.00^{d}
24 h warm water + stratification	3.00^{d}	0.00^{c}	3.18^{d}
15 minutes H_2SO_4	17.50^{c}	9.50^{b}	18.18^{c}
30 minutes H_2SO_4	22.00^{bc}	13.50^{b}	23.15^{bc}
15 minutes H_2SO_4 + 0.2% KNO_3	13.00^{c}	7.00^{bc}	14.03^{c}
30 minutes H_2SO_4 + 0.2% KNO_3	16.50^{c}	12.00^{b}	17.14^{c}
mechanical scarification	36.00^{a}	27.00^{a}	36.72^{a}
mechanical scarification + 0.2% KNO_3	28.50^{ab}	23.00^{a}	29.08^{ab}

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

There was no considerable difference between real germination (a percentage of viable seeds that germinated) rate and germination rate (Table 2) indicating that large percent of the tested seed was viable, but did not germinated. Miras-Avalos and Baveye (2018) indicated that seed will successfully germinate in 25 -50 days and we conducted germination test for 21 days. Also, caper bush seed viability is about 2 years when kept at 4°C and low relative humidity (Chedraoui et al., 2017) and we kept the seeds at room temperature, for 6 months.

Additionally, Khalil et al. (2009) reported that germination of caper bush seed was considerably higher in soli substrate (64%) compared to testing on filter paper (24%), after the same seed pretreatments.

Conclusion

Caper bush is a multipurpose plant, that can be grown as a medicinal plant, suitable for culinary uses, but it is also the important low-maintenance ornamental plant suitable for arid conditions and very adaptable in environmental changes. Its propagation is dificult due to seed coat and embryo dormancy, and germination percentage is usually low. Our reserach showed that selected elite genotype from Montenegro has large and viable seeds, but the further research is necessary to overcome dormancy. Additional treatments, including the effect of GA_3 treatments should be tested in order to improve germination rate of caper bush collected in Montenegro.

Abstract

Nitrogen management in winter wheat is one of the most studied agricultural practices. Optimization of nitrogen nutrition and sowing density requirements of specific winter wheat cultivar are major objectives for improvement of trade-offs between grain yield, environmental sustainability and maximum profitable production. Therefore, the aim of this study was to assess the effects of interaction between nitrogen fertilization and sowing density on grain yield and yield determinants of modern wheat cultivars. The trial consisted of five winter wheat cultivars, four top-dressing nitrogen doses and four sowing densities was carried out under rain-fed conditions at the experimental field of the Institute of Field and Vegetable Crops, Novi Sad, Serbia. The analysis of variance showed statistically significant effects of all three factors on studied traits, while significance of interactions between studied treatments varied among traits. On average, grain yield between cultivars varied from 8.64 to 9.69 t ha^{-1}. Generally, the highest grain yield was achieved under conditions of 100 kg N ha^{-1} treatment. By increasing N fertilization thousand grain weight decreased almost linearly, while maximum grain number per square meter was recorded with 100 and 150 kg N ha^{-1}. The highest yield and grain number per square meter were obtained under increased sowing densities (700 and 900 viable seeds m^{-2}), while the thousand grain weight had lower variation and the highest values were realized with 300 and 900 viable seeds m^{-2}. In conclusion, the presence of significant interaction between cultivars, N fertilization and sowing densities, indicated necessity to adjust different management practices to each cultivar in order to achieve highest grain yield potential.

Introduction

Wheat is one of the oldest and most important cereal crops, widely cultivated for its grain which is a worldwide staple food. In Serbia, the southern part of the Pannonian plain, wheat is the main winter cereal crop with a harvested area over 550,000 ha. Wheat production needs to continue to grow with increasing demands, and both aspects increasing the yields and sustainability represent major challenges (Hawkesford, 2014). Production systems in the world vary greatly, depending on climatic and soil fertility factors. The agricultural areas of the Pannonian basin are characterized by a relatively short growing season, winter frosts, occasional spring heats and frequent drought stresses at the end of the grain filling period, which influences significant grain yields variations of many cereal crops across different growing seasons (Mirosavljević et al., 2018). For all agricultural systems, especially in areas of higher production there is a constant need for adequate amounts of nutrients, mostly supplied as fertilizers. Efficient nitrogen fertilization is one of the key elements for economical wheat production. Moreover, nitrogen is the most limiting nutrient for wheat production that affects grain yield and biomass production, as well as establishment of high grain weight and grain number per unit area (Lawlor et al., 2001). Adequate nitrogen use is also important in order to protect underground and surface water from pollution caused by the leaching of nitrates due to excessive and inappropriate fertilization (Vuković et al., 2008). Beside balanced nutrition, sowing density also plays an important role for achieving high yields with desirable grain quality. Optimum plant densities greatly vary across areas, diverse climatic and soil conditions as well as cultivar specificity. Due to the presence of different mechanisms of yield determination in wheat cultivars, each cultivar needs to be evaluated over wide range of fertilization and seeding rates to determine optimal combination of agronomic practices (Wiersma, 2002). Considering constant development of new wheat cultivars with specific requirements for appropriate management practices, there is a lack of information about their response to different fertilization and sowing density. Therefore, the objectives of this study were to quantify the variation in grain yield and main agronomic traits of the five new developed wheat cultivars across different N fertilization levels and sowing densities in order to improve wheat production under agroecological conditions of Pannonian Plain.

Materials and methods

This study included five new winter wheat cultivars (NS Pudarka, NS Nafora, NS Petrija, NS Tavita and NS Ilina) released by the Institute of Field and Vegetable Crops, Novi Sad, Serbia. The cultivars were grown under field conditions with combinations of four top-dressed N fertilization levels and four sowing densities. N fertilization treatments included an unfertilized control (0 N) and N fertilization with 50 (50 N), 100 (100 N) and 150 kg N ha^{-1} (150 N), and sowing densities of 300, 500, 700 and 900 viable seeds m^{-2}. Treatments were arranged in a split-split-plot design with three replications. Main plots were assigned to the nitrogen levels, sub-plots to cultivars and sub-sub-plots to sowing densities.
The trial was set up at experimental fields of Institute of Field and Vegetable Crops, Novi Sad under rain fed conditions on carbonate chernozem, with soybean as a preceding crop in 2015/16 growing season. Crops were sown on recommended sowing date for southern Pannonian plain. A fertilizer combination (NPK – 11:52:0) was applied before ploughing to avoid N, P and K deficit, based on previous soil agrochemical analysis. The soil was prepared by ploughing along with two harrowing procedures. Each plot consisted of 10 rows, with row spacing of 0.10 m and length of 5 m. Pests, weeds and diseases were prevented or controlled by applying the recommended insecticides, herbicides and fungicides. No additional irrigation was applied. Grain yield (GY) was determined from combine-harvested plots in each of the three replications. Moisture content was determined using grain analysis computer (Model GAC2100, Dickey-John, Auburn, IL) and GY was corrected to 130 g kg^{-1} moisture. From harvested sample, thousand grain weight (TGW) was determined by three sets of 300 grains per plot and expressed as the weight of 1000 grains. Number of grains per m^2 (GN) was calculated as the ratio of the grain yield and the thousand grain weight. Analysis of variance (ANOVA) and data mean comparison by Duncan multiple range test were performed using Infostat (student version).

Results and Discussion

In combined analysis of variance cultivar (C) contributed the most to the total sum of squares of the studied traits (Tab. 1). Cultivars behaved differently under various N-fertilization (F) and sowing density (SD) treatments. The effect of F × C interaction was significant for all studied traits, with the highest influence of GY. The contribution of F × SD, C × SD and F × C × SD interaction was significant only for TGW.

Tab. 1. Relative contribution to the total sum of squares (%) and the level of significance for grain yield (GY), thousand grain weight (TGW) and grain number (GN) of wheat cultivars (C) under different fertilization (F) and sowing density (SD) treatments

Source of variation	Degrees of freedom	GY	TGW	GN
F	3	5.9**	17.4**	21.5**
C	4	13.4**	71.7**	27.8**
SD	3	8.2**	0.3**	5.5**
F × C	12	8.9*	4.9**	7.6**
F × SD	9	1.6^{ns}	0.4**	1.0^{ns}
C × SD	12	2.3^{ns}	0.6**	1.0^{ns}
F × C × SD	36	3.4^{ns}	1.8**	2.3^{ns}

* significant at 0.05; ** significant at 0.01; ns - not significant

Overall GY average of the analyzed cultivars in the trial was 9.16 t ha^{-1} (Tab. 2). N fertilization significantly altered GY of five winter wheats cultivars, resulting in GY increase in comparison with the unfertilized treatment. On average, the highest GY was observed at 100 N (9.50 t ha^{-1}) and 150 N (9.24 t ha^{-1}). However, absence of N application (control treatment) resulted in the lowest GY average of 8.80 t ha^{-1}. Moreover, cultivars differed significantly in GY, and the average values among cultivars ranged from 8.64 (NS Ilina) to 9.69 t ha^{-1} (NS Pudarka). Also, there was a significant influence of F × C interaction on GY, indicating different cultivar responses to N application, e.g., NS Petrija achieved the highest GY at 50 N, whereas NS Tavita at 150 N treatment. Similarly, various studies showed GY increase with nitrogen application as a result of enhanced tillering, higher biomass production, GN and GW. (Kristensen et al., 2008, Jaćimović et al., 2014; Yang et al., 2019). Although, negative influence of N-fertilizer application on GY (severe lodging) were recorded due to favorable conditions for organic matter mineralization and consequently higher mineral N content in the soil (Aćin et al., 2013; Aćin et al., 2014).

Tab. 2. Grain yield (t ha^{-1}) of wheat cultivars across fertilization and sowing density treatments

Cultivar	**N-fertilization**				**Sowing density**				**Average**
	0 N	**50 N**	**100 N**	**150 N**	**300**	**500**	**700**	**900**

Different letters represent significant differences (p<0.05; Duncan multiple range test)

On average for examined cultivars, significantly highest yields were achieved with 700 and 900 viable seeds m^{-2}. In general, GY of each cultivar improved with increasing sowing densities, but due to the absence of C × SD interaction, differences were not significant for most of the cultivars, except for NS Petrija and NS Ilina (Tab. 2). In agroecological conditions of Serbia, optimal SD of winter wheat varieties should vary between 500 and 600 viable seeds m^{-2}, thus producing a sufficient number of good quality spikes. Plants compensate lower population densities by increasing production and survival of tillers and, to a lesser extent, increasing grain numbers per spike (Bokan and Malesevic, 2004). However, although low plant density induces a higher GN and GW per spike, generally this is not sufficient to compensate for the lower spike density per m^{2} generated by a lower tiller density. Therefore, an appropriate increase in plant density to balance yield component factors would appear to be an appropriate agronomic management strategy for enhancing wheat grain yield (Li et al., 2016). The grand mean of TGW was 43.8 g, and it was significantly affected by the change in nitrogen top-dressing doses (Tab. 3). TGW values decreased with higher application of nitrogen, ranged from 46.6 g in 0 N to 41.9 g in 150 N treatments. Moreover, significant differences among cultivars were recorded for TGW, where average values varied from 38.0 g to 49.2 g, for NS Ilina and NS Tavita, respectively.

Tab. 3. Thousand grain weight (g) of wheat cultivars across fertilization and sowing density treatments

Cultivar	N-fertilization				Sowing density				Average
	0 N	50 N	100 N	150 N	300	500	700	900	
NS Pudarka	45.6^{d}	44.1^{ef}	44.2^{ef}	44.6^{e}	45.1^{bc}	44.7^{b-d}	44.1^{d}	44.5^{cd}	**44.6^{c}**
NS Nafora	48.1^{c}	45.5^{d}	43.5^{f}	43.7^{f}	45.4^{b}	45.3^{b}	44.9^{b-d}	45.1^{bc}	**45.2^{b}**
NS Petrija	45.4^{d}	43.4^{f}	41.0^{h}	38.1^{i}	42.4^{e}	40.9^{f}	42.0^{e}	42.6^{e}	**42.0^{d}**
NS Tavita	51.5^{a}	49.9^{b}	47.5^{c}	48.0^{c}	49.7^{a}	49.3^{a}	49.0^{a}	49.0^{a}	**49.2^{a}**

Average	**46.6^{a}**	**44.3^{b}**	**42.4^{c}**	**41.9^{d}**	**44.1^{a}**	**43.5^{b}**	**43.6^{b}**	**44.0^{a}**	**43.8**

Different letters represent significant differences ($p<0.05$; Duncan multiple range test)

Differences in TGW were also observed due to the effects of various SD (Tab. 3). Highest TGW values were recorded with 300 and 900 viable seeds m^{-2}, for all studied cultivars. In comparison with 500 and 700 viable seeds m^{-2}, differences were not have considerable extent, but statistically significant. However, effects of SD on GY were not significant for cultivars NS Nafora and NS Tavita. According to Valerio et al. (2013), TGW did not reveal an effect on the yield variations, due to a change in SD rates. Similar results have been reported, where the TGW appears to be less affected by seeding density but significantly affected by environment and cultivar (Lloveras et al., 2004; Hiltbrunner et al., 2005). However, increase in SD from 500 to 650 viable seeds m^{-2} resulted in increase of TGW, as higher plant density provides a greater number of primary tillers per m^2, which causes the formation of grains with larger size and weight (Zecevic et al., 2014). An increase in N application resulted in an increase in GN, with a trial average of 21109 (Tab. 4). For all examined cultivars, the highest GN were obtained at 100 N and 150 N treatments, respectively, followed by 50 N and 0 N treatment with the lowest value.

Average	**18972^{c}**	**20648^{b}**	**22611^{a}**	**22204^{a}**	**19960^{b}**	**21019^{a}**	**21791^{a}**	**21665^{a}**	**21109**

Different letters represent significant differences ($p<0.05$; Duncan multiple range test)

Furthermore, cultivars differed significantly in GN, with an average for all F and SD treatments ranged from 18073 (NS Tavita) to 22924 (NS Ilina). Due to the significant F × C interaction cultivars responded differently to various N treatments. So, cultivars NS Tavita and NS Ilina achieved the highest GN at 150 N and 100 N, respectively, while the increase in N doses resulted in not significant GN variation for NS Pudarka.

In addition, an increase in plant density was followed by increase in the GN, with no significant differences between 500, 700 and 900 viable seeds m^{-2} (Tab. 4). However, interaction of C × SD for GN was merely significant for cultivars NS Nafora and NS Petrija, with lowest values obtained at 300 viable seeds m^{-2}.

Conclusion

Nitrogen fertilization, cultivars, sowing densities and their interactions showed significant influence on GY and grain yield components, whereas cultivar had the highest contribution to the total sum of squares. Nitrogen application resulted in additional yield increase when compared to 0 N, and highest average GY for all examined cultivars and sowing densities was recorded at 100 N treatment. Similarly, N application increased GN up to the 100 N, but conversely, led to significant TGW decrease at higher N doses. In general, highest average GY were achieved with 700 and 900 viable seeds m^{-2}, without significant differences for most of the examined cultivars. Moreover, no significant differences in GN were recorded between 500, 700 and 900 viable seeds m^{-2}. Finally, the significant influence of interactions indicate the importance of constant examination of simultaneous effects of different nitrogen doses and sowing densities on grain yield formation in wheat cultivars in order to adjust management practice for a specific cultivar.

Abstract

In the experiments that were carried out in 2019 on two localities (East Sarajevo and Bijeljina) in the entity of Republic of Srpska (Bosnia and Herzegovina), the influence of the application of superapsorbent "*Tverdaya Voda*" on the morphological properties of potatoes was examined. The control variant, superapsorbent "*Tverdaya Voda*", superapsorbent "*Tverdaya Voda*" enriched with growth stimulants, superapsorbent "*Tverdaya Voda*" enriched with microorganisms, superapsorbent "*Tverdaya Voda*" enriched with microelements and superapsorbent "*Tverdaya Voda*" enriched with growth stimulants, microorganisms and microelements in the amount of 20 kg ha^{-1}, were applied for this examinations. The morphological traits of potatoes that were monitored are: plant height (cm), number of offshoots, mass of plant (g) mass of leaves (g) mass of stalks (g), leaf area per plant (m^2). In comparison with the multiyear averages, the year 2019 is characterized by higher temperatures and higher precipitation. Temperatures were lower only in May at both localities, which significantly influenced the slower sprouting of potatoes in East Sarajevo. When we used superapsorbent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements, plant height was 88 cm, number of trees was 6.38, plant weight was 896 grams, weight of leaves was 492.9 grams, weight of stem was 403.1 grams and assimilation surface 0.5529 m^2 per plant, while in variant without the use of superapsorbent "*Tverdaya Voda*" obtained results for plant height was 62.62 cm, number of trees was 3.38, weight of plant was 365.5 grams, weight of leaves was 215.3 grams, weight of stem was 150.2 grams and assimilation surface was 0.3401 m^2 per plant.

Keywords: *superapsorbent, potato, morphological properties, locality.*

Introduction

Potatoes grow under different climatic conditions, but it succeeds the best in climates with moderate temperatures, about 20 °C, during the vegetation period. The optimal temperature for the development of the above-ground vegetative part (tree and leaves) of the potato plant is 15-19 °C (Tadesse et al., 2001), and this temperature also represents a biological optimum for the development of underground vegetative organs (stolons and tubers). Potatoes have somewhat higher demands for water at the time of butonization, full blooming and blossom fall, as well as in the initiation phase, early development of tubers and filling of tubers (Poštić et al., 2012a). Dry seasons are often followed by high temperatures, and production is often carried out in conditions of extremely unfavorable agroecological factors. The undesired effects of high temperature on growth and potato yield are numerous and include: reduction of photosynthesis and increased breathing, reduction of root growth, inhibition of initiation and growth of tubers, reduction of dry matter (Struik 2007). Therefore, water scarcity, particularly in arid and semi-arid regions, is viewed as a major threat to long-term food security (Zhang et al., 2014). Good soil-water management is the most important factor of agricultural production in arid and semi-arid areas (Debaeke and Aboudrare, 2004). Applying water absorbing materials to soils may be a viable alternative and practical strategy for solving the problems of limited and intermittent rainfall. These soil amendments can improve soil physical and chemical properties and soil nutrient status, and have a positive impact on soil microorganisms to improve soil productivity (Mann et al., 2011). It was reported that polymer addition to sandy soil increased water and fertilizer use efficiency for plants (Bhardwaj et al., 2007; Islam et al., 2011). Furthermore, polymers potentially influence infiltration rates, density, soil structure, compaction, aggregate stability, crust hardness, and evaporation rates (Sepaskhah and Bazrafshan-Jahromi, 2006). Previous research indicated that application of polymers not only prevents pollution of agro-ecosystem, but also increases farmers' economic return (Islam et al., 2011). By applying some of the soil amendments such as super absorbent polymers, it may be possible to maintain good soil moisture under erratic rainfall and optimize use of water resources for crop production in the arid and semi-arid regions. Effect of synthetic and natural water absorbing soil amendments on soil moisture content, yield and water use efficiency (WUE) of potato production was investigated in a field experiment in a semi-arid region in northern China (Xu et al., 2014). Synthetic polymers had good interaction with natural soil amendment HA; they had positive effect in plant growth, and improved yield and WUE, this was consistent with Huang et al. (2007). The main goal of this research is to determine the influence of the superadsorbents "*Tverdaya Voda*" (created at the Voronezh State Agrarian University named after Emperor Peter the Great) different composition on morphological properties of potato in different cultivation conditions.

Material and methods

Outdoor experiments were set up in 2019 at two localities: locality 1- on the territory of the city of East Sarajevo (Tilava), altitude 550 m (43°49'01 " north latitude and 18°20'57" east longitude) and locality 2 - in the territory of the city of Bijeljina (Trnjaci), elevation of 90 m (44°83'23" north latitude; 19°29'29" east longitude). The agroecological conditions in East Sarajevo are characterized by the strong influence of the continental climate. The average annual temperature is 10.2 ° C, and the average amount of precipitation is about 900 mm. The experiment was set on alluvial soil (fluvisol). The second locality is characterized by a moderate continental climate. The average annual temperature is 12.5 ° C, and the average amount precipitation is 757.2 mm. The experiment was set on a semigley-type soil. The experiments were set by random block system in four reps with a set of 53.333 plants per ha^{-1}. The ground area of basic plot is 15 m^2 (four rows of 5 m length with 20 plants in a row, distance between rows 0.75 m and distance between plants in the row of 0.25 m). For examination of influence of superapsorbent "*Tverdaya Voda*" on morphological properties of potato we used control variant (A_0), superapsorbent "*Tverdaya Voda*" (A_1), superapsorbent "*Tverdaya Voda*" enriched with growth stimulants (A_2), superapsorbent "*Tverdaya Voda*" enriched with microorganisms (A_3), superapsorbent "*Tverdaya Voda*" enriched with microelements (A_4) and "*Tverdaya Voda*" superapsorbent enriched with growth stimulants, microorganisms and microelements (A_5) in the amount of 20 kg ha^{-1}. The experiment in Bijeljina was set on March 24, 2019. Potatoes began to sprout equally on April 13, 2019, and began to flourish on June 2, 2019. Samples for analysis were taken on June 14, 2019. The experiment in East Sarajevo was set on April 25, 2019. Potatoes began to sprout equally on May 15, 2019, and began to flourish on June 29, 2019. Samples for analysis were taken on July 10, 2019. From the morphological properties of potatoes, the following are observed: height of plants (cm) (measurement from the soil surface to the top of the upper flower); number of offsprings; leaf surface per plant (m^2) by contour sheet on paper method (Prokić i Savić, 2012); fresh offspring plant weight (g), weight of leaves (g) and potato stalk weight (g). The obtained results are analyzed by the twofactorial reflection variance analyze (locality, absorbent), and the individual differences tested by the LSD test, using the SAS /

STAT program (SAS Institute, 2000). Soil samples were taken from experimental parcels in East Sarajevo (B_1) and Bijeljina (B_2). After laboratory analysis it was established that alluvial soil from East Sarajevo has pH_{H2O} 6.63, it contains 3.62% humus, 0.23% N, and in 100 g^{-1} soil, it has 14.75 mg of soluble P_2O_5 and 15.59 mg of soluble K_2O, while humophluvisol from Bijeljina had pH_{H2O} 7.16, containing 4.12% humus, 0.27% N and 100 g^{-1} of the soil had a 40 mg soluble P_2O_5 and 36.41 mg of soluble K_2O. The land from both sites is dried to the same constant. In comparison with the multiyear averages, the year 2019 is characterized by higher temperatures and higher precipitation (Table 1). Temperatures lower at both localities only in May, which significantly influenced the slower growth of potatoes in East Sarajevo. Frequent and higher amounts of precipitation with the appearance of high temperatures also affected the occurrence of the causative agent of the disease, that was the reason for repeated treatmant of potatoes with protective agents.

Table 1. Average monthly air temperatures (°C), monthly precipitation (mm) and multiyear averages for Bijeljina and East Sarajevo.

Month			I	II	III	IV	V	VI

Results and Discussion

The decrease in stem height with water deficit during the growing season and in the absence of superapsorbenta use is consistent with the results of research by Motalebifard et al. (2014). Cell growth is the most sensitive stage under the influence of water stress. The size of organs is limited by decreasing cell growth and the first palpable effect due to water deficiency in the crops is shown by decreasing leaf size and crop height (Kirank et al., 2003). Statistically analyzed, significant differences were found for the height of plants, number of shoots, plant mass, leaf mass, stable and leaf surface when using different variants of superapsorbent "*Tverdaya Voda*". A highly significant influence of the locality for plant height, plant mass, leaf mass, tree mass and leaf surface was determined, while the highly significant interaction of the superapsorbent x locality was determined for plant mass, leaf mass, stable and leaf surface. The highest plant height is in the variant where the superapsorbent "*Tverdaya Voda*" is enriched with growth stimulators, microorganisms and microelements (88 cm). The application of various variants of enriched superapsorbent "*Tverdaya Voda*" had a significantly higher potato plant than the control variant (62.62 cm) and a variant where "*Tverdaya Voda"* superapsorbent was applied (75.25 cm) Highly significant differences were determined in plant height between the variant where superapsorbent "*Tverdaya Voda*" and the control variant were applied. The height of plants in Bijeljina is 91.29 cm, while in East Sarajevo it is 68.71 cm. These differences are highly significant. The results of studies by Jahan et al. (2013) and Islam et al. (2011a) showed the positive effect of superapsorbenta on crop height which is consistent with the results of this research. The control variant had the smallest number of offshoots (3.38), and the largest number of offshoots had superapsorbent "*Tverdaya Voda*" enriched with growth stimulators, microorganisms and microelements

(6.38). The determined differences are statistically significant, as well as differences of other variants of the "*Tverdaya Voda*" superapsorbent in comparison with the control variant. Number of offshoots in Bijeljina was 4.96, and in Eastern Sarajevo was 4.42. These differences were not statistically significant.

Table 2. Influence of superapsorbent and locality on the morphological properties of potatoes

		Plant height (cm)	No. of offshoots	Mass of *plant* (g)	Mass of leaves (g)	Mass of stalks (g)	Leaf surface area of 1 plant (m^2)

*** F-test significant at 0.01; * F-test significant at the 0.05 level; ns non-significant*

The mass of the plants ranged from 365.5 to 896 grams. Using the "*Tverdaya Voda*" superapsorbent enriched with growth stimulators, microorganisms and microelements, potato plants were obtained, which, compared with other variants, had statistically significant weight of plants, while the control variant compared with the use of different variants of superapsorbent "*Tverdaya Voda*" had statistically significant the smallest mass of plants. We determined a significant variation in the mass of plants between the superapsorbent "*Tverdaya Voda*" (A_1), the superapsorbent "*Tverdaya Voda*" enriched with growth stimulants (A_2), the "*Tverdaya Voda*" superapsorbent enriched with microorganisms (A_3) and the "*Tverdaya Voda*" superapsorbent enriched with microelements (A_4).
The mass of plants in Bijeljina was 797.9 g, and in East Sarajevo was 464.3 g. These differences are highly significant. At both localities, the largest plant mass was in the A_5 variant of 1130 g; 661.4 g), and the smallest 332.6 g in the control variant (Bijeljina), ie 381 g in variant A_2 in East Sarajevo.
The weight of leaves ranged from 215.3 grams to 492.9 grams. Using the "*Tverdaya Voda*" superapsorbent enriched with growth stimulators, microorganisms and microelements, potato plants were obtained, which, compared to other variants, had statistically significantly higher leaf mass, while the control variant compared to the use of different variants of the superapsorbent "*Tverdaya Voda*" had statistically significant the smallest leaf mass. High weight variation of the leaves weight was determined between the superapsorbent "*Tverdaya Voda*" (A_1), the superapsorbent "*Tverdaya Voda*" enriched with growth stimulants (A_2), the superapsorbent "*Tverdaya Voda*" enriched with microorganisms (A_3) and the "*Tverdaya Voda*" superapsorbent enriched with microelements (A_4).
The weight of leaves in Bijeljina is 426 g, and in East Sarajevo 248.5 g. These differences are highly significant. At both localities the highest mass of leaves was in the variant A_5 658.5 g; 327.3 g), and the smallest 179.6 g in the control variant (Bijeljina), or 213.4 g in variant A_2 in East Sarajevo.
The mass of the stem ranged from 150.2 grams to 403.1 grams. Using the "*Tverdaya Voda*" superapsorbent enriched with growth stimulants, microorganisms and microelements (403.1 g) and superapsorbent "*Tverdaya Voda*" enriched with microorganisms (384.6 g), potato plants were obtained which, compared to other variants, had a statistically significant increase in the weight of the stem, while the control variant compared with the use of different variants of the "*Tverdaya Voda*" superapsorbent had a statistically significant smallest mass of stem. A significant variation of the mass of the stem between the superapsorbent "*Tverdaya Voda*" (A_1), the superapsorbent "*Tverdaya Voda*" enriched with growth stimulants (A_2) and the "*Tverdaya Voda*" enriched with microelements (A_4) superapsorbent were determined. The mass of the stem in Bijeljina is 371.9 g, and in East Sarajevo 215.8 g. These differences are highly significant. At both localities, the highest mass of the stem was in variant A_5, and the smallest in the control variant.
Awareness of processes linked to the formation and growth of the surface area of leaves helps provide a clearer forecast about the productivity of photosynthesis. the total surface area of leaves defines and differentiates the efficiency of the agrotechnics applied, depending on the specific conditions of growing the plants. the formation of biomass is indirectly linked to the surface area of leaves which in turn participates in photosynthesis (Stoimenov and Kirkova, 2009). The leaf surface ranged from 0.3401 m^2 per plant (A_0) to 0.5529 m^2 per plant (A_5). These differences were statistically significant, as well as the differences between variant A_5 and other combinations of "*Tverdaya Voda*" superapsorbent, as well as the differences between enriched "*Tverdaya Voda*" superapsorbents and "*Tverdaya Voda*" superapsorbent. Potato cultivated in Bijeljina (0.5395 m^2 per plant) had a statistically significantly higher surface area compared to potatoes grown in East Sarajevo (0.3544 m^2 per plant). These differences are highly significant. At both localities, the highest mass of the stem was in

variant A_5, and the smallest in the control variant. At both localities, the largest leaf surface per plant was in variant A_5, and the smallest in the control variant.

Conclusion

The use of different variants of the "*Tverdaya Voda*" superapsorbent at both localities had a positive effect on the morphological properties of potatoes. The use of "*Tverdaya Voda*" superapsorbent, enriched with growth stimulators, microorganisms and microelements, especially stands out, where we had the best results for: plant height, number of stems, plant mass, leaf mass, stem weight and leaf surface per plant. Good results of the examined properties were found in the use of the "*Tverdaya Voda*" superapsorbent enriched with microorganisms (A_3), and the variant in which the superapsorbents were not used (the control variant) had poorer results for the examined properties. In the experiments carried out in Bijeljina, due to better agroecological conditions, better results were obtained for the examined potato properties, compared with those in East Sarajevo.

Abstract

Oat (*Avena* spp. L.) belongs to the family *Poaceae* and to the group of grasses (*Gramineae*). In human nutrition, it is mainly used as source of food fiber, β-D-glucan, carbohydrates and proteins. These ingredients are considered health benefits with positive effects for the consumer. The objective of the submitted study was to realize complete characterization of different varieties of oat among the genus *Avena* to find natural sources of beneficial components of the seed (contents of proteins, dietary fibre, β-D-glucan, lipids, starch…) for their next use in the breeding programmes and application in the food industry. Other aim of this work was to determine the effect of oat flour addition at the level of 5, 10, l5, 20, 25 and 30% to wheat flour on baking quality and to determine optimal portion of oat flour to by acceptable by consumers. The study involved determination of protein content, starch content, lipids content, β-D-glucan content and total dietary fibre content in wheat flour and two chosen oat genotypes (Valentin-hulled and Detvan-naked). Effects of oat flour on the flour properties, the rheological properties of dough by farinograph, the quality of final products and their sensory evaluation were determined. Oat is beneficial in nutritional value especially in total dietary fibre, β-D-glucan and lipids content compared to wheat seeds. Addition of oat flour up to 20% to wheat flour is acceptable for technological quality, rheology properties of dough and final products in overall flavour, appearance and texture for consumers.

Keywords: *Oat, nutrition value, β-D-glucan, composite flour, baking quality*

Introduction

Bread is an ideal functional food product, since it is an important part of our daily diet (Flander *et al*., 2007). The nutritional value of bread can be enhanced through the addition of a large number of flours of different origin, as reviewed by Mariotti *et al*. (2006) who also indicated that acceptable bread can be produced with a wheat flour substitution of up to 25–30%. Wheat (*Triticum aestivum* L.) is the most important crop for breadmaking due to its supreme baking performance compared to other cereals (Dewettnick *et al*., 2008). However, the interest in alternative grains is increasing due to the consumer demand for novel and healthy foods (Zhou *et al*., 1998). Oat (*Avena sativa*) is one of the most adventurous cereal grains for human diet since it contains naturally high amounts of valuable nutrients such as soluble fibres, proteins, unsaturated fatty acids, vitamins, minerals and phytochemicals (Flander *et al*., 2008). Integration of wheat flour with oat enhances the β-D-glucan content of bread and may have a significant effect on human health. Potential benefits of soluble dietary fibre include reduction of bowel transit time, reduction in the risk of colorectal cancer, lowering of serum blood cholesterol, regulation of glucose metabolism and promotion of the growth of beneficial gut microflora (Welch & McConnell, 2001; Brennan & Cleary, 2005; Mariotti *et al*., 2006). The effects of oats on dough properties and bread quality have been studied mainly on composite breads made from wheat and oats, with addition levels ranging from 10 to 51 % of oat bran or flour (Flander *et al*., 2007).

The aim of this study was make screening of oats genotypes for analyse nutrition composition and to analyse and compare technological parameters of composite flours (mixture of major component wheat flour and added out flours- minor crops known as donors of nutritional quality), rheological parameters of dough made from composite flours, and quality traits of final bakery products (breads).

Material and Methods

Analyses of oats genotypes. All oat genotypes were obtained from Research and Breeding station in Vígľaš-Pstruša, Slovakia. We made screening of this genotypes for analyse nutrition composition, 63 genotypes were hulled and 13 genotypes were naked. We determined protein content, lipids content, starch content, dietary fibre and β glucan content. Nitrogen content was determined using Dumas method (CNS-2000 Elemental Analyzer, LECO Corp., USA). Protein content was calculated as N x 6.25 for oat. Total dietary fibre content of oat wholemeals was determined using Total dietary fibre assay procedure, AOAC 991.43 (Megazyme, Ireland), β-D-glucan content was determined using Mixed-linkage Beta-glucan assay procedure, AOAC 995.16 (Megazyme, Ireland). The starch content was determined according to Ewers (STN EN ISO 10520, 2002), lipids by Soxhlet extraction (STN 46 1011–28, 1988).

Flour samples and composite flour formulations. Commercial common wheat flour was used and was obtained from PENAM Trnava mill. Oat seeds of two genotypes Valentin (hulled) and Detvan (naked) were obtained from research-breeding station Vígľaš-Pstruša. Oat seeds were grounded with hammer mill, using 1 mm sieve to wholemeal. Composite flours were prepared by mixing wheat flour and oat groats in proportion of 5%, 10%, 15%, 20%, 25% and 30%. Single basic wheat flour was used as control.

Flour analyses and rheological tests. Wet gluten and swelling of gluten were determined according to STN ISO 5531 (1994) (6-places mechanical washing of gluten), total ash content according to STN ISO 2171 (2006), sedimentation index, Zeleny test according to STN EN ISO 5529: 2008 (shaker, Brabender, Germany) and Falling number was determined according STN EN ISO 3093: 2010 (Falling Number 1800, Perten Instruments, Sweden). The rheological properties of doughs were determined using Brabander farinograph by standard procedure ICC No. 115/1 for wheat flour, (ICC 1992).

Baking test. A straight dough breadmaking process was performed. A basic bread formula, based on flour weight, was used: 250 g of flour, 12,5 g yeast, 3,75 g salt, 2,5 g sugar, 2,5 g lard and variable water on the basis of farinograph water absorption. Doughs were optimally mixed, fermented for 20 min near 32 °C ± 1 °C, divided into 2 the same pieces, hand-moulded and sheeted, put into proofer box for 25 min near 32 °C ± 1 °C. Bread was baked in an electric oven for 20 min at 230 °C.

Bread quality evaluation. After 2 h cooling at room temperature, loaves were weighed and loaf volume was measured by rapeseed displacement method. Loaf specific volume (ml/100g) was calculated. Breads were sensory evaluated (5 hedonic rating scale was used, score 1 means extreme dislikes, score 5 means extreme likes). Sensory evaluations of breads were conducted by 5 panellists. We evaluated form of product, colour of crust/crumb, taste of crust/crumb, aroma of crust/crumb, porosity of crumb, pliancy of crumb, firmness of crust/crumb, thickness of crust, tackiness of crumb. The maximal number of points in evaluation was 53.

Statistical analyses were performed by the software package Statgrafics plus for Windows. All determinated parameters were analyzed in two replications.

Results and Discussion

Average, minimum and maximum values of nutrition parameters (proteins, lipids, starch, dietary fibre and β-D-glucan) of oat genetic resources are presented in Table 1 (hulled oat genotypes) and in Table 2 (naked oat genotypes). For next bakery analyses we used genotypes

Valentin and Detvan. The oat flour from both genotypes (Valentin, Detvan) were used in composite flours as a donor of higher content of proteins, starch, lipids, total dietary fiber and β-D-glucan (Table 3). According author Butt *et al*. (2008) oat groat contains significant amounts of β-D-glucan that varies between 2.3% and 8.5%. According to Šterna *et al*. (2018) the concentration of protein in oat grain depending on genotype ranged from 10.4% to 14.9%, and the richest were grains of the variety 'Peppi', the concentration of lipids in oat grain was from 5.4% to 7.9%, β-D-glucan concentration in oat grains varied from 2.9% to 3.6%. In our set of hulled oat genotypes we observed protein content from 10,2% to 14,9% and in set of naked oat genotypes from 15.3% to 18.2%, β-D-glucan content of hulled oats was from 1,73% to 4,40% and of naked oats genotypes from 3,0% to 5.7%

Ash content of basic wheat flour was 0.52%. Ash content increased significantly ($P<0,05$) in wheat-oat flour continually (Table 4). The decreasing ratio of wheat in composite flour significantly ($P<0,05$) reduced the content of wet gluten (Table 4). This is related to the substitution of wheat proteins (gliadins and glutenins) competent to produce viscoelastic gluten by oat proteins which are unable to do this. The wet gluten content was lower than 26%, i.e. the value required by a relevant technical norm for standard bakery quality grade in flours with oat ratio >10%, respectively.

The swelling of gluten significantly ($P<0,05$) decreased at 10% ratio of oat flour, respectively. It may be concluded that each percent of added oat flour reduces swelling of gluten by approximately 1%. Sedimentation index was decreased significantly ($P<0,05$) with increasing ratio of oat flour, but only flour with oat ratio 30% had a lower sedimentation index than is the minimal value of 23 ml required by the relevant technical norm for food wheat (STN 46 1100–2, 2018).

$LSD_{0.05}$	0.023	1.462	1.134	0.706

SD - standart deviation, superscripts represent statistically significant differences at P<0.05

The falling number as the parameter of amylolytic activity of grain enzymatic complex increased significantly (P<0,05) by addition of ≥10% of both oat flours (Figure 1). We determined differences between oat genotypes. The genotype Detvan more increased values of falling number than Valentin.

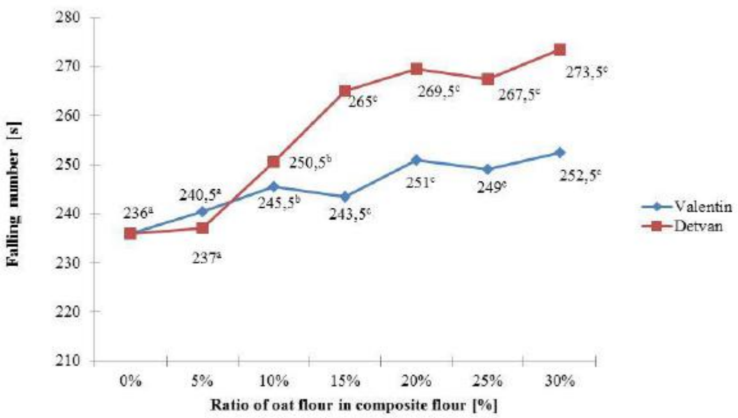

Figure 1. Falling number of composite flours

Farinograph parameters of wheat flour also strongly affect the content and type of proteins (Khatkar *et al*. 1996; Skendi *et al*. 2010). The farinograph parameters of created composite flours determined in our study are given in Table 5. Increased content of oat increased non-significantly (P<0,05) water absorption. With ratio 30 % oat flour was water absorption increased only about 1 or 2 %. Mariotti *et al*. (2006) reported similar effects for the addition 20 %, 30 % and 40 % oat flour. Values of dough development time and dough stability were significantly higher by composite flours than by control. The specific loaf volume in all composite flours decreased this parameter, additions 15 % and more, significantly (P<0,05) (Figure 2). The similar effect reported Mariotti *et al*. (2006).

Table 5. Rheological parameters of dough from composite flours wheat-oat

Composite oat flour	**Water absorption [%]**	**Dough developme nt time [min]**	**Dough stabilit y [min]**	**Dough softeni ng 10 min after test starting [BJ]**	**Dough softening 12 min after maximal consisten cy [BJ]**	**Farinogra ph quality number**
Basic wheat flour	56.2	1.7	2.7	75	82	34
Valentin 5%	56.1	1.9	6.3	49	73	76
Valentin 10%	56.6	5.0	6.2	50	99	80
Valentin 15%	56.9	5.0	4.3	49	96	76
Valentin 20%	57.4	4.5	3.4	51	95	69
Valentin 25%	57.9	4.9	4.8	31	83	88
Valentin 30%	58.4	5.5	7.5	16	81	117
Detvan 5%	56.6	1.7	6.1	45	73	74
Detvan 10%	56.7	6.0	7.4	38	104	89
Detvan 15%	57.3	5.5	6.6	40	111	85
Detvan 20%	56.8	5.8	6.1	38	113	90
Detvan 2 %	57.6	5.5	5.5	34	109	98
Detvan 30%	57.2	6.2	5.8	27	107	110

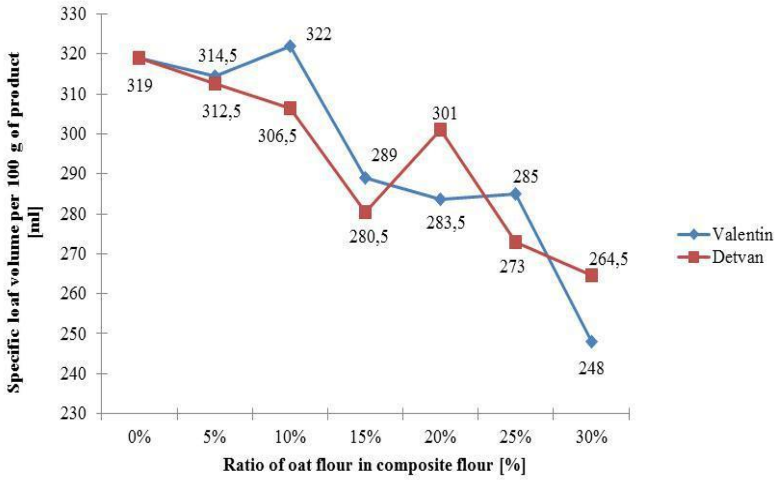

Figure. 2 Specific loaf volumes of berads from composite flours

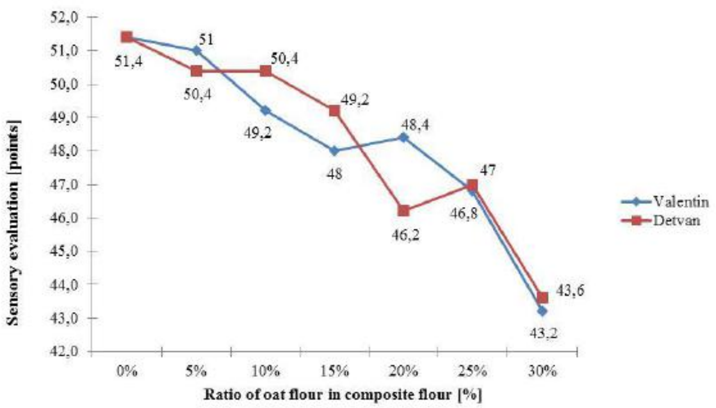

Figure.3 Sensory evaluation of breads from composite flours

Significantly differences in complex sensory parameters of wheat-oat loaves compared to the control were observed only after the ratio of oat was at least 25% when breads were less accepted by referees (Figure 3). The oat addition affected mainly quality of crumb, which was darker by genotype Detvan, with higher elasticity. The taste and aroma of breads changed positively, breads were very tastly, but only to 20%. Optimim addition of both oat flours is maximum 15 %. The optimum amount needed for the brown bread quality, which was improved not only in the crust colour and bread softness but also in the taste itself, was achieved by adding 10 % of oat flour (Gormley, Morrisey, 1999). The addition influences positively not only the sensoric properties and stronger taste but also structure and health benefit of the final product (Flander *et al*. 2007; Škrbić *et al*. 2009).

Conclusions

Flours of oat enhanced composite flours in the amount of starch, lipids, β-D-glucan and total dietary fiber in comparison with wheat flour. Additions of oat into composite flour increased ash content and decreased content and quality of gluten, decreased sedimentation index. The falling number was increased by both oat genotypes. Flours from oat changed parameters of dough by increasing water absorption, dough development time, and increasing dough stability. Specific volume of baked loaves were reduced in composite flours with increased content of oat, respectively. Breads containing oat flour were acceptable in sensory parameters up to the oat ratio of 20%.

Abstract

Butternut squash *(Cucurbita moschata* Duch. ex Poir.) is an annual plant of the genus *Cucurbita.* Its fruits are one of the most important crop-plants in traditional agricultural systems in the world and a source of biologically active components. This vegetable has been less grown in Slovakia so far. The aim of the work was to evaluate the influence of genotype on the physical and chemical properties, including carotenoids, vitamin C, and mineral contents of butternut squash in the conventional growing system under the field conditions at Slovak University of Agriculture in Nitra in 2018. Six cultivars of butternut squash (Liscia, Serpentine, Orange, UG 205 F1, Matilda F1, Waltham) were examined in experiment. The physical parameter analysis showed that the average weight of fruit was from 1.59 to 2.25 kg. The edible part of fruit was from 0.52 to 0.75. The fruits of the Orange variety had very unbalanced size, what may have negative impact on the marketing, especially in large commercial chains. The tested varieties are an important source of mineral substances, especially potassium, magnesium and calcium. The total carotenoids content in the pulp of fresh fruits ranged from 3.80 to 8.42 mg.100 g^{-1} FW. Its highest value was determined in case of Orange variety. The vitamin C content ranged in interval from 5.50 to 12.00 mg.100 g^{-1} FW.

Keywords: *butternut squash, variety, minerals, carotenoids, vitamin C*

Introduction

Man has been cultivating important agricultural crops since ancient times. Conventional and also fewer known fruits have represented in various fields of gastronomic, industrial and pharmaceutical spheres (Quintana *et al*., 2018). *Cucurbita moschata* is one of the crops, with crucial role in the agricultural systems of the world. The *Cucurbita* genus is known to be native to the area of central America (Welbaum, 2015). Currently, pumpkins are cultivated as a source of seeds, pumpkin oil (Pinke *et al.*, 2018), edible flowers and nutritionally valuable fruits. However, cultivation of *Cucurbita moschata* in Slovakia is only at development stage being cultivated in small areas of the southern parts of Slovak territory. Butternut squash is a significant crop in terms of the content of bioactive substances with antioxidant properties – vitamin C, vitamin E, carotenoids, polyphenol compounds – as well as B-complex and potassium, vitamins are appreciated by the consumer both raw and heat treated. It is suitable for storage, consumption in the fresh state or heat treatment thanks to its interesting sensory properties (Andrejiová *et al*., 2016). *Cucurbita moschata* is also known as a good source of carotenoids with decent antioxidant properties. The content of these bioactive substances in fresh fruits is variable, they differ from one species to another and can also be influenced by external factors – climate, nutrition, habitat, storage conditions, etc. (Sarah *et al*., 2018). From the nutritional point of view, the key substances in these fruits are mainly pectins, fiber, minerals (Zdunić *et al*., 2016), carotenoids, polyphenol compounds and vitamin C (Grassmann, 2005) are important for antioxidant activity. Gonzales *et al*. (2001) report that α-

carotene and β-carotene, which are precursors of vitamin A have been significantly represented by carotenoids identified in the fruit of pumpkin. From xanthophylls, lutein has been identified. Other carotenoids, such as phytofluene, ζ-carotene, neurosporin, violaxanthin, neoxanthine, flavoxanthine, have been reported to a lesser extent. Other authors also recall the presence of β-cryptoxanthine xanthophyll (Burri *et al*., 2016). The importance of carotenoids for humans is because of the provitamin activity and their antioxidant effect. Carotenoids have been proved to be able to deactivate reactive forms of oxygen, which in excess cause oxidative stress and negatively affecting the body. It is possible that carotenoids have the ability to inhibit the transformation and reproduction of cancer cells and also regulate the expression of genes playing an important role in the formation of certain types of cancer. Furthermore, this squash has been reported with antiinflammation, antibacterial, antidiabetic, antihypertensive and immunomodulation activities (Merhan, 2017; Bogacz-Radomska – Harasym, 2016).
The aim of this research was to evaluate the impact of the genotype on the selected physical and chemical parameters (vitamin C, total carotenoids, refractometric dry matter and the mineral content) of the fresh pulp of *Cucurbita moschata*.

Material and Methods

Experiment site
A field experiment was founded in 2018 in Botanical Garden of Slovak University of Agriculture (below BG SUA) under conventional system of cultivation. Before the experiment was established, a sample of soil was taken from the experimental site in the spring. An agrochemical analysis of the soil was carried out at the Department of Agrochemistry and Plant Nutrition of the Faculty of Agrobiology and Food Resources of the SUA (tab. 1).

Tab. 1 Agrochemical characteristics of the soil before the experiment

humus %	pH/KCl	Nutrients content in mg.kg^{-1} of soil					
		N	P	K	S	Ca	Mg
4,09 H	**6,98** N	**9,6 L**	**177,5 VH**	**615 VH**	**15,0 L**	**7300 VH**	**897,3 VH**

Explanatory notes: Nutrients content: L – low, H – high, VH – very high, pH: N – neutral

Based on the agrochemical analysis of the soil and the recommended normative for the cultivation of pumpkins depending on the production line in the given year, we applied nitrogen in the experimental area two weeks before the planned planting in the form of nitrogen fertilizer LAD (27% N) (60% of the recommended normative) and during vegetation the intense flowering and fruit formation were fertilized with LAD nitrogen fertilizer (27% N) (40% of the recommended normative), which was nitrogen fertilization at 150 kg N.ha $^{-1}$. Other macroelements have not been applied because their content in the soil has met the requirements for growing pumpkins.
A field experiment was founded on 11th of May 2017 from the direct sowing. We used 2.50 x 1.50 m row spacing in frame for every observed variety in 3 repeatings, which represents 2666 plants on 1 ha. Treatment of plants during the vegetation was carried out according to common agricultural techniques. The vegetation was maintained in non-weed condition by manual hoeing 2-3 times up to the stand and treated against the fungal diseases. Fruit harvesting was carried out gradually by picking in botanical ripeness on 10th September, 5th and 19th October.

Characteristics of used varieties

We used 4 varieties and 2 available hybrids of *Cucurbita moschata*: ˈLisciaˈ, ˈOrangeˈ, ˈSerpentineˈ, ˈWalthamˈ, ˈUG 205 F1ˈ, ˈMatilda F1ˈ. The supplier and the origin of the evaluated varieties of *Cucurbita moschata* are listed in tab.2

Tab. 2 Assortment of the evaluated varieties of Cucurbita moschata

Variety	Supplier	Origin
Liscia	**Semo a.s.**	**Czech republic**
Orange	**ZKI Vetőmag KFT**	**Hungary**
Waltham	**Hollar Seeds**	**USA**
Serpentine	**Semo a.s.**	**Czech republic**
UG 205 F1	**Unigen Seeds**	**USA**
Matilda F1	**Enza Zaden**	**Netherlands**

Physical parameters evaluation
We evaluated the physical parameters (fruit dimensions and fruit components weight) after each fruit harvesting period. The length was measured with a tape flexible meter along the curvature of the stalk from end to end (Fig. 1A). The diameter of the bulb was measured by placing the flex meter around the bulb of the squash (Fig. 1B). The diameter of the neck was determined around the thickening section at the end of the neck. Each squash samples and their pulp, shell and seed yield were weighted individually (Fig. 1C).

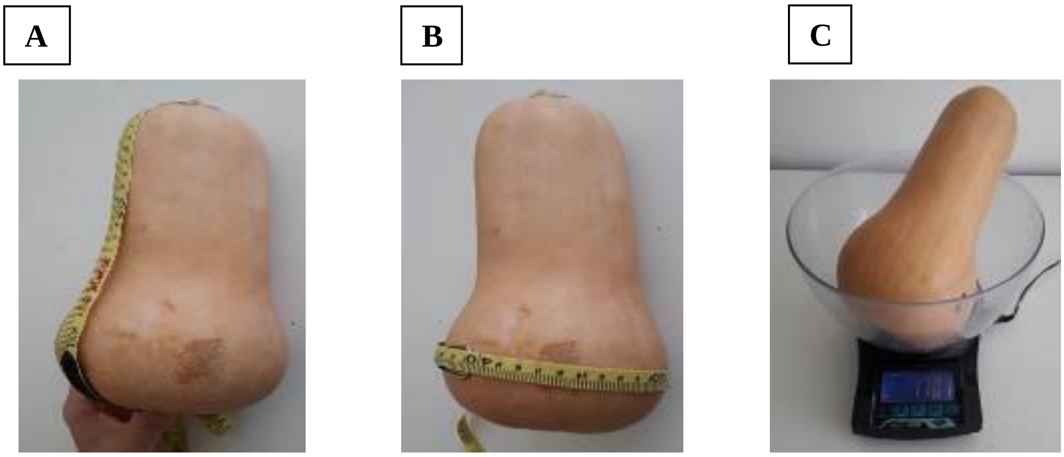

Fig. 1. Physical characterization of *Cucurbita moschata* fruits: external length (Fig. 1A), diameter of the bulb (Fig. 1B), fruit weight (Fig. 1C).

Laboratory analysis
For laboratory analysis were used only fresh fruits in full botanical maturity of all observed varieties of butternut squash. An average sample of 2 000 g was prepared from the harvested fruit yield. We homogenized the opposite two quarters of each sliced fruit within average sample and used it for the determination of total carotenoids and vitamin C content. Fresh fruit analysis was performed within 24 hours after the harvest.

Qualitative parameters

The qualitative parameters were estimated in laboratory of Department of vegetable production, SUA, in Nitra involving:

Total carotenoids estimation - Carotenoids were estimated by spectrophotometric measurement of substances absorbance in petroleum ether extract on spectrophotometer PHARO 100 at 450 nm wavelengths.

Ascorbic acid estimation (AA) - HPLC method of vitamin C content estimation was used for its quantity estimation with the help of liquid chromatograph with UV detector (HPLC fy VARIAN).

Mineral substances estimation – optical emission spectrometry with inductively bounded dual-mode plasma ICP-OES apparatus iCAP7600 (Thermo Scentific, USA).

Detectability Limits (LOD) and Quantitation Limits (LOQs) were calculated from BEC value (Background Equivalent Concentration) determined from the condition of the intensity of the analytical signal to the background intensity S/B = 1 (Thompsen, 2012).

Statistical analysis

The analysis of variance (ANOVA), the multifactor analysis of variance and the multiple Range test were done using the Statgraphic Centurion XVII (StatPoint Inc. USA).

Results and Discussion

The evaluation of the physical parameters of selected varieties of *Cucurbita moschata* is shown in Tables 3a, 3b. The largest external length of the fruit was found in the 'Serpentine' variety (80.66 cm), which has a cylindrical shape. Other squash varieties have a pear-shaped fruit and their average length ranged from 30.44 to 36.56 cm. The authors Jaeger de Carvalho *et al*. (2015) found that the average fruit weight was in the range of 1.46 kg to 7.82 kg when evaluating 20 genotypes of *Cucurbita moschata*. Based on the results of our experiments, we can conclude that the average weight of the fruit in the monitored varieties of the squashes at 2,666 plants per ha varied from 1.59 to 2.25 kg. The lowest variability of the fruits weight was found in the 'Waltham' variety. The edible part of the fruit ranged from 0.52 to 0.75. The fruits of the 'Orange' variety have very unbalanced size, which may have a negative impact on marketing, especially in large commercial chains. Jacobo-Valenzuela *et al*. (2011) indicate a higher average weight for the fruit of *Cucurbita moschata* of 3.25 kg.

Tab. 3a Physical parameters of *Cucurbita moschata*

Variety	External length (cm)	Bulb diameter (cm)	Neck diameter (cm)	Fruit weight (kg)
Liscia	32.78 ± 2.70	38.54 ± 2.06	26.28 ± 4.22	1.59 ± 0.35
Orange	36.56 ± 4.04	42.18 ± 2.72	25.12 ± 3.16	1.91 ± 0.46
Waltham	30.44 ± 2.85	37.03 ± 3.27	25.50 ± 3.32	1.32 ± 0.20
Serpentine	80.66 ± 8.08	33.36 ± 3.95	15.48 ± 1.92	1.62 ± 0.40
UG 205 F1	33.08 ± 3.26	38.60 ± 8.47	30.34 ± 3.62	1.87 ± 0.38
Matilda F1	34.52 ± 2.66	44.62 ± 4.24	32.60 ± 3.23	2.25 ± 0.41

Tab. 3b Physical parameters of *Cucurbita moschata* - structural components of fruit (%)

Variety	Pulp	Seed	Placenta	Shell
Liscia	70.74	2.21	4.47	22.58
Orange	70.68	2.54	3.91	19.58
Waltham	67.64	3.56	3.93	24.87

Tab. 5 Mineral content in the pulp of *Cucurbita moschata* (mg.kg^{-1})

Variety	Ca	Na	K	Fe	Mg	Zn	Cu	Mn
Liscia	1654.9	53.6	13263.5	7.44	408.56	3.32	1.73	0.67
Orange	1084.1	52.7	11473.5	6.88	257.24	3.86	1.32	0.57
Waltham	625.1	56.5	14467.6	10.28	459.27	6.90	2.16	1.20
Serpentine	2682.7	58.1	20913.0	8.17	615.51	3.50	1.50	0.50
UG 205 F1	1303.1	52.7	12423.7	9.20	447.15	5.40	1.52	1.52
Matilda F1	1174.6	63.0	9358.9	5.60	466.88	3.45	1.28	0.43

According to several authors, the content of total carotenoids in the pulp of the fruits is very variable and ranges from 2.34 to 25.45 mg.100 g^{-1} FW (Pandey *et al*., 2003; Tamer *et al*., 2010; Jacobo-Valenzuela *et al*., 2011). In our work, the total carotenoids content in the pulp of fresh fruits ranged from 3.80 to 8.42 mg.100 g^{-1} FW. Its highest value was determined in case of 'Orange' variety. Carvalho *et al*. (2015) examined 20 different genotypes of *Cucurbita moschata*, while the total carotenoid content in the fresh matter ranged from 12.46 to 69.9 mg.100 g^{-1}. Jacobo-Valenzuela *et al*. (2011) states that in the pulp of *Cucurbita moschata*

fruit, there is 2.67 mg.100g^{-1} and in the shell 0.33 mg.100g^{-1} of β-carotene. The vitamin C content ranged in interval from 5.50 to 12.00 mg.100 g^{-1} FW. Pandey *et al*. (2003) report that the content of vitamin C in the evaluated assortment of *Cucurbita moschata* was in the range of 1.53 to 6.74 mg.100g^{-1} fresh matter. On the other hand, Andrejiová *et al*. (2016) report the range of interval from 13.88 to 18.69 mg.100g^{-1}.
The tested varieties of *Cucurbita moschata* are an important source of mineral substances, especially potassium, magnesium and calcium as well. Priori *et al*. (2017) indicate in their research, that in the pulp of these fruits are present minerals in following amount: potassium ranged from 33.97 to 94.57 mg.kg$^{-1,}$ magnesium 0.86 to 2.84 g.kg^{-1} and calcium 2.26 to 7.49 g.kg^{-1}.

Conclusion

The butternut squash (*Cucurbita moschata* Duch. ex Poir.) is consumed in small rate in Slovak Republic. In the world, especially in South America, it is one of the crops with a long history of cultivation due to the good climatic conditions of the locations, high biological potential of the crop itself and application in nutrition. The aim of this research was to evaluate the impact of the genotype on the selected physical and chemical parameters of the fresh pulp of *Cucurbita moschata.* In the experiment there was observed 6 butternut squash varieties. The total carotenoids content in the pulp of fresh fruits was varied in the interval from 3.80 to 8.42 mg.100 g^{-1} FW. The vitamin C content ranged in interval from 5.50 to 12.00 mg.100 g^{-1} FW. Based on the evaluation of the average fruit weight and the structural components of the fruit for direct fruit sales, we recommend the following varieties: 'Liscia', 'Orange', 'Waltham' and 'UG 205 F1', for which the average weight of the fruits during the reference period was less than 2 kg. The ´Matilda F1´ variety has large fruits, with average weight 2.4 kg and the fruits of the ´Serpentine´ fruits have very strong curvature (average 80.66 cm external lenght).

Acknowledgement

The work was supported by VEGA project No. 1/0087/17: Lesser-known species of horticultural crops as potential sources for production of food with increased content of chemoprotective compounds.

Abstract

Sweet cherry (Prunus avium L.) is one of the major fruit species grown in the Ohrid region. The assortment is primarily based on the indigenous genotype of 'Ohridska Dolga Šiška', which is characterized by very useful biological and agronomic properties that provide high economic value, and which is surrounded with sporadic trees from the other local genotypes for which the growers believe that they are good pollenizers. As the origin of these old genotypes is uncertain, and cases of homonyms or synonyms might occur, a reliable identification is required. Since sweet cherry exhibits gametophytic self-incompatibility, controlled by the multi-allelic S-locus that prevents self-fertilisation, determination of S-alleles of indigenous genotypes is an important step in molecular characterization that is also of enormous significance for growers and breeders to choose appropriate pollenizers in the orchard aiming to the efficient production of fruits and planning crosses in developing new cultivars. The paper presents the results of identification of S-alleles and incompatibility group in eight Macedonian indigenous sweet cherry genotypes [four genotypes of 'Ohridska Dolga Šiška' (ODŠ), two genotypes of 'Ohridska Crvena Krcka' (OCK), 'Ohridska Brza' and 'Ohridska Crna'] collected in the Ohrid region. The use of the polymerase chain reaction (PCR) with consensus primers for the second introns (PaConsII-F and PaConsII-R) of S-RNase and allele-specific primers revealed the following S-allelic constitutions in the assessed genotypes: S2S4 ('OCK-1'), S3S9 ('Ohridska Brza'), S3S12 ('ODŠ-O1', 'ODŠ-O2', 'ODŠ-S1' and 'ODŠ-S2') and S4Sx ('OCK-2' and 'Ohridska Crna'). Based on the obtained S-allelic constitutions, the assessed genotypes have been assigned to incompatibility groups XIII, XVI and XXII.

Keywords: *Prunus avium, autochthonous genotype, S-allelic constitution, incompatibility group.*

Introduction

The Balkan Peninsula is characterized by a large number of indigenous genotypes of many fruit species, which are adapted to difficult and different environments and potentially provided with rich and useful genetic variability. Gjamovski *et al.* (2016a) reported that the genotypes with useful attributes can extend the list of cultivars with a potential to be used as parents in breeding programmes and can also be an important factor for revitalizing major Macedonian fruit growing regions. The Ohrid region is a typical area for sweet cherry growing. In this region, sweet cherries are generally grown in the traditional way, often as isolated trees or in small orchards, and assortment is primarily based on the indigenous genotypes, mainly 'Ohridska Dolga Šiška', which is characterized by high quality fruits (Gjamovski *et al.*, 2016a). Other study of Gjamovski *et al.* (2016b) pointed out that this indigenous genotype showed the highest fruit weight and higher values of fruit-quality parameters among nine commercially important sweet cherry cultivars evaluated in the Ohrid region. A recurrent problem that occurs in the collection and conservation of indigenous

sweet cherry genotypes worldwide is the frequent case of different names for a genotype and different genotypes with the same name.
Apart from very few exceptions, sweet cherry is allogamous and exhibits gametophytic self-incompatibility controlled by the multiallelic *S*-locus with two linked genes, *S-RNase* and *SFB* expressed in the style and the pollen, respectively (Bošković and Tobutt, 1996; Yamane *et al.*, 2003). Therefore, only pollen tubes carrying an *S*-haplotype differing from the two stylar *S*-haplotypes can successfully complete fertilization. The use of the consensus and allele-specific PCR-based methods has enabled the identification of 25 *S*-alleles in sweet cherry (Vaughan et al. 2008). This polymorphism allowed identification of 47 incompatibility groups (IGs), a group of '0' of unique *S*-genotypes and a group of self-compatible cultivars (Schuster, 2012). Due to the high polymorphism, the *S*-locus has also been used as a genetic marker for genotyping and identification of domestic and foreign sweet cherry cultivars at Fruit Research Institute, Čačak (Marić and Radičević, 2014; Radičević *et al.*, 2015).
Since Ohrid region has a distinctive germplasm of sweet cherry that need to be well studied, reliable phenotyping and genotyping are required. Therefore, this study was aimed to identify the *S*-alleles of indigenous sweet cherry genotypes collected in the Ohrid region, as an important step in molecular characterization aiming to assign the genotypes to accurate IGs for planning parental combinations in further breeding programmes and for orchards management by choosing the suitable pollenizer.

Material and Methods

Eight indigenous sweet cherry genotypes, including four genotypes of 'Ohridska Dolga Šiška' ('ODŠ-O1', 'ODŠ-O2', 'ODŠ-S1' and 'ODŠ-S2'), two genotypes of 'Ohridska Crvena Krcka' ('OCK-1' and 'OCK-2'), 'Ohridska Brza' and 'Ohridska Crna', were sampled from the Ohrid region which is located in the south-western part of the Republic of Macedonia at an altitude of 690 m and coordinates 41°7'1"N and 20°48'6"E. Young leaves of the selected genotypes were collected, frozen in liquid nitrogen and stored at –80°C prior to DNA isolation. Frozen leaves were ground in Mixer Mill MM 400 (Retsch GmbH, Haan, Federal Republic of Germany) and extraction of genomic DNA was based on the method reported by Doyle and Doyle (1987), with the addition of β-mercaptoethanol (1%) and polyvinylpyrrolidone (2% PVP 40) in the extraction buffer. DNA samples were dissolved in TE buffer (10 mM Tris pH 8.0 and 1 mM EDTA) and kept at –20°C until using.
Identification of the *S*-alleles in assessed sweet cherry genotypes was performed according to Sonneveld *et al*. (2001, 2003). The PCRs were carried out by using the consensus primer pairs specific for the second introns of the *S-RNase* (PaConsII-F + -R, Sonneveld *et al*., 2003) and the allele-specific primers for S_2, S_3, S_4, S_9 and S_{12} (Sonneveld *et al*., 2001, 2003). For these alleles, the following annealing temperatures were used: 60°C for S_2, 66°C for S_3, 63°C for S_4, 61°C for S_9 and 62°C for S_{12}. Sweet cherry cultivars with known *S*-allelic constitutions were used as standards.
PCR products obtained with the consensus primers specific for the second introns of *S-RNase* were separated by electrophoresis in a 2% agarose gel (70 V/cm for 4 h), whereas products of allele-specific PCRs were separated by electrophoresis in a 1.5% agarose gel (70 V for 2–3 h). Visualization of PCR products was performed by ethidium bromide staining and taking photographs under ultraviolet light in BIO-PRINT-1500/26M imaging system (Vilber Lourmat, Collégien, French Republic). For sizing of DNA fragments, 1 Kb plus DNA ladder (Invitrogen, Groningen, the Netherlands) was used.

Results and Discussion

The identification of *S*-alleles of the assessed indigenous sweet cherry genotypes from the Ohrid region was conducted in two steps, i.e. the second introns of *S-RNase* was amplified using consensus primers in the first step, followed by the next step in which the allele-specific primers were used. The amplification of the second intron of *S-RNase* with consensus primers PaConsII-F + -R revealed two PCR products, which corresponded to *S*-alleles of the assessed sweet cherry genotypes, except for genotypes 'OCK-2' and 'Ohridska Crna'. The size of PCR product for the second intron ranged from ~800 (S_9 or S_{10} allele) to ~2,200 bp (S_2 or S_7 allele) (Figure 1). As reported in earlier studies (Sonneveld *et al*., 2003, Schuster *et al*., 2007, Ipek *et al*., 2011), small size differences were found when using consensus primers for the amplification of the second intron of the S_1 and S_3, as well as S_2 and S_7 alleles. Also due to the similar size of PCR products of the alleles S_9 and S_{10}, an additional analysis with allele-specific primers was required for discrimination of these alleles on an agarose gel, particularly in genotypes in which *S*-allelic constitutions have not been published to date. In order to confirm *S*-allelic constitutions of the assessed sweet cherry genotypes obtained by consensus primers, the genomic fragment of *S-RNase* was amplified using the specific primers for the S_1, S_2, S_3, S_4, S_7, S_9, S_{10} and S_{12} alleles (Table 1). The *S*-allelic constitution of each genotype was determined upon integrating the obtained results with the consensus and the allele-specific primers.

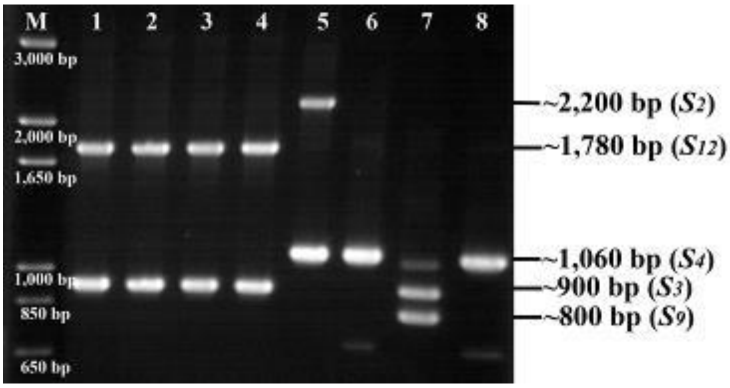

Figure 1. PCR products of the *S-RNase* amplified fragment obtained with consensus primers for the second intron in the indigenous sweet cherry genotypes: 1 – 'ODŠ-O1'; 2 – 'ODŠ-O2'; 3 – 'ODŠ-S1'; 4 – 'ODŠ-S2'; 5 – 'OCK-1'; 6 – 'OCK-2'; 7 – 'Ohridska Brza'; 8 – 'Ohridska Crna'; 1Kb plus DNA ladder (M).

The DNA fragment of ~640 bp corresponding to S_2 allele was identified in 'OCK-1' (Figure 2a). Use of S_3 allele-specific primers enabled amplification of fragment of ~960 bp in 'ODŠ-O1', 'ODŠ-O2', 'ODŠ-S1', 'ODŠ-S2' and 'Ohridska Brza' (Figure 2b). In 'OCK-1', 'OCK-2' and 'Ohridska Crna', the PCR product of ~820 bp corresponding to S_4 allele was obtained (Figure 2c). The PCR product of ~495 bp corresponded to allele S_9 and was identified in 'Ohridska Brza' (Figure 2d). Similarity in product size for S_1 and S_3, S_2 and S_7, S_9 and S_{10} alleles required additional PCRs with primers specific for S_1, S_7 and S_{10} alleles. The absence of amplification with S_1, S_7 and S_{10} allele-specific primers was another confirmation that S_3, S_2 and S_9 are present in abovementioned genotypes. In four genotypes – 'ODŠ-O1', 'ODŠ-O2', 'ODŠ-S1' and 'ODŠ-S2', the PCR product of ~562 bp corresponding to S_{12} allele was obtained (Figure 2e). The size of PCR products for identified *S*-alleles in indigenous genotypes were in agreement with results reported by Sonneveld et al. (2001, 2003).

The S-allelic constitutions for eight indigenous sweet cherry genotypes – 'ODŠ-O1' (S_3S_{12}), 'ODŠ-O2' (S_3S_{12}), 'ODŠ-S1' (S_3S_{12}), 'ODŠ-S2' (S_3S_{12}), 'OCK-1' (S_2S_4), 'OCK-2' (S_4S_x), 'Ohridska Brza' (S_3S_9) and 'Ohridska Crna' (S_4S_x) are published in this paper for the first time. Based on identified *S*-alleles, the genotypes were assigned to their corresponding IGs, previously reported by Schuster (2012). Therefore, the three following IGs (Table 2) were determined: XIII ('OCK-1'), XVI ('Ohridska Brza') and XXII ('ODŠ-O1', 'ODŠ-O2', 'ODŠ-S1' and 'ODŠ-S2').

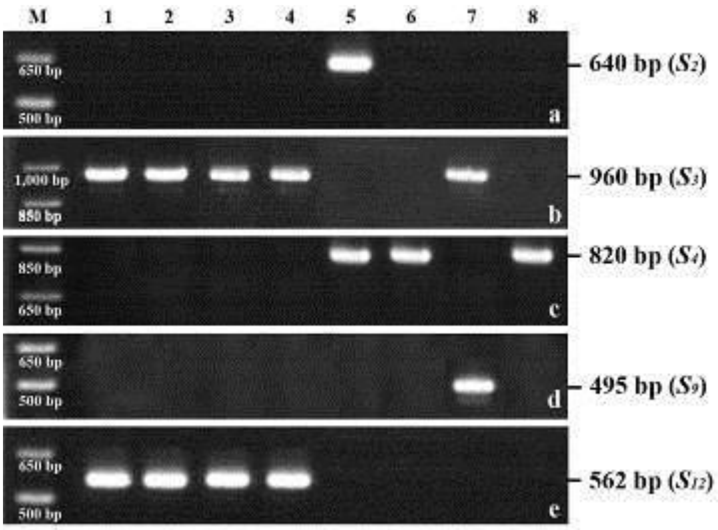

Figure 2. PCR products of the *S-RNase* amplified fragment obtained with primers specific for alleles S_2 (a), S_3 (b), S_4 (c), S_9 (d) and S_{12} (e) in the indigenous sweet cherry genotypes: 1 – 'ODŠ-O1'; 2 – 'ODŠ-O2'; 3 – 'ODŠ-S1'; 4 – 'ODŠ-S2'; 5 – 'OCK-1'; 6 – 'OCK-2'; 7 – 'Ohridska Brza'; 8 – 'Ohridska Crna'; 1Kb plus DNA ladder (M).

Table 1. Identification of *S-RNase* alleles in the indigenous sweet cherry genotypes with consensus and allele-specific primers.

Genotype	Results with consensus primer for the second intron		Amplification with allele-specific primers							
	Allele 1	Allele 2	S_1	S_2	S_3	S_4	S_7	S_9	S_{10}	S_{12}
'ODŠ-O1'	S_1 or S_3	S_{12}	–		+					+
'ODŠ-O2'	S_1 or S_3	S_{12}	–		+					+
'ODŠ-S1'	S_1 or S_3	S_{12}	–		+					+
'ODŠ-S2'	S_1 or S_3	S_{12}	–		+					+
'OCK-1'	S_2 or S_7	S_4		+		+	–			
'OCK-2'	S_4	/				+				
'Ohridska Brza'	S_1 or S_3	S_9	–		+			+	–	
'Ohridska Crna'	S_4	/				+				

The genotypes 'OCK-2' and 'Ohridska Crna', gave a single band in the S_4 position with consensus primers for the second intron of *S-RNase*, while the second allele is still unknown. In general, a single band on the agarose gel could mean either that the two alleles have introns of the same size, or that the second allele is not amplified because the primers do not match the sequence of that allele. Additionally, amplification of *S-RNase* with consensus primers in both genotypes showed weak band of ~650 bp, for which is unknown whether it represents *S* allele or a secondary band. Cloning and sequencing of the DNA fragments will provide their further characterization and possible identification of the second allele in these genotypes.

Table 2. *S*-allelic constitution and incompatibility group of the assessed sweet cherry genotypes.

Genotype	*S*-allelic constitution	Incompatibility group
'ODŠ-O1'	S_3S_{12}	XXII
'ODŠ-O2'	S_3S_{12}	XXII
'ODŠ-S1'	S_3S_{12}	XXII
'ODŠ-S2'	S_3S_{12}	XXII
'OCK-1'	S_2S_4	XIII
'OCK-2'	S_4S_x	/
'Ohridska Brza'	S_3S_9	XVI
'Ohridska Crna'	S_4S_x	/

Based on our current knowledge, some *S*-alleles are more frequent in some regions and certain alleles are specific to a particular geographic region. Tobutt *et al*. (2004) and Lisek *et al*. (2015) reported a relatively higher frequency of occurrence (> 20%) of alleles S_1 and S_3 in 247 cultivars of different origins, as well as for S_3, S_1 and S_4 in cultivars of Central and Eastern Europe, while the S_9 allele occurred with similar frequency (about 6%). Cachi and Wünsch (2014) showed that alleles S_3 and S_6 are highly frequent all over Europe. In each of four 'Ohridska Dolga Šiška' genotypes, S_3S_{12} allelic constitution was detected and based on it, the genotypes were assigned to IG XXII. Schuster (2012) reported that XXII represents an example of group with known cultivars like 'Schneiders Spate Knorpelkirsche', 'Nasenkirsche', 'Nordwunder', 'Germersdorfi', 'Noire de Meched', 'Ziraat 0900' etc., for which it has not yet been proven if they are different genotypes or only synonyms. Therefore, Macedonian 'Ohridska Dolga Šiška' genotypes also require further genotyping with a set of highly polymorphic microsatellites (SSRs) spanning the whole genome. In order to ensure successful cross-pollination and satisfactory fruit yield in commercial orchards, Radičević *et al*. (2015) reported that cross-compatible cultivars with different *S*-genotypes that flower simultaneously are needed to plant together. From this point of view and on the basis of the results obtained in this work, as well as data stated by Gjamovski *et al*., (2016a) regarding flowering phenophase of this material, some indigenous genotypes are cross-compatible with 'Ohridska Dolga Šiška' genotypes and can be recommended as potentially suitable pollenizers.

Conclusions

This study provides valuable insight into the *S*-allelic constitutions of eight Macedonian indigenous sweet cherry genotypes, as an essential precondition for effective pollination and fertilization. Among the assessed genotypes, 'OCK-1', 'OCK-2' and 'Ohridska Crna' can be potentially suitable pollenizers for 'Ohridska Dolga Šiška' genotypes. Knowledge about the *S*-genotype of indigenous sweet cherries is very important for breeders and growers, as well as for conducting further experiments in order to study other reproductive characteristics of these genotypes.

Abstract

The purpose of the present research was to improve the growth of tomato plants cultivated on mattresses with perlite in greenhouse conditions using various dilutions of horse urine in nutrient solution and to increase plant resistance to pathogenic fungi mediated by the development of microbial antagonists. In the study it has been used a control variant (non-treated) and two experimental variants treated with concentrations of 4ml/l and 6ml/l horse urine. The most significant effect with the highest plants and early production was registered for the variant with 4ml/l horse urine. Microbial density in perlite estimated by plate dilution method revealed high counts of heterotrophic aerobic bacteria and microscopic fungi. Taxonomic identification carried out by morphologic criteria revealed 7 to 9 bacteria species dominated by the development of *Pseudomonas fluorescens* known as an efficient antagonist for plant potential pathogenic fungi, especially from genus *Fusarium* and 8 to 9 fungal species, generally ubiquitous (from genera *Penicillium, Acremonium, Aspergillus, Fusarium, Cladosporium*) and with high enzymatic abilities for degrading various sources of nutrients (especially cellulose). The variant with 4ml/l horse urine proved to induce the best growth of tomato plants and the most equilibrate bacterial and fungal microflora, able to sustain plant health by the biological control of pathogens mediated by antagonistic fluorescent pseudomonads and actinomycetes.

Keywords: *tomato, horse urine, plant growth, Pseudomonas fluorescens, microbial antagonists*

Introduction

The horse urine contains important quantities of nutrients and because of their high amounts they must be diluted with water or solid matters. Urine boasts a N-P-K ratio of 10:1:4 and few trace elements. When not used properly, it can be a source of pollution for environment, especially for surface waters due to the contents in nitrogen, phosphorus and carbon (organic matter). Recent studies reported horse urine as safe fertilizer used for improving the growth of horticultural plants (cabbage, tomatoes and cucumbers) and microbial activity. Research of metabolites produced by microorganisms revealed the inhibitory role on the plant pathogenic bacteria and fungi. Fluorescent species of *Pseudomonas, Bacillus subtilis* and certain actinomycetes are recognized as antagonists able to produce various metabolites with antimicrobial action (Grosu et al., 2014). The development of species *Fusarium oxysporum* with antagonistic activity against various plant pathogens was stimulated by the fertilization with manure as compared with non-fertilized soil and was positively influenced by root exudates produced by tomato or lettuce plants (Papacostea, 1976). The aim of the present research was to improve the growth of tomato plants cultivated on mattresses with perlite in greenhouse conditions using various dilutions of horse urine in nutrient solution and to increase plant resistance to pathogenic fungi mediated by the development of microbial antagonists.

Materials and methods

Test plant: Tomato plants (*Solanum lycopersicum* L.) cultivar Cindrel, indeterminate type, with excellent cold tolerance, early maturity and fruits with 100-120 g weight were cultivated on mattresses with perlite in experiment under controlled conditions. Research has been conducted in greenhouse of HORTINVEST-Research Center for Studies of Food Quality and Agricultural Products, from University of Agronomic Sciences and Veterinary Medicine – Bucharest, Faculty of Horticulture, during summer 2018.

Experimental variants: a control variant (non-treated) and two experimental variants treated with different concentrations of horse urine, respectively 4ml/l and 6 ml/l horse urine. The horse urine used was collected from animals aged 3 years. Analyzes were made regarding the chemical composition of the urine. It contained 1.23% nitrogen, 0.03% phosphorus and 1.6% potassium.

Plants height (cm) was measured and **early production** (kilograms/plant) accumulated after 120 days from planting was determined by weighing tomato plants from experimental variants with horse urine solutions and from the control.

Microbiological analysis: Substrate samples from the control and variants with 4ml/l and 6ml/l horse urine horse urine were analysed by dilution plate method for the number and composition of heterotrophic bacteria and fungi communities (Dumitru & Manea, 2011). Microorganisms developed on culture media, respectively Nutrient Agar (NA) for bacteria and potato-dextrose-agar (PDA) for fungi, after incubation in the dark at 25°C were counted and identified according to specific determinative manuals for bacteria (Bergey & Holt, 1994) and for fungi (Watanabe, 2002). Microbial density was reported per gram of dry soil (oven-dried soil at 105°C for 24 h). All data represent the average value of triplicate analyses.

Results and discussion

Plants growth parameters from the variants treated with both concentrations of horse urine were positively influenced as compared to non treated control. The highest plants after 120 days from planting grew at the variant treated with 4ml/l horse urine (Figure 1.a). Early production of tomatoes was similar in both variants with horse urine but higher than in non-treated control (Figure 1.b).

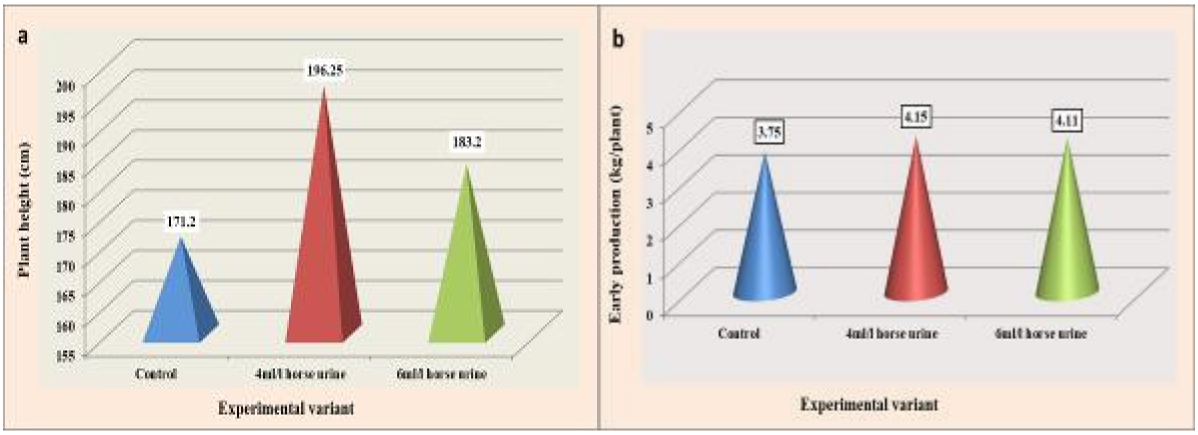

Figure 1. The influence of application of horse urine on the height (a) and early production (b) of tomato plants

The results of microbiological analysis of substrate sampled from mattresses under tomato plants consist of total counts and taxonomic composition of bacterial and fungal communities for control and variants with perlite + 4ml/l horse urine and perlite + 6ml/l horse urine. From the quantitative point of view, the values of bacteria density in analysed samples were considered to be high, especially for Control and the variant with perlite + 6ml/l horse urine and twice lower values (19.466 x 10^6 viable cells x g^{-1} dry soil**)** for the variant with perlite + 4ml/l horse urine (Table 1). Fungal counts from samples presented very high values as compared with values usually registered in soil samples. It was noticed the tendency of equilibration of fungal populations by reducing total counts when horse urine was aded in doses of 4ml/l and 6ml/l as compared with nontreated control.

Table 1. Effect of horse urine solutions on microbial counts

Experimental variant	**Fungal counts** (x 10^3 cfus x g^{-1} dry soil)	**Bacteria counts** (x 10^6 viable cells x g^{-1} dry soil)
Perlite-Non-treated Control	750.879a*	45.230a
Perlite+4ml/l horse urine	495.520b	19.466c
Perlite+6ml/l horse urine	519.325b	41.337b

***** Values in a column followed by the same letter are not significantly different for $P < 0.05$ (Student test)

Microbial communities from soil with perlite and horse urine included 7 to 9 species of heterotrophyc bacteria and actinomycetes identified on Nutrient Agar (NA) medium (Table 2).

Table 2. Taxonomic composition of bacterial microflora

Experimental variant	**No. of species** (S)	**Bacterial Microflora** (Taxonomic Composition)
Perlite-Non-treated Control	11	***Pseudomonas fluorescens, Bacillus sphaericus, Arthrobacter oxydans, Bacillus circulans, Pseudomonas aeruginosa, Flavobacterium sp., Bacillus megaterium, Sarcina ureae, Micrococcus sp.*** Actinomycetes Series Griseus and Albus
Perlite+4ml/l horse urine	**7**	***Pseudomonas fluorescens, Arthrobacter oxydans, Pseudomonas aeruginosa, Arthrobacter citreus, Bacillus circulans, Arthrobacter simplex, Bacillus subtilis,*** Actinomycetes Series Fuscus
Perlite+6ml/l horse urine	8	***Pseudomonas fluorescens, Pseudomonas sp., Micrococcus sp., Bacillus circulans, Bacillus subtilis, Sarcina ureae, Bacillus mesentericus*** Actinomycetes Series Albus

Analysis of species composition of bacterial communities revealed the dominance of fluorescent (*Pseudomonas fluorescens*, producing over 75 metabolites with antimicrobial action) and non fluorescent representatives of the genus *Pseudomonas*, (specific for improving conditions in plant rhizosphere, able to use sugars by oxidative pathway and to reduce nitrates from easily degradable organic materials), accompanied by bacillaceae**,** actinomycetes from Series Albus, Fuscus and Griseus or by species of the genus *Arthrobacter* (Figures 2 - 3). The genus *Flavobacterium*, known to be well developed in substrates with conditions of high humidity, was identified in non treated control, as well as *Sarcina ureae*, more abundant in the substrate from the variant with perlite and 6ml/l horse urine.

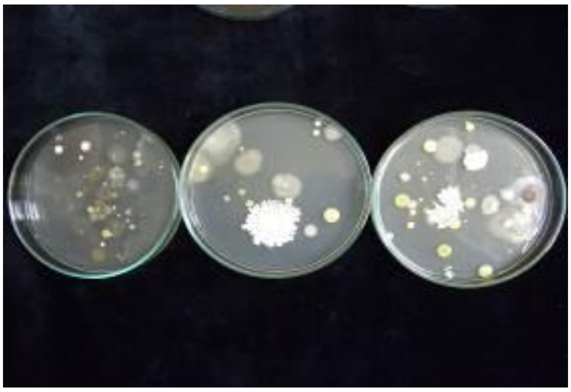

Figure 2. The bacterial microflora in experimental variants
(NA medium, 7 days)

Figure 3. Detail with bacteria in the variant with 6ml/l horse urine (NA medium, 7 days)

The results of taxonomic identification revealed that the fungal coenoses were composed by 8 to 9 species belonging to ubiquitous genera *Penicillium, Acremonium, Aspergillus, Fusarium, Cladosporium* (Figure 4 and Table 3).

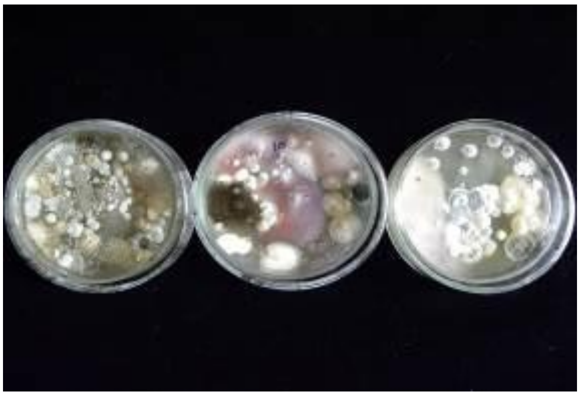

Figure 4. Fungal microflora in experimental variants (PDA medium, 7 days)

Table 3. Taxonomic composition of fungal microflora

Experimental variant	**No. of species** (S)	**Fungal Microflora** (Taxonomic Composition)
Perlite-Non-treated Control	**9**	***Penicillium chrysogenum, Acremonium charticola, Geotrichum candidum, Acremonium strictum, Aspergillus terreus, Cladosporium herbarum, Aspergillus fumigatus, Fusarium verticillioides, Penicillium brevicompactum***
Perlite+4ml/l horse urine	**9**	***Penicillium griseofulvum, Acremonium strictum, Fusarium verticillioides, Geotrichum candidum, Aspergillus fumigatus, Aspergillus terreus, Cladosporium cladosporioides, Aspergillus sydowi, Aspergillus niger***
Perlite+6ml/l horse urine	**8**	***Acremonium strictum, Penicillium aurantiogriseum, Acremonium charticola, Penicillium sp., Cladosporium cladosporioides, Fusarium verticillioides, Aspergillus sydowi, Verticillium sp.***

Many of these species identified are known to possess high abilities for enzymatic degradation of various cellulosic substrates and their utilization as carbon sources in own metabolism. Species *Geotrichum candidum*, with simple morphology, as well as *Aspergillus fumigatus* typical for fungal communities in rhizosphere of cultivated plants were identified in control and in the variant with 4ml/l horse urine but not in the variant with 6ml/l horse urine.The results from the present research showed the presence of microbial species able to produce metabolites with antibiotic and antifungal action, such as: *Pseudomonas fluorescens*, bacillaceae, actinomycetes, *Fusarium oxysporum, Aspergillus terreus, Aspergillus sydowi, Penicillium chrysogenum* in samples from the variants with horse urine and are in concordance with data from experiments demonstrating the beneficial role of various natural sources of nitrogen on the development of species that exert biological control of pathogens by metabolites with antimicrobial properties. Literature cites certain species from bacterial genera *Bacillus*, *Pseudomonas*, especially fluorescent pseudomonads (Attitalla et al., 2001; Redouan et al., 2018), certain lactic acid bacteria (Magnusson et al., 2003; Matei et al., 2015), actinomycetes (Mazzola, 2007) and fungal species of genera *Trichoderma* (Cornea et al., 2009), *Gliocladium*, non-pathogenic *Fusarium* (Weller et al., 2002) as microorganisms acting as efficient agents for the biocontrol of soil-borne plant pathogens. The dominance of these species (able to produce metabolites with antimicrobial action) in microbiomes correlated positively with pathogen suppression and indicated good soil conditions for ensuring plants health (Matei et al., 2017). The mechanism of urine impact consists in stimulating the development of beneficial bacterial populations from rhizosphere, able to use horse urine as easy degradable source of nitrogen and sugars, equilibrating the ratio bacteria:fungi in the substrate, determining the proliferation of antagonistic species able to control pathogens by producing metabolites with antibiotic or antifungal activity and enhancing plant growth and resistance.

Conclusion

Taxonomic identification revealed 7 to 9 bacteria species dominated by the development of *Pseudomonas fluorescens* known as an efficient antagonist for plant potential pathogenic fungi, especially from genus *Fusarium*. 8 to 9 fungal species identified were generally ubiquitous (from genera *Penicillium, Acremonium, Aspergillus, Fusarium, Cladosporium*) and known for enzymatic abilities for degrading various sources of nutrients (especially cellulose). The variant with 4ml/l horse urine proved to induce the best plant growth and early production of tomato and the most equilibrate bacterial and fungal microflora, able to sustain plant health by the biological control of pathogens mediated by antagonistic fluorescent pseudomonads and actinomycetes. Further research are needed to compare the influence of horse urine with manure on plant growth and resistance to pathogens.

Abstract

Capillary dynamolysis or rising picture is a method widely utilized in EU countries, contributing to quality assessment of fresh foods, medicaments from medicinal plants, certification in biodynamic agriculture or to differentiation between various agricultural practices. A less studied aspect was its application to the assessment of plant quality and vitality under irrigation systems using different types of water. The aim of the present research was to use capillary dynamolysis as picture forming method for acquiring new images reflecting the vitality and biological quality of cucumber plants (*Cucumis sativus* L.) and to assess their usefulness in appreciating the effect of irrigation with structured water when compared with tap water under organic and chemical fertilization in greenhouse experiment. The results from biometric parameters measurements revealed that irrigation with structured water significantly increased plant height and fresh biomass accumulation as compared to tap water, the effect being more visible when associated with organic and especially chemical fertilization. Visual evaluation of the 6 paper images formed by capillary dynamolysis was carried out in the paper. Differences in the aspect of structural elements from both base, bowl and flag zone were observed with evidencing of a higher vital force and quality of plants by stronger, more intensely colored and better-defined images at variants with structured water. A similar pattern of image was recognized for organic fertilizers and for chemical fertilizers, too. Information derived from rising pictures analysis proved its usefulness in comparing the influence of irrigation water and fertilizing systems on quality of cucumber plants.

Keywords: *cucumber, structured water, capillary dynamolysis, biological quality, picture creating methods*

Introduction

Capillary dynamolysis or rising picture is a method widely utilized in EU countries, contributing to quality assessment of fresh foods, medicaments from medicinal plants, certification in biodynamic agriculture or to differentiation between various agricultural practices. As other two image forming methods, namely biocrystallization and circular chromatography utilized in discriminating produce from organic and conventional origin, capillary dynamolysis is based on the evaluation of structures formed by the reaction of product extract with certain inorganic salts. Characteristic qualitative traits result in typical and reproducible image structures (Fritz et al., 2011). A less studied aspect was the application of this method to the assessment of plant quality and vitality under irrigation systems using different types of water. Recent studies evidenced the beneficial effect of irrigation with structured water on plants growth, heat resistance, health, yields quality (Abraham, 2014; Dubey et al., 2018) in basil, tomato, strawberry or cucumbers as compared to plants watered with tap water. The aim of the present research was to use capillary dynamolysis as picture forming method for acquiring new images reflecting the vitality and biological quality of cucumber plants (*Cucumis sativus* L.) and to assess their usefulness in appreciating the effect of irrigation with structured water when compared with tap water under organic and chemical fertilization in greenhouse experiment.

Materials and methods

Test plant: Cucumber plants (*Cucumis sativus* L.) cultivar Siriana, with fruit type cornishon.
Structured water: The water is structured by quantum technology, created exclusively on the basis of natural elements. Tap water was introduced into the apparatus with quantum electromagnetic field (the magnitude of the waves is in the order of 10^{-40}) to obtain structured water. The information transported by this electromagnetic field during the water structuring process remains captive (stored) in the aqueous physical vacuum from the coherence fields of the water and the information is rewritten through the water into the body of the plant.
Experimental variants: cucumber plants were watered with structured water (V1) and using two supplementary variants of fertilization, namely organic product Formulex 5 ml/l (V3) and mineral UNIVERSOL 2 g/l (V5) in experiment under controlled conditions. We calculated so that the dose of nitrogen, phosphorus and potassium was the same for all variants. Similar pots were prepared and in these variants the plants were watered with tap water (V2) or supplemented with identic quantities of organic (V4) and mineral fertilizers (V6). The experiment was carried out in in controlled conditions regarding the humidity and temperatures (24^{o}C days and 22^{o}C night) in Hortinvest greenhouse, which belongs to the Research Center for Horticultural Products Quality, Faculty of horticulture, UASVM Bucharest, during March-June 2019.
Plants height (cm) was measured and **total biomass** (grams) **accumulated** was determined by weighing cucumber plants in experimental variants.
Capillary dynamolysis: Quality differences between cucumber plants under the influence of experimental conditions of irrigation and fertilizing were evaluated by capillary rising picture method also called capillary dynamolysis, according to the method described by Kolisko (1953) and refined by Zalecka *et al*. (2010). A measured standard quantity of aqueous filtered cucumber leaf extract was migrated on a vertical tube of filter paper in a Kaehlin glass dish, followed by intermediate drying, by metal salt (silver nitrate) and iron sulphate migration and development of specific images. Images obtained after the development of colors were scanned. For the analysis of structures developed in images of capillary dynamolysis were utilized the criteria described by Zalecka *et al*. (2010), Unluturk *et al*. (2011) and Böttgenbach (2018).

Results and discussion

The experimental results confirmed the initial hypothesis and evidenced that structured water exhibited plant growth promoting properties and supplementary added fertilizers (organic and mineral) were also beneficial for the development of cucumber plantlets as compared to those watered with tap water or non-fertilized. The results from biometric parameters measurements revealed that irrigation with structured water significantly increased plant height and fresh biomass accumulation as compared to tap water, the effect being more visible when structured water was associated with organic and chemical fertilization (Figure 1).

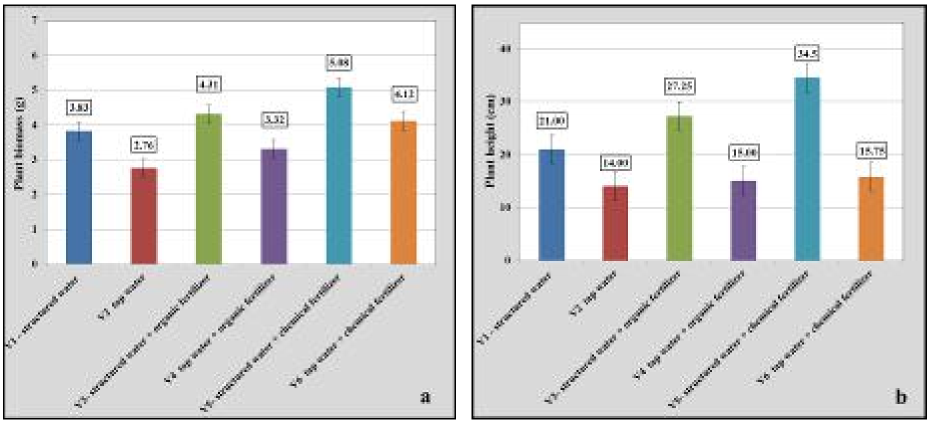

Figure 1. The effect of irrigation water and fertilizers on cucumber plants
a) total plant biomass accumulated b) plant height

The results from the present research confirmed the beneficial effect of structured water on cucumber plants that accumulated significantly more biomass (39%) and were with 50% higher and more vigorous than those watered with tap water. They are in concordance with results from literature reporting improvements in quality, quantity and health of cucumber and other three horticultural plants in Texas, when watered with structured water produced by NAT Structured Water Units from Natural Action Technologies Inc. (Nolte, 2019). Other research brought data on the antioxidant properties of structured water (Higgins *et al*., 2006), improvement of normal cells bioactivities and suppression of malignant cells development (Hwang *et al*., 2017). Sharma *et al*. (2017) listed the benefits of using structured water, including: up to 100% increase fruit/grain/vegetables; up to 100% reduction of chemicals consumption; up to 60% reduction in water usage; improves pests and molds control; increases plant resistance to extreme temperatures; healthier crops and animals; improves soil conditions; enhances taste, texture and shelf life of fruits and vegetables. Visual evaluation of the 6 paper images formed by capillary dynamolysis was carried out. Differences in the aspect of structural elements from both base, bowl and flag zone were observed with evidencing of a higher vital force and quality of plants by stronger, more intensely colored and better-defined images at variants with structured water (Figure 2). A similar pattern of image pairs was recognized for organic fertilizers (Figure 3) and for chemical fertilizers, too (Figure 4). In Figure 2, the colors of the three layers of the basal zone are more pronounced in the image from the sample watered with structured water (left) than in image from the sample watered with tap water (right). Corona is in the first case more irregular, with white beards and interrupted by the base of a long pipe and more regular (uniform parallel layers), without beard in the second image. Bowl zone is more or less diffuse in forms and contrast in both images, the structures from the left are larger, more colored and those from the right are present in compact thin form only on 2/3 of the image. The flag zone from the sample watered with structured water is higher with rare large parallel pipes (flags) narrowed towards the drop zone, open ended, some started from the base, continued in a diffuse grey zone and others formed on the apical third, few being in contact with long brown reduction spots that pass the white zone coming generally in pairs from the thin superior irregular layer. The same zone in image from the sample watered with tap water is shorter than the former, presents the small compact parallel and thin pipes continued with diffuse lighter grey zone without pipes and large, open, irregular flags formed towards a larger white zone ended with a thicker superior layer, with regular contour and reduction spots not in pairs. The pair of images from the samples with organic fertilizer added (Figure 3) revealed the presence of three colored layers in image from the sample watered with structured water, the relative compactness between bowls, the parallel, very large apical openness of the long continuous pipes and narrow end of those formed towards the border of flag zone and only two light colored layers in image from the sample watered with tap water, non-compact structures in bowl zone, with grey middle flags concave ended and large flags formed in apical region. Reduction spots are similar in form with those from the precedent pair of samples non-fertilized, but more dark-colored in the variant with structured water and longer in the variant with tap water. In the pair of images from the variants with mineral fertilizers added (Figure 4), the colors of both basal, bowl and the flag zone are more pronounced in the case of variant watered with structured water than in that with tap water but the differences in form, compactness of bowl structures and flags (pipes) broadness are less expressed than in the case of samples with organic fertilization. Even though a general pattern can be recognized for the fertilization type, the differences induced by irrigation water utilized were: a better zonation of basal zone, generally longer pipes in the flag zone, more pronounced colors and contours with a brown reddish tint and typical rounded reduction spots formed frequently in pairs, characteristic for the structured water and lighter colors, the grey tint of layers and structures from the flag zone and more regular superior margin with pointed reduction spots, not in pairs, characteristic for tap water.

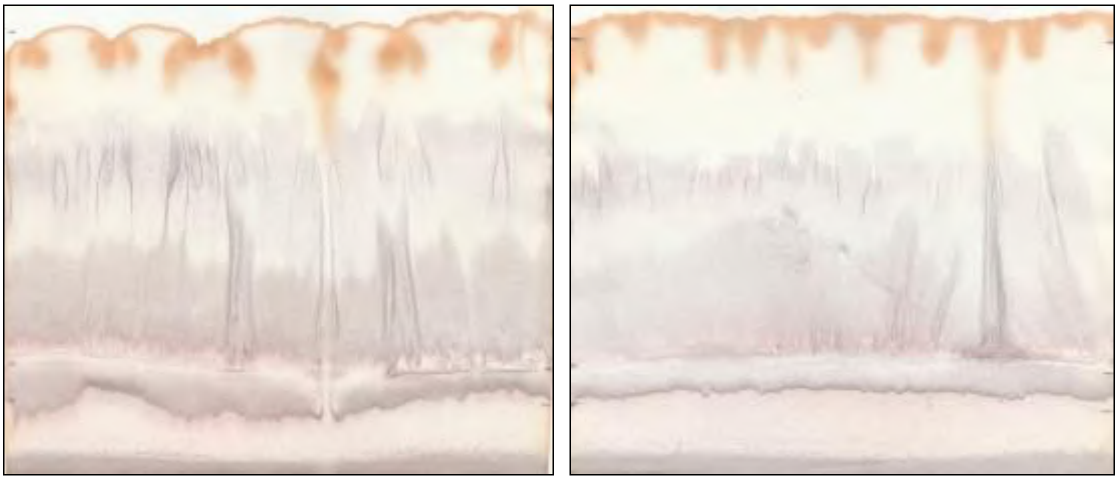

Figure 2. The capillary dynamolysis images from V1 (left) and V2 (right)

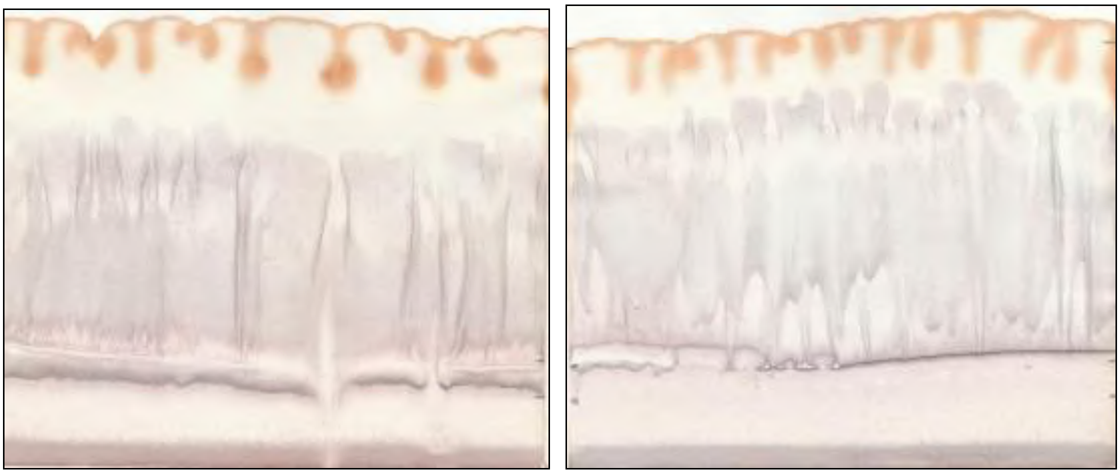

Figure 3. The capillary dynamolysis images from V3 (left) and V4 (right)

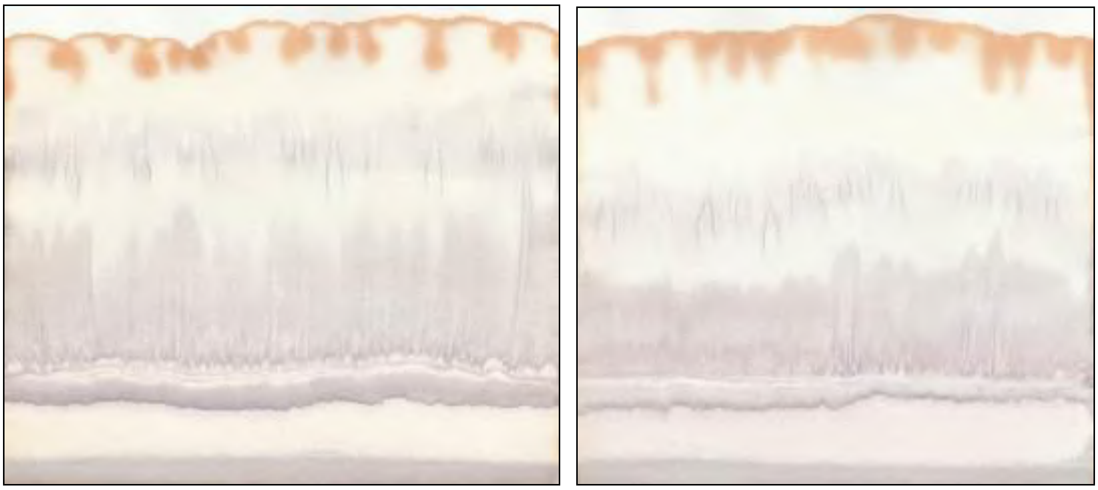

Figure 4. The capillary dynamolysis images from V5 (left) and V6 (right)

Information derived from rising pictures analysis, coupled with biometric data proved its usefulness in comparing the influence of irrigation water and fertilizing systems on cucumber plants. Similarly, Fritz *et al*. (2017) assessed the effects of conversion of vineyard plots from integrated to organic and biodynamic management versus integrated management on grape juice quality using three image forming methods, respectively circular chromatography, capillary dynamolysis and biocrystallization. The parallel application of three methods proved to be useful for successful differentiation and characterization of products from integrated vs. organic and biodynamic production plots and recommend image forming approach as a valuable tool complementary to established methods (chemical analysis) utilized for food quality evaluation. The analysis of images generated with capillary dynamolysis evidenced that for certain samples, images were different in their color in the lower part and by bigger and darker bowl-like forms. Similar to images obtained by circular chromatography, the images produced using the capillary dynamolysis promoted quality characterization with respect to strength of form expression for four samples. As in our interpretation of images, the authors considered that samples yielding images characterized as "strong form expression" were ranked higher than those characterized as "weak form expression" in the qualitative assessment of juice. The image forming methods evidenced the high quality of products from biodynamic plots, followed by organic plots as compared to integrated ones and for the first time, the different application schemes of horn silica were differentiated. The results support other research that proved the use of image forming methods to differentiate the quality of agricultural products from different farming systems or plant production measures (Fritz *et al*., 2011). Authors concluded that the different fertilization systems influence image structures in a reproducible and typical manner and permit the grouping and classification of wheat samples from organic and conventional production plots. Literature cites other trained authors (Skjerbaek *et al*., 2004) capable of visual interpreting and judging the images of capillary dynamolysis and to connect pictures with different farming systems but others used the Gram-Charlier Neural Network (GCNN) methodology for the discrimination of capillary dynamolysis images and successfully applied it to quality assessment of organic and conventional tomatoes (Unluturk *et al*., 2011).

Conclusion

Irrigation with structured water significantly increased plant height and fresh biomass accumulation as compared to tap water, the effect being more visible when associated with organic and chemical fertilization, too. Differences in the aspect of structural elements from both base, bowl and flag zone were observed with evidencing of a higher vital force and quality of plants by stronger, more intensely colored and better-defined images at variants with structured water. A similar pattern of image was recognized for organic fertilizers and for chemical fertilizers, too. Information derived from rising pictures analysis proved its usefulness in comparing the influence of irrigation water and fertilizing systems on quality of cucumber plants. Further investigations are necessary to link capillary dynamolysis results with other image forming methods and chemical analysis for better elucidating the nature of quality differences obtained.

HARVEST TIME IMPACT ON SHATTERING HABIT AND MILLING QUALITY OF RICE CULTIVARS

Alireza ALLAMEH

Rice Research Institute of Iran (RRII), Agricultural Research, Education and Extension Organization (AREEO), Rasht, Iran
Corresponding author: a.allameh@areeo.ac.ir

Abstract

During harvest season, grain shattering is an important trait which affects both yield and milling quality of rice crop. A two-year study was carried out in order to investigate the variation of grain shattering habit and head rice yield at different harvest times. The experiments were laid out in a factorial based on completely randomized design with five replications in order to examine the effects of rice varieties (Hashemi, Khazar, and Ghohar), harvest time (26, 28, 30, 32, and 34 days after 50% flowering), and grain position on the panicle (upper, middle, and lower portions) on rice grain pedicel breaking tensile strength (BTS) and head rice yield (HRY). The results revealed that the highest and lowest BTS were associated with Hashemi and Ghohar with an average of 0.60 and 0.35 N, respectively. With delaying in harvesting, grain detaching force from the pedicel decreased by approximately 50% among the earliest and the latest harvest time. Because of the non-uniformity in grain maturity, there was a nearly 30% variation in BTS of the grain pedicel for upper and lower portions of a single panicle. For selected intervals, harvesting time had no significant effect on HRY by itself but interacted significantly with other parameters. Rice variety affected HRY ($p<0.01$), whereupon other variables could intensify its effect.

Keywords: *Rice, shattering habit, harvest time, breaking tensile strength, milling*.

Introduction

Grain shattering is defined as detachment of a grain from its pedicel at relative ease during maturity. Shattering habit as an impressive trait affects harvest efficiency. Easy shattering grains cause remarkable yield loss within harvest period. Also, hard shattering varieties lead to higher threshing force and machine power requirement in consequence. Mainly, rice grain shattering is influenced by its genetic characteristics but such parameters as climate conditions, nourishing, pests and diseases, harvesting implements and machines, and harvest management can affect it. Therefore, in breeding, scientists should select a cultivar which has an appropriate shattering threshold. Before releasing a cultivar, conducting experiments regarding its engineering properties is necessary in order to recognize it thoroughly. Having such information, it would be possible to manage harvesting so that crops encounter the minimum damage and losses.

Studies have been accomplished by researchers to characterize engineering aspects of rice shattering habit. Ichikawa *et al.* (1990) introduced two testing devices and examined shattering habit of 42 varieties. Kawamura *et al.* (2002) used a tensile tester to measure detaching force of a single grain from stem. In a research, shattering habit was evaluated by using the grain detachment force in two forms of parallel and perpendicular pull (Inoue *et al.*, 2003). In an attempt, Ji *et al.* (2006) employed breaking tensile strength (BTS) to measure the degree of shattering at different intervals after heading. Oduori *et al.* (2008) developed a model to evaluate shattered rice grain loss in a combine header. Their model consisted of crop properties and interactions of reel and crop. Lamo *et al.* (2011) developed a hand-held, single grain shattering tester suitable for field assessment of shattering habit. In an investigation, a

universal testing machine was employed to determine the BTS of the rice grain pedicel instead of conventional shattering tester devices (Matsushita *et al.*, 2012).
Another issue is the role of various factors on rice quality properties. Among them, appropriate harvest time has a great importance in preventing crop loss. In a research by Lu *et al.* (1995), it was revealed that rice harvested at moisture contents lower than 15% or higher than 22% encountered significant gross income reduction. Sürek and Beşer (1998) announced that the maximum grain yield and white rice, the minimum breakage during milling, the least unfilled and partially filled grains, acceptable moisture content, and the minimum chalkiness in white rice obtained at 49 days after flowering (DAF) in Turkey. Thompson and Mutters (2006) reported that average rice moisture content could not be an adequate predicting measure for head rice yield (HRY). Siebenmorgen *et al.* (2007) found out that the optimum harvest moisture contents in which head rice yield had the highest value varied from 18.7 to 23.5% and 21.5 to 24% for long and medium grains, respectively. Hossain *et al.* (2009) concluded that aromatic rice should be harvested at 30 to 35 DAF in order to have higher HRY, elongation, volume expansion ratio, and amylose.
This study aimed to investigate rice shattering habit through measuring the BTS of the grain pedicel at different harvest times, grain shedding trend for a single panicle, and the effect of various harvest time on head rice yield.

Materials and Methods

This study was conducted at Rice Research Institute of Iran (RRII), Rasht, Iran over two cropping season of 2016 and 2017. Rice varieties were Hashemi (a local cultivar), Khazar and Ghohar (two improved cultivars). Samples were collected from fields with proper uniformity. The BTS of the grain pedicel was measured by a force gauge (Lutron, FG-5000A, Taiwan) mounted on a specially designed platform. The same procedure described by Alizadeh and Allameh (2011) was followed.

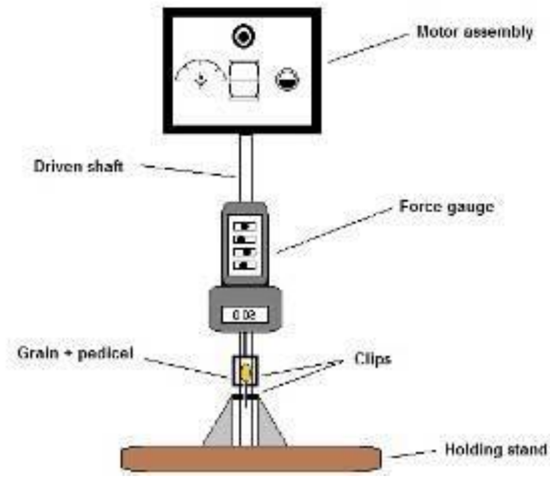

Figure 1. Schematic diagram of the BTS testing device

After finishing the BTS experiments, milling test was commenced. The milling tests were performed as the method mentioned by Allameh and Alizadeh (2013). The experiments were conducted in the form of factorial based on complete randomized design (CRD) in five replications. Independent variables were as rice variety (at three levels of Hashemi, Khazar, and Gohar), harvest time (at five levels of 26, 28, 30, 32, 34 days after 50% flowering), and the grain position on the panicle (at three levels of upper, middle, and lower portions). Dependent variables were defined as the breaking tensile strength (BTS) of the grain pedicel and HRY. Data analysis was performed by the SAS 9 software (2004, SAS Institute, USA).

Results and Discussion

Data analysis indicates that the effect of year, variety, harvest time, and grain position on the panicle is significant on BTS of the grain pedicel. Table 1 displays mean values of BTS for two years of study. The highest force (1.14 N) required for separating a grain from its pedicel belonged to Hashemi cultivar at the first harvest time of the second year of the study. In case, the lowest one related to Khazar cultivar harvested at 32 DAF of the first year of the study. The downswing of the required force for detaching a grain from its pedicel is clearly viewed in the second year of the study in particular.

Table 1 Mean value of BTS at different harvest times (N)

year	Harvest time (DAF)	variety		
		Hashemi	Khazar	Ghohar
1	26	0.33^{jk}	0.15^{p}	0.33^{jk}
	28	0.33^{jk}	0.2^{no}	0.3^{kl}
	30	0.34^{j}	0.16^{p}	0.27^{lm}
	32	0.23^{mn}	0.14^{p}	0.23^{mn}
	34	0.25^{lm}	0.16^{p}	0.17^{op}
2	26	1.14^{a}	0.81^{d}	0.75^{e}
	28	1.05^{b}	0.58^{f}	0.53^{g}
	30	0.94^{c}	0.61^{f}	0.44^{hi}
	32	0.82^{d}	0.47^{h}	0.32^{jk}
	34	0.59^{f}	0.43^{i}	0.2^{no}

Common letters represent no significant difference at 1% level.

There was a significant difference between the two years of study. The reason was that in the first year, due to an unintentional incident, it became inevitable to use samples of a late cultivated crop. Chosen varieties cultivated with a delay of roughly 30 days compared to normal. Therefore, harvest time faced to seasonal rainfalls that resulted in damage to rice plants. Cultivars have behaved differently. Hashemi, a locally grown cultivar, has medium shattering characteristic genetically, while Khazar and Ghohar, high yielding cultivars, are easy shattering. In other words, by applying a lower force, grain will detach from its pedicel and shed. Scientists suggest that genetic rules on shattering habit and other factors rank next to it (Ji *et al.*, 2006; Lin *et al.*, 2006). Investigations demonstrate that the development of abscission layer is in association with shattering habit and in easy shattering varieties, it is completely formed (Fukutae *et al.*, 1994; Ji *et al.*, 2010; Okubo, 2014). Ichikawa *et al.* (1990) expressed that easy shattering varieties needed force less than 1 N to separate grain from its pedicel. In Figure 2 the variations of the BTS of the grain pedicel has been illustrated based on grain position on the panicle. It could be clearly seen that for every single cultivar, the grain position on the panicle had a significant effect on the required force for detaching the grain from its pedicel. From top to down, there was an increasing trend for detaching force.

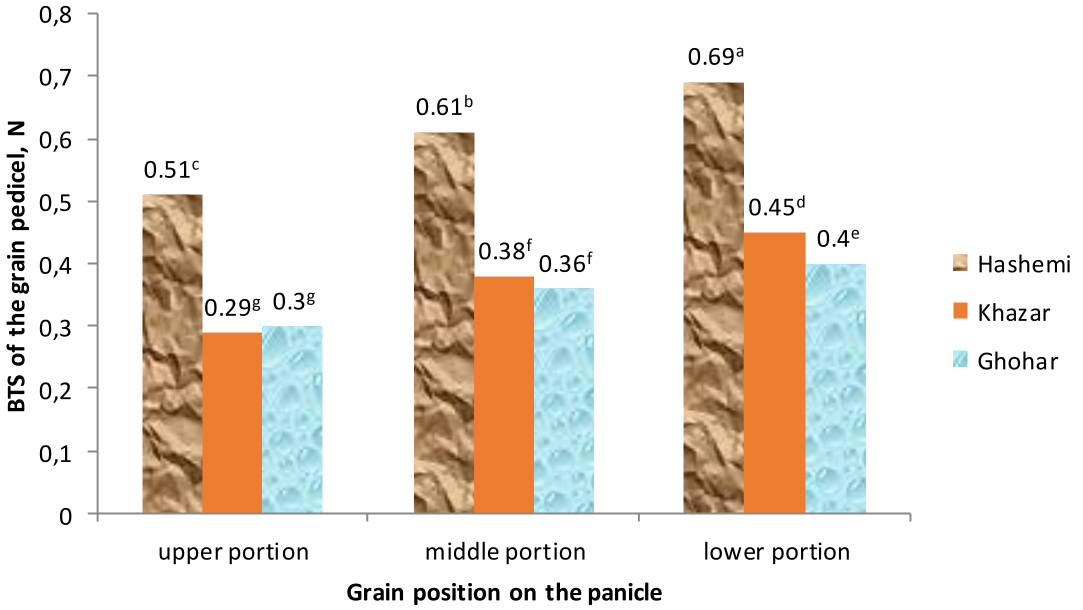

Figure 2. Variations of BTS of the grain pedicel across a panicle

On a panicle, the grain maturity starts from upper portions to lower ones. Upper grains mature soon, lose their moisture content and become yellowish. Hence, they would separate from the pedicel by applying less force. Whereas, lower parts of a panicle have immature or ripening grains which are greenish. Some researchers have pointed out this in their studies (Suastawa *et al.*, 1996; Szot *et al.*, 1998; Kawamura *et al.*, 2002; Ji *et al.*, 2006; Choe *et al.*, 2013; Tang *et al.*, 2015). Head rice yield variations of tested cultivars are illustrated in Figure 3. The maximum variation is related to Hashemi cultivar (nearly 10%) due to late cultivation in the first year. Late cultivation made rice crop encounter seasonal rainfalls which in turn caused lodging and damaging the grains. This has been reported by others (Ghosh *et al.*, 2004; Sha and Linscombe, 2007). Many studies have also referred to the effect of variety on HRY (Zhao and Fitzgerald, 2013; Zhou *et al.*, 2015).

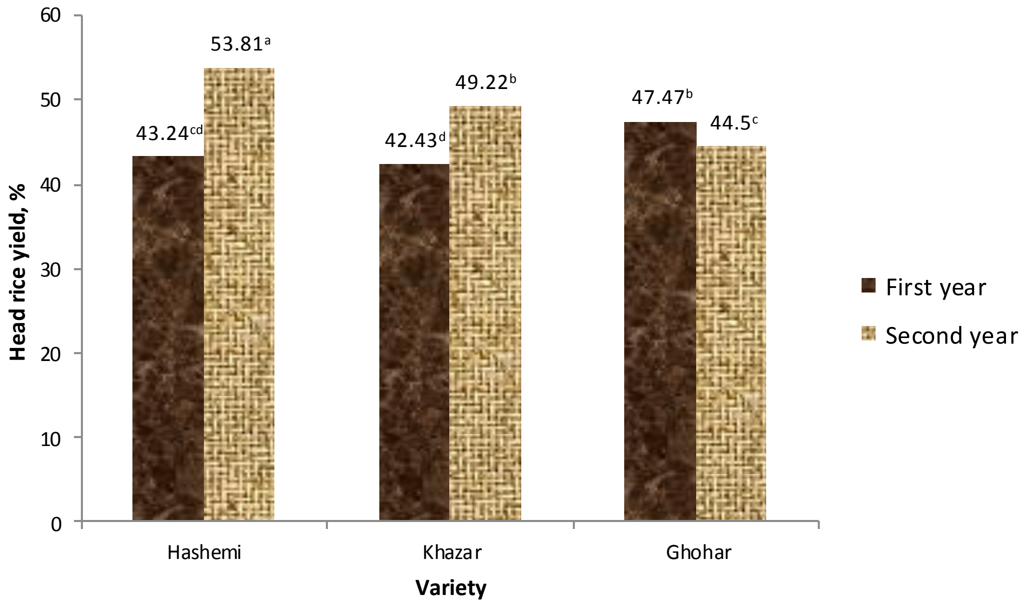

Figure 3. Interaction of year and variety on HRY

In Figure 4, HRY variations have been shown in terms of different harvest time. Over the time interval assigned for this study, with the exception of Hashemi cultivar that its growth period completes nearly 30 DAF and whole the panicle becomes uniformly yellowish, the two other cultivars do not have such a situation. Khazar and Ghohar are among late matured cultivars and it takes 5-10 days longer in comparison with Hashemi. This usually coincides with seasonal rainfalls which causes grain damage and crop loss. For Ghohar cultivar, while upper parts of the panicle turned totally yellow, lower parts were still green or greenish. This conformed to other investigators (Siebenmorgen *et al.*, 2007; Hossain *et al.*, 2009).

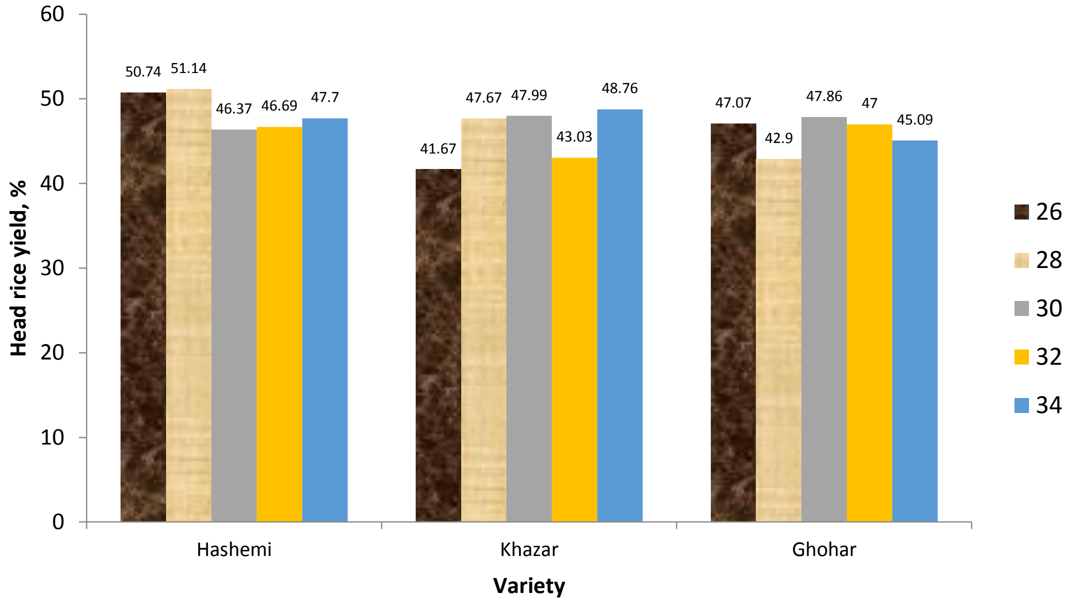

Figure 4. HRY variations at different harvest times

Conclusions

According to the results obtained, the followings could be summarized:

- Among the cultivars studied in this research, Hashemi had the highest mean BTS (0.6 N) but the lowest belonged to Ghohar (0.35 N).
- The more delay in harvest, the lesser would be BTS and the more shedding in consequence. Within the time interval in this study, a reduction of nearly 50% in BTS of grain pedicel occurred from the first to the last harvest time.
- Grain maturity will not proceed across an individual panicle uniformly. On the average, there was a rough difference of 30% in BTS of grain pedicel between the upper and lower portions of a single panicle.
- In each cropping season, planting date had significant effects on BTS and HRY. Late cultivation, through creating specific physiological circumstances, led to decrease in BTS of grain pedicel and easier shattering of the grain subsequently. In addition, coinciding harvest time with seasonal rainfalls lowered milling quality. For instance, Hashemi experienced an approximate reduction of 10 percent in HRY because of late cultivation.

ANALYSIS AND CHARACTERISTICS OF THE NEW VIRGINIA HYBRID LINES IN CMS FORM

Ilija RISTESKI, Karolina KOCOSKA

St. KlimentOhridski University - Bitola - Scientific Tobacco Institute - Prilep, Kicevski pat bb 7500 Prilep, Republic of Macedonia
*Corresponding author: ilija.r@t-home.mk

Abstract

V-88/09 CMS F1, V-120/15 CMS F1 and V-79/09 CMS F1 are male-sterile hybrid lines of Virginia tobacco created during 2009-2017 at the Scientific Tobacco Institute-Prilep by inter-varietal hybridization. Following the previously obtained data on their characteristics, they were included in the comparative trials carried out in the experimental field of Tobacco Institute –Prilepin 2012-2016. Foreign tobaccos were included in the trial as check varieties. Throughout this period, the lines V-88/09 CMS F_1, V-120/15CMS F_1 and V-79/09 CMS F_1showed better bio-morphological and production traits in comparison with the check varieties. It allowed them to overcame all other lines and varieties included in the trials. The time of flowering, the length of the growing period and the stalk height in these lines are characters typical of Virginia tobacco. Excellent results were obtained with regard to yield and quality (average price USA $ / kg) and to the gross income (USA $ / ha). In most of the traits, these lines exceeded the control varieties and achieved statistical significance level of 1% and 5%. The purpose of this paper is to inform the domestic and general public with the achievements in this area, in hope to raise their attention and interest. Data presented here shall recommend these lines to be enrolled in the National list of varieties.

Key words: *tobacco, Virginia, line, traits.*

Introduction

Virfinia tobacco is the most common type of tobacco in the word. Raw material of this tobacco participates with 60-70 % in the composition of modern cigarette blends. Which require precisely determined agro-ecological conditions and cultural practices for their growth and development. The Virginia tobacco raw material is an inevitable component of modern cigarette brands, participating with varying percentage in their composition. The conditions for obtaining a good yield and quality of this tobacco are: good variety, strictly controlled production and proper curing, typical of the type. According to Beljo J. (1996) and Uzunoski M. (1985), the Virginia tobacco belongs to the group of high tobaccos (about 200 cm), which require precisely determined agro-ecological conditions and cultural practices for their growth and development, including the specific method of drying (flue-curing). In R. Macedonia the production of Virginia tobacco was ceased in 2002 and this discontinuance has been unjustifiably extended until now. In the production chain of this tobacco, variety is highly important segment which determines the yeld and quality of the raw material. Tobacco Institute – Prilep has created a number of hybrid lines in CMS form. The solution for this problem is only in the restart of production. In the production chain of this tobacco, variety is highly important segment which determines the yield and quality of the raw material. Tobacco Institute – Prilep has created a number of hybrid lines in CMS form. The results of comparative studies with other varieties and lines show that they can be of interest to potential primary producers.

Material and methods

Cultivation and testing of some newly created lines of Virginia tobacco was carried out at the experimental field of Tobacco Institute - Prilep in the period 2009/2017. Prior to hybridization and creation of a new line, the goals were set up and parental pairs were determined. Breeding lines in male-sterile form (minimum F7 generation) were used as mothers, and fertile varieties and lines (also of min. F7 generation) were used as fathers. The newly obtained progeny (line) is also male-sterile (unisexual), indicating that this trait is inherited by the mother line, in which the heterotic effect is strongly expressed. Hawks S.N. (1978) and Gornik R. (1973) reported that F1 hybrids in male sterile form are characterized by higher yields, higher resistance to some diseases, early maturation etc. The results presented in the tables are summarized average values from the comparative trials in which these lines were included. Statistical data analysis was made and the above lines showed significant differences at a level of 5% and 1% compared to the check varieties, but they also dominated over the other investigated varieties and lines. Conversion in US$ was calculated by middle exchange rate of National Bank of Republic of Macedonia on 22.08.2019 55.38 den. For 1 US$.

Results and discussion

Some more important traits of the newly created Virginia tobacco lines included in the investigation are presented in Table 1.

Table 1. Flowering and length of the growing season

Line	Beginning of flowering, in days	50% flowering	End of flowering, in days	Length of the growing season, in days
V-79/09 CMS F_1	72	77	82	125
V-120/15 CMSF_1	68	73	77	118
V-88/09 CMS F_1	67	73	79	120

- Beginning of flowering – Flowering and formation of seed to prolong the species is a natural phenomenon also present in tobacco. The hybrid lines that are subject of this research are blooming but they do not form a seed. Rubin B. A. (1971) concluded that the first flower that blooms is the central (top) flower of the inflorescence. Naumoski K. et al. (1977) reported that tobacco plant has already built 90% of its plant mass by the end of flowering. Data in Table 1 show that line V-88/09 CMS F_1 ends with flowering in 67 days, line 120/15 CMS F_1 in 68 days and line V-79/09 CMS F_1 in 72 days.
- 50% flowering – After the beginning stage, the process of flowering is intensified and in just a few days (5-7) 50% of flowering is reached. Lines V-120/15 CMS F_1 and V-88/09 CMS F_1 reach this stage in 73 days and line V-79/09 CMS F1 in 77 days. According to Beljo (1996), all investigated lines belong to the group of tobaccos with moderate time for 50% flowering.
- End of flowering - It is varietal and type characteristic strongly affected by the soil and climate conditions, applied agricultural practices, day length, etc. Risteski and Kocoska (2014) in investigation of 7 domestic and foreign tobacco varieties and lines in the region of Prilep in 2010/2011 reported that the end of flowering occurs after 71.5 - 79 days. S.N. Hawks (1978) reported that in some Virginia varieties with so-called mammoth characteristics the beginning and end of flowering stage occurs later, as a result of the day length. The data in

Table 1 show that the line V-120/15 is the first to finish the flowering (77 days) and the line V-79/09 is the last (82 days).

- Length of the growing season – This trait is measured in days from the day of planting until the day when the last leaves are harvested. Data in Table 1 show that the length of the growing season ranged from 118 days in line V-120/15 CMS F_1, 120 days in line V-88/09 CMS F_1 and 125 days in line V-79/09 CMS F_1. According to Beljo (1996), all these lines belong to the group with early to moderate growing season.
- Morphological features

Table 2. Morphological traits

Line	Leaf size Length/Width, cm			Leaf number	Stalk height, cm
	5th leaf	10th leaf	15th leaf		
V-79/09 CMS F_1	52×37	69×40	65×35	34	213
V-120/15 CMS F1	54×39	64×42	61×33	31	207
V-88/09 CMS F_1	55×34	66×41	60×30	33	186

- Leaf size – it is very important that the length of the middle belt leaves (5th-15th) in Virginia tobacco exceeds 35 cm, because it is the first condition for them to be ranked as a first class tobacco. Dražić S. et al. studied 13 genotypes of Virginia tobacco in Nova Pazova (Serbia) in 2011 and found that the average size of the middle-belt leaves was 64 cm length and 30 cm width. Kalamanda O. (2009) in Republika Srpska performed 3-year investigations with two Virginia tobacco varieties and reported that the middle belt leaf had 48.7 cm average length and 22.7 cm average width. From the data presented in Table 2 it can be seen that the leaf length ranged from 52 cm in the 5th leaf of the line V-79/09 CMS F_1 to 69 cm in the 10th leaf of the same line. In other lines, this trait ranges from 54 cm in V-120/15 CMS F_1 to 66 cm in V-88/09 CMS F_1. The largest width of 42 cm (10th leaf) was measured in line V-120/15 CMS F1 and the smallest width of 30 cm (15th leaf) was found in line V-88/09 CMS F_1. According to the established Purchasing rules and due to the adequate length and width of their leaves, all the analyzed lines are ranked in the Class I.
- Leaf number is genetically controlled character which is also affected by the length of the day, applied cultural practices, soil and climate conditions, etc. Devcic K. and Triplat J. (1982) in their trials with 3 varieties of Virginia tobacco (H-30, H-31 and H-32) in three locations in Croatia, reported that the leaf number ranged from 22 in H-31 and H-32 to 23 in H-30. Dražić S. et al. (2012) investigated 13 genotypes of Virginia tobacco in Nova Pazova during 2011 and found that the number of leaves ranged from 22 to 26. According to the data in Table 2, the largest leaf number (34) was counted in line V-79/09 CMS F_1 and the smallest (31) in V-120/15 CMS F_1. In line V-88/09 CMS F_1 the number of leaves was 33. According to Beljo J. (1996), all analyzed lines belong to the group of multifoliate tobaccos.
- Stalk height - Virginia tobacco belongs to the group of high tobaccos. Risteski I. (1999) in his investigations of Virginia variety MV-1 in Prilep found that, depending on the size of nutrient area, the height of the stalks averaged between 193 cm and 213 cm. Devčić K. et al. (1982) reported that the height of the Croatian varieties H-10, H-31 and H-32 was 170 cm. Data presented in Table 2 reveal that the largest average height (213 cm) was measured in line V-79/09 CMS F_1 and the smallest (186 cm) in line V-88/09 CMS F_1. The height of the stalk in line V-120/15 CMS F1 was 207 cm. In all the analyzed lines this trait is within the range cited in literature and is typical of the Virginia tobacco.
- Yield and quality

Data on this characteristic are presented in Table 3.

Table 3. Yield and gross income

Line	Yield kg/ha	Average price, USA $ kg	Gross income, USA $ ha
V-79/09 ЦМС F_1	3450	1.28	226 158
V-120/15 ЦМС F_1	3180	1.23	251 788
V-88/09 ЦМС F_1	3591	1.22	242 825

-Yield per hectare - In addition to the genetic properties of the type and variety, the yield is closely related to soil and climate conditions where tobacco is grown, applied agrotechnics, etc. Risteski I. and Kocoska K., (2012) reported that in 1987 the yield of the first recognized Macedonian Virginia variety MV-1 was about 2,500 kg. In the process of selection, the yield in all further lines increased gradually and presently it is about 3590 kg in line V-88/09 CMS F_1. Dražić S. et al. (2012) studied 13 varieties and lines in the location of Starchevo, Serbia, in which the yield varied between 1710 kg/ha and 4030 kg/ha. S.N. Hawks (1978) presented the movement of yields in the United States by periods. Thus, in the period 1934-1938 the average yield was only 959 kg/ha, and in the period 1964-1967 it raised up to 2224 kg/ha. The data in Table 2 show that the yield per hectare in the analyzed lines ranged from 3693 kg/ha in line V-120/15 CMS F_1 to 3591 kg/ha in line V-88/09 CMS F_1, while in V-79/09 CMS F_1 it was 3450 kg/ha. The above data indicate that the yield obtained in the analyzed lines is quite satisfactory and is typical of the hybrid varieties and lines.

- Average price - The quality of tobacco raw material determines the average price per 1 kg. It is highly affected by the variety, proper and timely applied agrotechnics, yellowing, curing and other factors. The data presented in Table 3 show that the average price ranged from 1.22 USA $ /kg in line V-88/09 CMS F_1 to 1.23 USA $ /kg in line V-120/15 CMS F_1 and 1.28 USA $ /kg in line V-79/09 CMS F_1. According to the above data, it can be concluded that there are no major differences in terms of price or quality between lines. In the period of investigation (2012 – 2016), the lines included in the trials achieved higher average price compared to other varieties and lines.

- Gross income - economic effect - This trait is a summarized expression of the average price per 1 kg of raw tobacco and the yield per hectare achieved by the lines represented in the trial. The data in Table - 3 reveal that line V-120/15 CMS F_1 had the highest gross income (251 788 USD $ ha), primarily due to the high yield per hectare. This parameter in line V-88/09 CMS F_1 was 242 825 den/ha and in line V-79/09 CMS F_1 it was 226 165 den / ha.

Conclusions

Based on the results of the research, the following statements can be drawn:
According to the time required for completion of the flowering stage, the analyzed lines can be included in the group of tobaccos with moderately long time of flowering.
With regard to the length of the growing season, all analyzed lines belong to the group of tobaccos with early to moderate length of growing season.
According to the leaf size (length and width) and in compliance with the Purchasing rules, the investigated lines can be ranked in Class. Regarding the number of leaves (31 to 34), the studied lines belong to the group of multifoliate tobaccos.

According to the stalk height (186 cm - 213 cm), all three lines belong to the group of high tobaccos.
The yield per hectare is relatively high (3450 kg/ha - 3693 kg/ha), which is considerably good result, typical of hybrid varieties and lines.
The amounts of the average price and gross income guarantee a stimulating production of these lines.

EVALUATION OF ANDROGENIC COMPETENCE OF DIFFERENT PEPPER, TOMATO AND EGGPLANT GENOTYPES

Marija POCKOVSKA, Fidanka TRAJKOVA*, Liljana KOLEVA GUDEVA

Department of Plant Biotechnology, Faculty of Agriculture, Goce Delcev University – Stip, Republic of North Macedonia
*Corresponding author: fidanka.trajkova@ugd.edu.mk

Abstract
The methods of biotechnology such as androgenesis introduce new possibilities for faster creation of new varieties or at least faster development of improved genotypes with desirable traits that can give an answer to new abiotic and biotic challenges in agricultural production. Androgenesis is a method that opens possibilities for development of haploids and spontaneous dihaploids plants via anther culture. *In vitro* anther culture utilized for gaining haploid/dihaploid plants serves as a tool for improvement of some solanaceous crops such as tomato, eggplant and pepper, but it always faces obstacles for high productivity of regenerants in those crops. In the present study, androgenic competence of 3 pepper genotypes (Edita, Bela Duga and Homera), 3 tomato genotypes (Bellfort, Rally and Policarpo) and 1 eggplant genotype (Domaci srednje dugi) were evaluated. The pepper anthers were cultured according to the method developed by Dumas de Valux *et al.* (1981), tomato anthers were cultivated according to Corral-Martínez *et al.* (2011), while eggplant anthers were cultivated according to Dumas de Valux and Chambonnet (1982). The experiment showed that androgenesis was successfully implemented only in pepper genotype Edita, whereas the eggplant genotype did not show any response to anther induction media. Cultivation of anthers from all tomato genotypes resulted only in callus formation. Our results are one more confirmation that androgenesis applied on pepper, tomato and eggplant has its limitations and the successfulness of androgenesis depends on many factors as growing conditions and donor plant age, donor plant genotype, microspore developmental stage, culture media and cultivation conditions.

Keywords: *Androgenesis, Anther culture, Capsicum annuum, Lycopersicon esculentum, Solanum melongena*

Introduction
Androgenesis is one of the successful biotechnological methods that is included in the group of novel techniques for improving agricultural crops and it can be combined with other biotechnological methods for achieving new selection goals (Koleva Gudeva *et al.*, 2008; Irikova *et al.*, 2016). It is considered as the fastest way to achieve homozygosity and to get homozygotic lines, where dihaploids have many advantages for their involvement in fundamental and breeding research (Koleva Gudeva *et al.*, 2007a; Seguí-Simarro, 2016). Nevertheless, obtaining regenerated and fertile androgenetic plants in the Solanaceae horticulture crops is still low (Seguí-Simarro, 2016).
Generally, there are a small number of scientific publications related to the full regeneration of the androgenetic solanaceous plants, their characterization and evaluation and direct participation in selection programs for scientific and commercial purposes. According to Seguí-Simarro *et al.* (2011), pepper (*Capsicum* sp.) is characterized as a third-class crop by fam. Solanaceae which is "resistant" to methods of androgenesis, after tomato (*Lycopersicon esculentum* Mill.) and eggplant (*Solanum melangena* L.). The aim of our research was to test and establish effective androgenesis protocols for pepper, tomato and eggplant.

Material and Methods

Pepper anther culture

Three pepper (*Capsicum annuum* L.) varieties were used as anther donors in the experiment: Edita (sweet, long type), Bela Duga (sweet, long type), Homera (long, hot type). The flower buds were harvested when the corolla was of the same length as the calyx or slightly longer. Flower buds were surface sterilized in 70% ethanol for 2 minutes, then in 5% Isozan G for 10 min, and rinsed three times in sterile distilled water. After the removal of the filaments, anthers from three flower buds were placed in Petri dish, with the concave face down, touching the culture medium. The media employed for anther culture was: Cp (Dumas de Valux *et al.*, 1981) supplemented with kinetin (0.01 $mg \cdot l^{-1}$) and 2.4-D (0.01 $mg \cdot l^{-1}$). The anthers cultivated on Cp medium with the supplementary hormones were incubated for 8 days at 35±2 ^{o}C in the dark, and then transferred to 25 ± 2 ^{o}C with 12 h photoperiod. After 12 days of induction on Cp medium, the anthers were transferred each month onto fresh R_1 medium supplemented with 0.01 $mg \cdot l^{-1}$ kinetin and simultaneously the deteriorated or infected anthers were removed. The cultures were observed regularly, and the data were recorded every week. The frequency of callus formation and the number of emerged embryoids were recorded. Young shoots emerging from the anthers were transferred onto hormone free V3 media in order roots to be formed.

Tomato anther culture

Three tomato (*Lycopersicon esculentum* Mill.) varieties were used as anther donors in the experiment: Bellfort (rounded shape), Rally (rounded shape) and Policarpo (plum-shaped tomato). Buds varying in length were collected from flowering plants and they were surface sterilized in 70% ethanol for 2 minutes, then in 5% Isozan G for 10 min, and rinsed three times in sterile distilled water. The anthers were dissected and plated on the MS induction medium prepared according to Corral-Martínez *et al.* (2011). It consisted of MS basal medium + vitamins (Murashige and Skoog 1962), supplemented with 2.5 $g \cdot l^{-1}$ Phytagel, 20 g/l sucrose, 1 $mg \cdot l^{-1}$2ip and 2 $mg \cdot l^{-1}$ IAA, pH 5.7. Petri dishes were kept in a growth cabinet at 25 ^{o}C, in darkness for 1 month, and then under a 16/8 photoperiod. Anthers and developing calli were transferred to fresh medium on a monthly basis. Green or partially green, proliferating calli were transferred to regeneration medium composed of 4.4 g/l MS medium plus vitamins, 2.5 $g \cdot l^{-1}$ Phytagel, 20 $g \cdot l^{-1}$ sucrose and 0.25 $mg \cdot l^{-1}$ zeatin, pH 5.7.

Eggplant anther culture

One eggplant (*Solanum melanogena* L.) genotype, Domaci srednje dugi, was used as anther donor genotype. Flower buds of the certain size were harvested from anther donor plants and surface sterilized in 70% ethanol for 2 minutes, then in 5% Isozan G for 10 min, and rinsed three times in sterile distilled water and immediately dissected. Anthers were cultured according to Dumas de Vaulx and Chambonnet (1982) on Ct inductive medium. The Ct medium was supplemented with 0.01 $mg \cdot l^{-1}$ 2,4-D and 0.01 $mg \cdot l^{-1}$ kinetin. Anthers were inoculated in petri dishes on Ct inductive medium and cultured for 8 days in darkness at 35^{o}C. Then, they were transferred to light (12 h light/12 h darkness photoperiod) and 25 ^{o}C for 4 more days. At day 12, anthers were transferred to R_1 medium supplemented with 0.01 mg/l kinetin, where they were cultured indefinitely at 25 ^{o}C, with medium refreshing every 20 days.

Results and Discussion

The results of androgenic response of different pepper genotypes are presented in Table 1 and Figure 1. On the inductive Cp medium were incubated 555 anthers from Edita, 619 anthers from Bela Duga and 640 from Homera with mean anther length of 3.3; 3.3 and 3.2 mm, respectively. The cultivated anthers of three varieties responded with callus formation with different percentage as Edita (12.7%), Bela Duga (11.6%) and Homera (17.2%). The percentage of embryogenic anthers varied from 0.22% for Bela Duga and 2.3% for Edita. Only for the variety Edita there was successful regeneration of 5 embryo into plants. As expected, the anthers of the hot variety Homera did not responded with embryo formation.

Table 1. Androgenic response of different pepper genotypes (*Capsicum annuum* L.) incubated on Cp medium + 0.01 mg·l^{-1} kinetin and 0.01 mg·l^{-1} 2.4-D (+35 ^{o}C, 8 days in darkness).

Species / Variety	Total cultured anthers	Mean length of anthers (mm)	Callusogenic anthers (%)	Embryogenic anthers (%)	Regenerated androgenic plants
Edita	555	3.3	12.7	2.3	5
Bela Duga	619	3.3	11.6	0.22	/
Homera	640	3.2	17.2	/	/

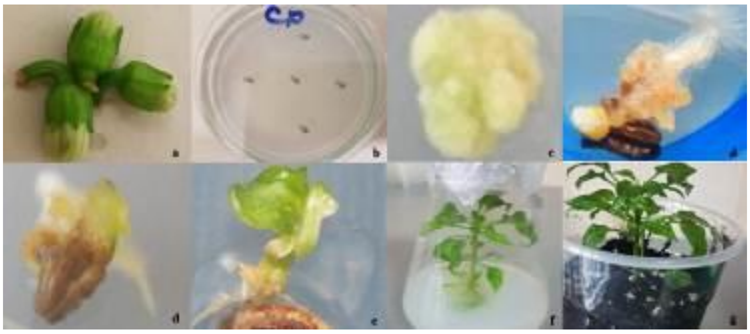

Figure 1. a) pepper buds collected for anther isolation b) anthers inoculated on R_1 medium developing c) callus developed from anther d) emerging androgenic embryo e) fully developed androgenic embryo f) regenerated androgenic plant on V_3 medium g) acclimatized androgenic plant.

According to Koleva-Gudeva *et al.* (2007a,b), the process of embryo formation on different media under different thermal conditions showed that the formation of haploid embryos occurred only in the CP medium exposed to heat thermal stress (+35 ^{o}C) and hot pepper genotypes are low in androgenic response which is in agreement with our results findings (Koleva Gudeva *et al.*, 2007a). Even with difficulties and low efficiency of pepper, there are several laboratories that successfully applied pepper androgenesis and fully regenerated androgenic plants which are characterized either phenological or/and molecular as the Hungarian group (Mitykó and Gémes Juhász, 2006); the Macedonian group (Trajkova, 2013; Trajkova and Koleva Gudeva, 2017); the Bulgarian group (Todorova *et al.*, 2013); the Korean group (Luitel *et al.*, 2012) and the Polish group (Olszewska *et al.*, 2015; Nowaczyk *et al.*, 2015).
The results of androgenic response of different tomato genotypes are presented in Table 2 and Figure 2. On inductive MS medium were incubated 80 anthers from Bellfort, 49 anthers from Rally and 64 from Policarpo with mean anther length of 2.4; 3.0 and 3.5 mm, respectively. The anthers of these three varieties responded with callus formation with different percentage as Bellfort (63.8%), Rally (28.6%) and Policarpo (28.1%). There was no embryo formation from tomato anthers from all three varieties, consequently no regenerated androgenic plants.

Table 2. Androgenic response of different tomato genotypes (*Lycopersion esculentum* Mill.) incubated on MS medium + 1 $mg \cdot l^{-1}$ 2ip and 2 $mg \cdot l^{-1}$ IAA (+25 °C, 1 month in darkness).

Variety	Total cultured anthers	Mean length of anthers (mm)	Callusogenic anthers (%)	Embryogenic anthers (%)	Regenerated androgenic plants
Bellfort	80	2.4	63.8	/	/
Rally	49	3.0	28.6	/	/
Policarpo	64	3.5	28.1	/	/

Figure 2. a) tomato buds collected for anther isolation b) inoculated anthers on MS medium c-d) calli developing from anthers.

In tomato, anther culture has also been demonstrated possible, but for very few genotypes. Seguí-Simarro (2016) highlight that mostly two key bottlenecks impose strong limitations to the efficiency of double haploids technique in recalcitrant solanaceous crops as induction efficiency and embryo development, where it is widely known that the genotype is the most influential factor. Seguí-Simarro (2016) discussed that only two laboratories have published the complete regeneration of entire tomato plants with a demonstrated haploid or DH origin (Shtereva *et al.*, 1998; Zagorska *et al.*, 2004; Seguí-Simarro and Nuez, 2005, 2007; Corral-Martínez *et al.*, 2011).

The results of androgenic response of one eggplant variety are presented in Table 3. On inductive Ct medium were incubated 144 anthers with mean anther length of 2.4 from eggplant genotype Domaci srednje dugi. The utilized medium and incubation conditions did not induce any response of cultivated anthers.

Salas *et al.* (2011) published successful protocol for eggplant androgenesis where responding anthers produced both calli derived from anther tissue and embryos derived from microspores, suggesting that the protocol established by Dumas de Vaulx and Chambonnet (1982) it's not always a source of androgenic competence among different eggplant genotypes.

Table 3. Androgenic response of eggplant (*Solanum melongena* L.) incubated on Ct medium + 0,01 $mg \cdot l^{-1}$ 2,4-D and 0,01 $mg \cdot l^{-1}$ kinetin (+35 °C, 8 days in darkness).

Genotype	Total cultured anthers	Mean length of anthers (mm)	Callusogenic anthers (%)	Embryogenic anthers (%)	Regenerated androgenic plants
Domaci srednje dugi	144	2.4	No response	No response	/

However, our results showed that the same protocol did not worked for the eggplant genotype Domaci srednje dugi and no anthers response was reached. On the other hand, Rivas-Sendra *et al.* (2017) evaluated androgenic capacity through microspore culture of the eggplant commercial F1 hybrid Bandera and its first and second generation of DHs and obtained a population of 80 DH individuals via microspore cultures. These findings show that beside the genotype, cultivation medium has the main role in positive androgenic response in eggplant, as well as thickness of eggplant anther walls and heterostyly, which might delay the access of inductive factors to the anther locule, thus reducing their effect over inducible microspores (Salas *et al.*, 2012).

Conclusions

The low androgenic rate in pepper and no androgenic response in tomato and eggplant, as shown in our experimental results, are one more confirmation that these solanaceous crops are still far from an efficient and reliable technology to be applied on a routine basis in breeding programs. Even with the incredible importance of this family for agriculture, double haploid technology is not yet competently applied in these crops and they appear to respond to androgenic induction very differently.

Abstract

In the total agricultural area of the Municipality of Ivanjica, natural grasslands predominate and they are present at about 64.3% of these surfaces. Depending on the way and intensity of the use in the soil, dynamic processes are taking place that lead to changes in structure, fertility, and microbiological activity. Microorganisms are key players in the cycling of organic matter and nutrients, their activity contributes to a wide variety of soil ecosystem functions, including and the emergence of soil structure. They are the most numerous group of organisms in overall metabolic activity of soil and represent good indicators of soil health, since they respond quickly to changes in soil ecosystem. The total number of microorganisms represents one of the indicators of the biogenicity of soil. Chemical composition of soil and the total microflora, as well as the floristic composition of 15 natural grasslands were determined. Examined soil samples had humus contents ranging from 1.43 to 4.85 % and acidic chemical reaction, except for one sample which pH was KCl 6.55. The total number of microorganisms ranged from 5.602 to 6.322 (log of number) of absolutely dry soil. The examined grasslands have different percentage of presence of grasses, leguminous and plants from other families.

Keywords: *total microflora, floristic composition, grasses, legumes*

Introduction

The territory of the municipality of Ivanjica lies in the south- west of Serbia, covering a part of the Moravički distict also known as. Stari Vlah and Raška plateau. A large part of Ivanjica municipality, excluding the valleys of the river, occupy grasslands that are very important primarily, which represent an important source of food for domestic and wild animals, and therefore a prerequisite for the development of livestock production is necessary. In addition, they are also important from the aspect of environment preservation, represent the habitat of many plant and animal species, the source of medicinal substances used in pharmacy, and they prevent soil erosion, etc. (Babić *et al.,* 2016). Their production potentials are different and under the influence of numerous factors. Dominant influences are the soil, precipitation level and management (Lazarević *et al.*, 2003).

Interactions between plants and soil microbes play an important role in structuring terrestrial ecosystems by influencing plant growth and competitive ability. Soil microbial communities can respond rapidly to changes in the environment (Meisner *et al*.,2013) and changes in the composition of the soil microbial community influence plant species, it can lead to changes in plant community composition (Hawkins and Crawford, 2018). Plant and microorganisms are indivisible whole. Microorganisms in their metabolic processes excrete a variety of biotic substances into their environment affecting plants, their growth and development, the process of photosynthesis, resistance to diseases and pests, and therefore, the yield and quality of cultivated plants (Šarčević - Todosijević *et al.,* 2018). On the other hand, plants, over root system, excrete different substances that stimulate the development and activity of rhizospheric microorganisms. They are the source of carbon and energy for rhizospheric microorganisms and their chemical composition and amount depend on the plant species. The

chemical compositions of the compounds differ from species to species of both plants as well as microbes. Also, the physiological status of plants affects the chemical composition (Huang *et al.*, 2014; Mitra *et al.*, 2019). Soil microorganisms are the main players in the nutrient cycling in soil systems, and soil microbial community structure has been shown to be influenced by both abiotic and biotic factors. Among the deterministic processes governing the composition of microbial communities, environmental factors such as soil pH, temperature and moisture are considered to be main drivers of microbial community assembly (Castro *et al.*, 2010; Kaiser *et al.*, 2016).
The aim of this investigation was to examine floristic composition and the total microflora in the soil of natural and sown grasslands in the Ivanjica municipality area.

Material and Methods

In August of 2018 soil samples from 15 natural and sown grasslands at altitudes between 703 m and 1239 m were taken for microbiological analyses from a depth of 0-25 cm. Thirteen samples were taken from natural grasslands and marked with N1 to N13, while two were from sown grasslands and had codes A1 and A2.
These grasslands located on the territory of the Municipality of Ivanjica. Soil sampling was carried out in three sites from different parts of one location, they are mixed and present as one sample. The chemical properties of the soil were determined by standard methods in the chemical laboratory of the Institute for Forage Crops Kruševac. From each grassland samples of green fodder were collected and the percentage of grasses, legumes and other species were analysed according to the Flora of Serbia (Josifović, 1970-1977).
Biological activity of the soil of grasslands was monitored on the basis of presence the total number of microorganisms. In the lab, each of the samples was analyzed in three repetitions. Total number of microorganisms was established with standard microbiological methods of introducing a certain specific quantity of soil suspension diluted 10^{-5}, method of agar panels (Pochon and Tardieux, 1962). The incubation lasted for five days on 28°C. The number of grown colonies was calculated per 1 g of absolutely dry soil (Jarak and Djurić, 2006).
The results were processed by means of STATISTICS 8.0 computer program, using Fisher's LSD test.

Results and Discussion

Based on the pH value, one could say that tested soils are acidic, between 3.79 and 4.92 and only one of the analyzed soils from one artificial grassland (A1) showed a neutral reaction (Tab. 1). The chemical reaction of the soil has a strong influence on the growth of plants, the regime and biological availability of nutrients and the way that the ions from nutrients reach the root of the plant. Soil pH is one of the most important soil properties related to the composition of microbial communities (Baah and Anderson, 2003). In a large sampling study including 150 forest and 150 grassland soils Kaiser *et al*. (2016) found soil pH as the best predictor for bacterial community structure, diversity and function.
According to the content of humus, nitrogen, potassium and phosphorus soil samples from different grasslands were under different among themselves (Tab. 1). The largest number of samples were characterized by the average content of humus, which is favorable from the aspect of the number and activity of the soil microflora. Microbial metabolism in soil is limited by the availability and types organic substrates, and the quantitative and qualitative differences in substrates between grasslands are responsible for the variation in microbial community (Moussa *et al.,* 2007). The sampled soils were relatively well provided by nitrogen and easily soluble potassium. The content of easily available phosphorus in the grassland soils, covered by our research, was generally low, which is directly related to the acidity of the soil. The application of adequate agro-technical measures creates conditions for

maintaining microbial population and increasing the capacity of these microorganisms for the mobilization of phosphorus (Jarak and Čolo, 2007). Phosphorus dynamics in soil is closely related to the dynamics of the biological cycle in which microorganisms play a central role (Wakelin *et al.*, 2004).

Table 1. The chemical composition and the total microflora (log of number) of studied soils

The samples	pH		N	P_2O_5	K_2O	Humus %	Total number of microorganisms
	H_20	KCl	%	mg/100g	mg/100g		Log of the number
N1	5.61	4.01	0.193	4.20	4.37	3.35	5.602 ^{n}
A1	7.17	6.55	0.359	15.30	225.2	4.87	6.322 ^{a}

N13	4.96	3.96	0.136	4.20	7.94	4.85	5.699 ^{m}

Note: Mean values with the same superscript(s) are not significantly different according to Fisher's LSD test ($p < 0.05$)

In our study the total microflora in soil samples from varied from 5.602 to 6.322 (log of number) per one gram of absolutely dry soil (Tab. 1). According the results of Fisher's LSD test, samples of soil among themselves shows statistically significant differences presence the total number of microorganisms. The vast differences in the composition of soils, together with differences in their physical characteristics and the agricultural practices by which they are cultivated, result in corresponding large differences in the microbial population both in total number microorganisms. many of the world's natural grasslands are in poor condition and showing signs of degradation (O'Mara, 2012). According to Grayston *et al.* (2001, 2004) comparing microbial community structure under different vegetation communities has established that microbial diversity is greater in unimproved than improved grasslands.

Distribution, quality and botanical composition of pastures and meadows largely depend on the management, whereas excessive utilization, such as over-grazing and fertilization at one point, and abandonment from the other, cause dramatic effects on floristic and vegetation diversity (Dajić - Stevanovic *et al.*, 2010).

Distribution (in %) of grasses, legumes and other plant species in studied grasslands

The samples	Family	Percentage	The most common species
N1	Grasses	18.49	*Agrostis capillaris, Anthoxantum odorattum, Festuca ovina*
	Legumes	16.41	*Trifolium pannonicum, Trifolium campestre, Trifolium pratense, Genista sagittalis*
	Other	65.10	*Stachys officinalis, Plantago lanceolata, Hypericum perforatum, Euphrasia stricta, Moenchia mantica*

N13	Grasses	53.54	*Agrostis capillaris*
	Legumes		-
	Other	46.46	*Polypodium vulgare*

For agronomic purposes, all species that participate in the floristic composition are classified into grasses and legumes and a group of other species (Stošić and Lazarević, 2007). Localities of the examined area differ in floristical composition and thus in capabillity in animal nutrition (Tab.2). The percentage of legumes and other plant species in the green matter yield indicated the state of the grassland, primarily the degree of degradation of these areas. Grasslands in this area have leguminous species from 2 % to 17.2 I% and presence of plants of this family at two locations was not recorded. Đurić *et al.* (2007) was recorded the distribution of legumes ranged from 6.73% to 34.12% on grasslands of the Moravicki District. The percentage of species from the Poaceae family anges from 18.49 to 83, while the group of other species present with 5 % to 65.10 %. Acoording to Grynia and Krysza (1998) environmental factors as well (precipitations, temperature, soil fertility) can affect the floristic composition of grasslands and their yield and quality.

Conclusions

Results of this study shown that the presence of microorganisms in the tested soil samples is influenced by numerous factors and that each soil provides different conditions for the life of the microbes. Grasslands in this area have a basic role in the production of fodder and provide important ecosystem services, including erosion control. In order to ensure adequate conditions for the development of the root system of plants and the activity of soil microorganisms, phosphatization and calcification measures should be applied.

Abstract

Quinoa (*Chenopodium quinoa* Willd.) is considered as a very important agricultural crop due to its nutritional value and tolerance to different stress factors. The aim of this study was to investigate the differences in yield, the content of starch and protein in the seed of two introduced genotypes of quinoa (Puno and Titicaca) and the possibility of their cultivation in Serbian agroecological conditions. The experiment was carried out during the 2017 growing season in the rain-fed condition in Subotica, Republic of Serbia. The seeds were sowed in the first part of April. Sowing was done at a depth of 2 centimeters, the distance between the rows was 50 cm and between the plants in the row 5 cm. The crops were harvested in the first half of August when quinoa seeds were mature and the amount of moisture in seed was 12%. The harvest of Puno and Titicaca seeds was made by hand. The content of crude proteins was determined according to the Kjeldahl method, while for starch measurement the Ewers polarimetric method was used. Obtained results showed that the yield of plants Titicaca genotype (24.4 g/plant) was higher compared to the yield of plants Puno genotype (21.3 g/plant). Our results did not show significantly different values in protein content between the seeds of Puno (14.1%) and Titicaca (14.0%). Also, the seeds of Titicaca and Puno contained similar starch content (54.1 and 55.6%, respectively). These results indicate that both investigation genotypes can be grown in Serbian agroecological conditions.

Introduction

Quinoa (*Chenopodium quinoa* Willd.) is a pseudocereal plant, belonging to the family Amaranthaceae, native to the Andean regions of South America. Quinoa being adaptable to different types of soil and climatic conditions and to adapt to different abiotic stress conditions including frost, drought, salinity (Jacobsen and Muica, 2002; Jacobsen, 2017). Furthermore, the crop has a remarkable adaptability to different agro-ecological regions. It can grow at relative humidity from 40% to 88%, and withstands temperatures from -4 °C to 38 °C. It is a highly water efficient plant, is tolerant and resistant to lack of soil moisture, and produces acceptable yields with rainfall of 100 to 200 mm (Valencia-Chamorro, 2003). In comparison to most cereals, quinoa seeds have a higher nutritional value (Matiacevich *et al*., 2006). The nutritional values of quinoa are the result of high content of minerals, vitamins, proteins and essential amino acids, high quality fatty acids, antioxidants and other important multiple bioactive compounds (Vilcacundo and Hernández-Ledesma, 2017). The nutritional value of quinoa seeds is reported to meet, and even surpass, that recommended by the World Health Organization (Hirose *et al*., 2010). It is known that quinoa has considerably positive effects on metabolic, cardiovascular, and gastrointestinal health in humans. The protein content of quinoa seeds varies from 8% to 22%, which is higher on average than that in common cereals such as rice, wheat, and barley. The storage reserves of proteins in the seeds are mainly located in the reduced endosperm and the cotyledons (Valencia-Chamorro, 2003), while carbohydrate reserves are found in the perisperm, nominated as seed storage tissues

(Prego *et al*., 1998). Agronomic research, including the plant density, potential ultivation, phenology, morphology, physiological maturity, yield, and weeds control, should be performed. Production of quinoa has been prevalently conducted in Bolivia and Peru and still is with small productions in other Andean countries like Ecuador, Chile, Argentina, and Colombia. Jacobsen (2003) and Pulvento *et al*. (2010) has been investigated quinoa adaptability to both northern and southern European conditions. Many other countries are performing tests on quinoa with very promising results. Growing period of quinoa varied between 70 to 200 days (Kenya 65-98 days, Denmark and Sweden 120-160 days, Greece 110-160 days) (Ramesh *et al*., 2017). The highest yield of 7.500 tons/ha was recorded in Lebanon closely followed by Egypt 3.872 tons/ha, while lowest yield was recorded in Mauritania 0.230 tons/ha.
The aim of this paper is present the possibility of cultivating quinoa and achieving satisfactory yields and quality (protein and starch content in the grain) in the agroecological conditions of Serbia.

Material and Methods

The experiment was carried out during the 2017 growing season in rain-fed conditions, using two introduced genotypes of quinoa adapted to the European climate, Puno and Titicaca. Used genotypes selected at the University of Life Sciences in Copenhagen, Denmark (Jacobsen and Muica, 2002). The quinoa was grown on Serbian farm near Subotica, located in Vojvodina, northern Serbia. The soil type was chernozem, medium rich in nitrogen (0.24%) and hummus (3,19%), highly rich in phosphorus (34.68 mg P_2O_5 per 100 g of soil) and rich in potassium (29.42 mg K_2O per 100 g of soil), slightly alkaline (pH 7.6). The analysis showed that the nutrient content of the soil was satisfactory and fertilizer wasn't applied during the vegetative season. The seeds were sowed in the first part of April. The experiment was laid out in a split-split plot system, with four replications. The size of the main plot was 12 m^2. The distance between the rows was 50 cm and between the plants in the row 5 cm (approximately 400 000 seeds per hectare). The seeds were sown at a depth of 2 centimeters. The crops were harvested in the second half of August when quinoa seeds were ripeness, the moisture content was 12%. The height of plants, plant fresh weight, number of flower branches and yield was measured. All investigated parameters were calculated on the basis of 120 plants. The seeds were ground by using a laboratory mill (model Cemotek Sample Mill Foss, Sweden) and then the contents of proteins and starch were analyzed. The content of crude proteins was determined according to Kjeldahl method (Stikić *et al*., 2012), while for starch measurement the Ewers polarimetric method was used (ISO 10520: 1997). The temperature data was obtained from the automatic meteorological station located in the center of Subotica (4-km from the experimental field). The measurements were collected using "Nexus" instruments and "Weather Display" software (http://www.sumeteo.info). The amount of precipitation was measured on site, at the experimental field.
Monthly reviews of average air temperature and total precipitation are represented in Table 1.

Table 1. Climate conditions during the 2017 growing season.

	Average temperature (°C)	Total precipitation (mm)
April	11.2	35
May	17.1	38
June	22.1	35
July	22.8	44
August	23.3	33

Results and Discussion

In the territory of Serbia, there is a tendency to increase the air temperature as well as the number of tropical days (Ruml *et al*., 2017). Growing period of quinoa in Serbia is from beginning of April to the second half of August (about 140 days). The growing season 2017 in the Palić (Subotica) area features a temperatura mean of 18.9 ºC and a total rainfall of 245 mm. A comparison with the perennial average (1971-2000) shows that the growing seasons of 2017 were warmer, which was most pronounced during July and August (Table 1). Regarding the amount of precipitation, the growing season 2017 has been very dry. August was the warmest (23.3ºC), with the least rainfall (33 mm). Growing season 2017 is characterized by a pronounced deficit, higher than the average in the area of Serbia, which is 286 mm (Matović *et al*, 2013). The quinoa's need was as much as 534 mm higher than the incoming rainfall.
Results of plant height, plant fresh weight, number of flover branches and yield two genotypes (Titicaca and Puno) are presented in Table 2.

Table 2. Plant height, plant FW, number of flover brances and yield of two investigation genotypes (Titicaca and Puno)

Genotype	Plant height (cm)	Plant fresh weight (g)	Number of flower branches	Yield (g/plant)
Titicaca	139.43	134	13	24.35
Puno	122.78	96.6	16	21.33

Our results did not showed the big variation between Titicaca and Puno plants in investigation parameters: plant hight, plant FW, number of flower branches and yield (as the most important parameter). Average yield of Titicaca plants was 24.35 g/plant (4.9 tons/ha), while the average yield of Puno plants was 21.33 g/plant (4.3 tons/ha) (table 2). If we compare the yield obtained in our agro-ecological conditions to other countries (Kenya 4 tons/ha, Greece 2 tons/ha) (Ramesh *et al*., 2017), it can be considered a high yield. Compared to the conventional cultures involved, quinoa production could be more cost-effective in existing agro-agroecological conditions. For example, corn and quinoa record a similar yield per ha. Higher economic cost-effectiveness of quinoa production lies in the cost of cost. In Serbia, in 2017, the same price of corn was recorded, and in 2010 it was 0.13 eur/kg, which is approximately 35 times lower than the quinoa price. Between 2006 and early 2013, quinoa crop prices have tripled. In 2011, the average of quinoa crop price was 3,115 USD per ton with some varieties selling as high as 8,000 USD per ton (Ruiz *et al*., 2014).
We have compared Puno and Titicaca cultivars and found similar percentages of proteins (14.1 and 14.0%, respectively) (Czekus *et al*., 2019). Similar protein content in grain Puno and Titicaca quinoa genotypes (14.7 and 14.4%, respectively) was found Aluwi *et al*. (2017) The main carbohydrate component of quinoa is a starch and in our research the seeds of Titicaca and Puno contained similar starch content (54.1 and 55.6%, respectively) (Czekus *et al*., 2019). According to Aluwi *et al*. (2017), a higher percentage of quinoa seed starches was detected in Puno (62.6%) than in Titicaca (56.4%). In general, as for the Titicaca cultivar, the total carbohydrate represents the main seed component at approximately 54-57%, according to the study of Pulvento *et al*. (2012).

Conclusions

In conclusion, our study demonstrated that quinoa cultivars Puno and Titicaca has grown in Serbia (Southeastern European agro-ecological conditions), gave a very satisfactory yield, as well as the starch and protein content in the seed, in the year with a high precipitation deficit. With their introduction in production, given the current prices of quinoa seed, high profits could be achieved. Quinoa is a plant species extremely tolerant to drought and its cultivation could contribute to overcoming the increasingly negative effects of drought on agricultural production in Serbia.

Abstract

Improvement of animal feed production and animal husbandry, particularly beef and sheep production, is interrelated with natural and sown meadows and pastures in hilly - mountainous region. High quality of forage has positive effect on profitability of milk and meat production and it is prerequisite for improvement and reduction of costs in livestock production. Because of that, the main role of grassland is to ensure a supply of livestock production as a source of healthy and safe animal food and that way they have strong contribution to rural agricultural and economic development. Grasslands in this area are preserved from the use of large amounts of mineral fertilizers and chemicals for plant protection, because of what production of healthy and safely animal food, with minimal investments, is still possible. The presence of useful and high quality species in grasslands enables the production of high quality biomass. One of the possibilities for improving the quality of biomass is to increase the percentage of quality plant species in grasslands. For this reason, research was carried out on the territory of the Pešter highlands were is collected 61 samples from natural grasslands on altitude of 1200 to 1300 m and determined botanical composition and dry matter quality. Natural grasslands analyzed in these research had an unsatisfactory botanical composition and low quality of dry matter. From analyzed samples, 54.1% showed low dry matter quality with less than 8% of the crude protein content, 37.7% samples contained 8-11%, and 8.2% samples contained 11-14% of crude protein.

Key words: *natural grasslands, botanical composition, quality, crude protein content.*

Introduction

Grasslands are the largest ecosystems in the world (Suttie et al., 2005) and representing more than 40% of the terrestrial areas, excluding Greenland and Antarctica. In Serbia, natural grasslands are the most important source of voluminous livestock feed in hilly mountainous regions. Also, they are important component of the environment, particularly in terms of conservation of biodiversity (Dajić Stevanović et al., 2010) and protection of soil from degradation and erosion. Natural grasslands are the most widespread in hilly mountainous region in Serbia. With altitude increase, the share of grasslands in the total agricultural area increases. The participation of grasslands in hilly mountainous regions is from 30 to 60% of the total agricultural land. In this area natural grasslands present main or only source of livestock feed. Intensive researches of methods and possibilities for improvement of livestock feed production on natural grasslands in Serbia have been initiated during fifties and sixties of the twentieth century. In previous period most researches were focused on the effect of fertilization on yield, botanical composition, dry matter quality, conservation on biomass from natural grasslands, etc. (Lazarević et al., 2005; Stošić et al., 2005; Tomić et al., 2005; Tomić et al., 2009). Natural grasslands are not fully exploited (average yield on natural grasslands is below 2 t ha^{-1} on meadows and about 0.5 t ha^{-1} on pastures), which is confirmed by numerous results obtained in previous period which have shown that production on the grasslands can be considerably increased in short time without big investments, with preserving the natural balance and without disturbing the environment. On natural grasslands is possible to produce over 4 t ha^{-1} dry matter yield (Vučković et al., 2005), and 7-10 t ha^{-1} on sown grass-leguminous mixtures (Lazarević et al., 2005). However, some natural grasslands are in most cases neglected, with low level of utilization. On Pešter highlands, share of natural grasslands in total agricultural lend is more than 60%, which indicates their great importance in this region. This area is characterized by typical climatic conditions with long and cold winters, low average temperature and short vegetation period.

Aims of this investigations was to determine to botanical composition (share of species of two the most important families, grasses and legumes, and group of other species) and dry matter quality of biomass collected on grasslands on Pešter highlands. Presence of legumes on grasslands is indicator of their quality and specific soil traits. Based on this, it is possible to determine appropriate agro-technical measures, especially mineral fertilizers, that can be used for improvement of forage yield and quality. Productivity on grasslands is possible to increase by application of fertilizers, especially nitrogen (Stošić et al., 2005), but this can change botanical composition and decrease presence of legume component in grasslands, which will lead to a decrease of forage quality (Salis and Vargiu, 2008). Only usage of balanced fertilizers will resulted in full contribution and will have the greatest influence on productivity and quality of grasslands on Pešter highlands. In this way, the direct effect on increase of milk and meat production is achieved, as well as final livestock products.

Material and methods

In August 2018 samples from 61 natural grasslands were taken for analyses. All sites are located in the territory on the Pešter highlands (southwestern Serbia) at altitudes between 1 200 and 1 300 m. Botanical composition was determined from sample of 1 m^2 from which plants were cutted and aboveground biomass is collected. In each sample the plants from the same botanical family are separated from total biomass and weighed and percentages calculated. Plants were separated per categories: quality grasses, quality leguminous and useful and conditionally useful species from other families, according to Kojić, 1990 and 2001. Dry matter quality (crude protein, fat, ash, ADF and NDF) were determined in the laboratory of the Institute for Forage Crops, by the Weende system.

Results and discussion

Grassland management has a decisive influence on the production capacity and floristic composition of grasslands. The grasslands from which the samples were taken are managed in a traditional way, but with a reduced number of domestic animals compared to the earlier period. In these grasslands, a small amounts of mineral fertilizers are used or this measure does not apply at all. The cutting is done usually very late, and after that the areas are left to the grazing of cattle or sheep. Considering the fact that the number of domestic animals on grasslands is significantly lower than in the previous period, in the biggest part of the grasslands no one of agrotechnical measures was applied.

According to results presented in Table 1, the largest number of analyzed samples had the highest percentage of species from *Poaceae* family (on average the share of grasses was more than 77%), while the share of legumes, as a carrier of dry matter quality, was lowest, only 12%. Species from other families are represented on average by 17% on natural grasslands on Pešter highlands.

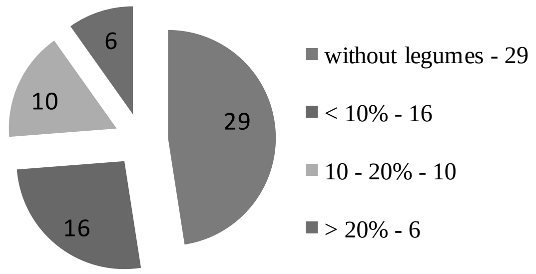
*KP – kadastar plots

In this study, on average, the share of legumes in analyzed samples from a natural grasslands from Pešter highlands, as a carrier of quality is very low (Chart 1). Of the 61 samples, 29 were without legumes, 16 contain less than 10% of plants from this family, 10 contain 10-20%, while over 20% of legumes are found in only 6 samples.

The share of plant species from other families is relatively satisfactory considering the fact that in these natural grasslands agrotechnical measures were applied at the minimum or did not applied. The greatest number of samples (29) had less than 10% plant species from other families, 12 samples had 10 to 20% of these species, 17 samples were with over 20% and only 3 samples did not contain unwanted plant species.



Graf. 1. Share of legumes

Botanical composition of analyzed grasslands in the best way illustrates how the way in the management and use of grasslands affects their productivity and quality. On grasslands with organic and mineral fertilizers application, plants are more productive, they contain a higher percentage of legumes and less species from other families. On poorly maintained grasslands dominated rough grass species, weeds and other undesirable species.
The largest number of biomass samples had less than 8% crude protein content (33 samples or 54,1%), 8-11% crude protein content had 23 samples, respectively 37,7%, and 11-14% was found in only 5 samples of biomass (8,2%), Table 2. High levels of precipitation during June and July 2018 did not allow timely cutting, which affected low quality of biomass in the analyzed areas.

Table 2. Quality of biomass from natural grasslands (% in absolutely dry matter)

Forage quality from the analyzed natural grasslands is not at the satisfactory level. The main reason for the poor quality of biomass is late cutting and a large amount of precipitation during the vegetation season. With late cutting, the share of structural carbohydrates (ADF and NDF) increases, which reduces the digestibility and nutritional value of forage. According to fact that first cut, in hilly mountainous regions, participates with two thirds to 90% in total production, it is necessary to make compromise between yield and quality (Lazarević et al., 2010). The main problem in forage production is the low level of crude protein which is usually compensated by concentrated nutrients or is not compensated at all, so the production of milk and meat is at a very low level. Addition of protein in the form of concentrates makes production more expensive and increases the cost unit of end products in total costs.

Conclusion

In order to revitalize livestock production it is necessary to implement the agrotechnical measures to improve natural grasslands as the most important source of voluminous livestock feed in hilly mountainous regions in Serbia. An easy way to improve the forage quality is earlier cutting, approximately, at the beginning of heading the dominant grass species on the grassland and increasing the share of legumes in grasslands. Low level of legumes in grasslands is possible to increase by application agrotechnical measures like in-sowing, balanced fertilization, the way of utilization, adequate melioration measures, etc. In this way is possible to improve current quality on natural grasslands.

Abstract

Mineral concentrations in forages vary greatly, and are affected by soil mineral level, soil pH, plant species, stage of maturity, and application of fertilizers or waste materials. Soil tests are not useful in determining some mineral levels and are only good at predicting growth responses from applied P and K when test levels are very low. Plant tissue test is very reliable for minerals regardless of growth stage, but is not as reliable in predicting P and K responses with alfalfa sampled from early bud to 1/10 bloom. The aim of this study was evaluating the nutrition status of the alfalfa regarding to the best results of alfalfa dry matter yield. The samples were collected at three stages of alfalfa growth: early bud, full bud and at the beginning of flowering - 10% of bloom. 40-60 stems including leaves were collected from at least 30 plants. The top third samples were discarded and dried. Top third samples were analyzed for nitrogen, phosphorus, potassium, calcium, magnesium, sodium, iron, zinc, mangan, boron and sulphur regarding to DMY (dry matter yield) of alfalfa at different stages of growth. Results of investigation showed that alfalfa top had sufficient amount of nitrogen, phosphorus, potassium, calcium, magnesium, sodium, iron, zinc, mangan, boron and sulphur in all stages of growth, but it was deficient in potassium at full bud stage and zinc at the begining of flowering.

Keywords: *alfalfa top, mineral concentration, dry matter yield*

Introduction

Mineral concentrations in forages vary greatly, and are affected by soil mineral level, soil pH, plant species, stage of forage maturity, and application of fertilizers or waste materials. Forage mineral concentrations are of limited value in assessing mineral status of ruminants, because little is known regarding availability and factors affecting availability of minerals in ruminants fed forage diets (Spears, 2003). The relatively high solubilization of forage minerals in the rumen suggests that, in most instances, the release of minerals in a soluble form is not a major factor limiting absorption. Interactions of minerals with other minerals, other plant constituents, and microbial cells following solubilization appear to be more important as regards mineral absorption (Khan et al., 2007).

Due to the economic and agronomic importance of alfalfa, a considerable amount of inorganic fertilizer is applied to this crop (Gardner et al., 2000; Koenig et al., 1999). Determining when applications of phosphorus, potassium, sulfur and boron are needed is important to insure adequate alfalfa yield and quality. Therefore, some form of soil and tissue testing program must be used to identify deficiencies and monitor the nutrient status of alfalfa over time (Koenig et al., 2001; 2002; Mortvedt et al., 1996). Improvements in forage production have the potential to increase income and significantly reduce livestock production costs. Rotating forages with annual grain crops can increase grain yields, reduce weeds, improve soil quality, and reduce system energy requirements (Entz et al., 2002). Soil fertility is important for forage production, stand health/longevity, and forage quality (Smith et al., 2007).

Adequate amounts of P, K, S and B are necessary for healthy root growth, withstanding drought and winter stres, high quality forage, and N fixation in legumes. Soil testing helps fine-tune nutrients needed for early growth and identify possible limitations for establishment. Because P and K are relatively immobile, they should be placed in the root zone. If soil P and K are below critical levels, soil P and K levels should be build up prior to planting by incorporating broadcast fertilizer. Unfortunately, soil tests for sulfate-S are not a reliable indicator of plant available S. Therefore, plant tissue analysis is the best tool to determine S status and a valuable tool for in-season management of other nutrients. The critical tissue nutrient concentration is the level at which approximately 90-95 percent of maximum yield is obtained and varies with growing conditions. Because tissue concentrations change with plant maturity, it is important to sample the correct tissue at the correct time. Plant and soil samples taken from an affected area can be compared to healthy samples to help identify a limiting nutrient (Meyer et al., 1997).

The aim of this investigation was to determine the level of some nutrients such as macrominerals and microminerals in the soil and in the same time to investigate the levels of those nutrients in the top alfalfa samples taken at the different growth stage. These data should be used as tool for fertilizer application if it is necessary for achieve high yield and forage quality.

Materials and methods

The experiment was designed with three replications according to a randomized complete block. Alfalfa was grown at the experimental field of Institute for forage crops, Kruševac – R Serbia (21° 19' 35" E, 43° 34' 58" N). The study area was situated at altitude of 166 m above sea level in Central Serbia.

Soil and plant material were sampled in May 2015, which was the second production year of alfalfa. In pre-arranged field preparation, NPK 15:15:15 fertilizer was broken up in an amount of 300 kg ha^{-1}. Soil samples were collected in disturbed state using agricultural probe from 0-30 cm depth. One composite soil sample consisted of 15-20 individual samples. The collected samples were air-dried and grinded to particle size < 2 mm according to SRPS / ISO 11464:2004.

Alfalfa (*Medicago sativa* L.) – *cv* K 28 selected at Institute for forage crops, Kruševac was sampled at three stages of maturity I – full bud (harvested on the 04^{th} May – 20 days of vegetation), II - early bloom – 10-15% of flowering (harvested on the 21^{st} May – 32 days of vegetation) and III - mid bloom – 50-60% of flowering (harvested on the 29^{th} May – 42 days of vegetation). 40 to 60 stems from at least 30 plants in each of the parcels were collected. The top alfalfa – 15 cm was analyzed for macro and micronutrients.

Soil pH was determined by potentiometric method according to ISO 10390:2005. Total nitrogen in soil was determined by Khejldal method. Extraction of available phosphorus and potassium from the soil was carried out according to the AL method. Potassium was determined by flame emission on AAS PERKIN ELMER 1100 B, and phosphorus was measured on a HALO RB.10 spectrophotometer at a wavelength of 580 nm. Humus content in soil was determined according to Tjurin method. Calcium carbonate content in soil was determined by volumetric method according to ISO 10693:1995. The soil samples for boron determination were extracted with hot water. The suspension was filtered. The aliquot part of the filtrate was evaporated on an aqueous bath or heated plate with the addition of a sodium hydroxide solution and burnt in a furnance at a temperature of 450° C to destroy the nitrates and the organic substance. The residue was dissolved in 0.5N hydrochloric acid. In the aliquot part of this solution, a colored complex of boron with carmine was developed. The carmine solution in concentrated sulfuric acid is red and, in the presence of boron, turns into a purple-blue color. The color intensity is measured on a HALO RB-10 spectrophotometer at a wavelength of 585 nm. Sulphur was determined gravimetrically according method by

Jakovljević et al. (1985). The concentrations of Na, Ca, Mg, Fe, Zn and Mn were measured by atomic absorbance spectrophotometry - AAS PERKIN ELMER 1100B.
The amount of total nitrogen was measured by the Kjeldahl method on the TECATOR KJELTEC AUTO ANALYZER 1030. The total phosphorus in the plant was determined according to the standard method ISO 6491 with a molybdenum-vanadate reagent, spectrophotometrically. Potassium was determined from the solution by direct measurement of the intensity of the emission at a wavelength of 766 nm, using AAS PERKIN ELMER 1100B. Sulphur in the plant was determined gravimetrically according to the method by Sarić et al. (1967). The determination of boron in plant samples with carmine was based on the formation of a complex boric acid ester with carmine which was purple blue color. The color intensity was measured on a HALO RB-10 spectrophotometer at a wavelength of 585 nm. The concentrations of Na, Ca, Mg, Fe, Zn and Mn were measured by atomic absorbance spectrophotometry. Samples for Ca and Mg analysis were prepared with $1gL^{-1}$ lanthanum.
Study data were processed by the methods of descriptive statistics. Significance of differences between treatments was tested by analysis of variance (ANOVA). The significance of differences between arithmetic means was tested by Fisher's LSD test. Effects were considered different based on significant ($p< 0.05$) F ratio.

Results and discussion

The content of available nutrients in the experimental soil site is presented in the Table 1.

Table 1. The content of available nutrients in the experimental soil site, 0-30 cm depth

Parameter	Unit	Values
pH (H_2O)		6.98
pH (KCl)		5.96
Total Nitrogen	%	0.170
P_2O_5	mg 100 g^{-1}	4.40
K_2O	mg 100 g^{-1}	18.58
Humus	%	2.86
Ca-carbonate	%	0.80
Boron	mg 100 g^{-1}	2.75
Sulphur	mg kg^{-1}	35.66
Calcium	mg 100 g^{-1}	12.08
Magnesium	mg 100 g^{-1}	5.49
Sodium	mg 100 g^{-1}	19.03
Iron	mg kg^{-1}	6.96
Zinc	mg kg^{-1}	5.73
Manganese	mg kg^{-1}	226.0

The results of investigation showed that soil was mild acidic in reaction (pH in suspension of 1N KCl: 5.96); with middle level of total nitrogen (0.170%); low in available phosphorus (4.40 mg 100 g^{-1}); medium in available potassium (18.58 mg 100 g^{-1}) and low in humus content. The soil was high in available S (35.66 mg kg^{-1}) and B (2.75 mg 100 g^{-1}). In general, the fertility status of the experimental site was optimum with few limitations.
Mean alfalfa DMY and mineral concentration in top alfalfa are presented in the Table 2. The harvest time at a certain stage of development significantly influenced the alfalfa DMY. The highest DMY was obtained when the plants had 50-60% of the flowers (5.74 t ha^{-1}), and the lowest when they were in the bud stage (3.78 t ha^{-1}). A large number of investigations indicated that domestic varieties have excellent adaptability to existing in certain environmental conditions which influenced high DMY throughout the period of explaitation

(Lukić et al., 2001; Mladenović et al., 2001; Popović et al., 2003). The results of this investigation showed that concentrations of phosphorus and iron did not differ significantly between stages of growth, whereas concentration of phosphorus increased from 3.93 g kg^{-1} to 4.06 g kg^{-1} and concentration of iron increased from 126.41 to 127.76 mg kg^{-1} from the full bud to mid bloom stage. Although, concentrations of both those elements were above critical levels in top alfalfa (Table 3).

Table 2. Effect of alfalfa growth stage on DMY, macro and microminerals content in top alfalfa (15 cm)

	I stage of growth	II stage of growth	III stage of growth
DMY, t ha^{-1}	3.78^{c}	5.03^{b}	5.74^{a}
Ash, g kg^{-1}	9.92^{a}	8.39^{b}	$9{,}80^{a}$
Nitrogen, g kg^{-1}	49.90^{a}	41.90^{b}	49.65^{a}
Phosphorus, g kg^{-1}	3.93^{ns}	4.00^{ns}	4.06^{ns}
Potassium, g kg^{-1}	23.82^{a}	19.65^{c}	21.39^{b}
Calcium, g kg^{-1}	24.20^{b}	14.46^{c}	27.06^{a}
Magnesium, g kg^{-1}	2.81^{c}	5.85^{a}	3.93^{b}
Sodium, g kg^{-1}	0.75^{a}	0.55^{b}	0.50^{b}
Iron, mg kg^{-1}	126.41^{ns}	126.69^{ns}	127.76^{ns}
Zinc, mg kg^{-1}	42.11^{b}	40.23^{c}	44.94^{a}
Manganese, mg kg^{-1}	41.91^{b}	38.55^{c}	48.71^{a}
Boron, mg kg^{-1}	51.80^{a}	50.55^{a}	44.38^{b}
Sulphur, mg kg^{-1}	4.33^{a}	3.92^{b}	3.64^{b}

Different letters denote significantly different means ($P< 0.05$)

Concentration of nitrogen, potassium and calcium decreased from the first to the second stage of plant growth, and with plant development content of those elements increased. The highest content of nitrogen and potassium were in the first stage of growth, whereas the highest content of calcium was in the third stage of growth (Table 2). Mean top alfalfa nitrogen and calcium content were above the critical level in all samples taken from the different growth stage, but content of potasssium was below the critical level in the second and third stage of growth. Concentration of zinc and manganese also decresed from the first to the second stage of growth and after that increased with plant growth (Table 2), but the concentrations of those elements were above critical level at all samples taken from different stage of growth (Table 3). On the other hand, concentration of magnesium increased from 2.81 g kg^{-1} at the first stage of growth to 5.85 g kg^{-1} at the second stage of growth, and after that decreased to 3.93 g kg^{-1} (Table 2), but the concentrations were above critical level (Table 3). Concentrations of sodium, boron and sulphur decreased with alfalfa growth and development (Table 2), and the results of this investigation showed that the concentration of those elements were above critical levels of nutrients (Table 3).

Table 3. Sufficiency levels of nutrients, top alfalfa – 15 cm, (Meyer et al., 1997).

Nutrients	Low	Sufficient	High
Nitrogen, g kg^{-1}	< 25.00	25.00-40.00	> 40.00
Phosphorus, g kg^{-1}	< 2.50	2.50-4.50	> 4.50
Potassium, g kg^{-1}	< 22.50	22.50-34.00	> 34.00
Calcium, g kg^{-1}	< 7.00	7.00-25.00	> 25.00
Magnesium, g kg^{-1}	< 2.50	2.50-7.00	> 7.00
Sodium, g kg^{-1}	-	-	-
Iron, mg kg^{-1}	< 30.00	30.00-250.00	> 250.00

Zinc, mg kg^{-1}	< 20.00	20.00-60.00	> 60.00
Manganese, mg kg^{-1}	< 20.00	20.00-100.00	> 100.00
Boron, mg kg^{-1}	< 25.00	25.00-60.00	> 60.00
Sulphur, mg kg^{-1}	< 2.50	2.50-5.00	> 5.00

Soil and plant tissue tests have been developed to assess the nutrient content of both the soils and plants. By analyzing this information, plant scientists can determine the nutrient need of a given plant in a given soil. In addition to the levels of plant-available nutrients in soils, the soil pH plays an important role in nutrient availability and elemental toxicity (Uchida, 2000). Plant analysis consist of testing nutrient concentrations in specific plant parts during specific growth stage (Jacobsen and Jasper, 1991). If nutrient concentrations in a sample are below or above on established sufficiency range, then the plant is defficient or in excess for that element. Plant analysis can be performed relatively quickly in the field using semi-quantitative test kits or more extensively in a laboratory (Havlin et al., 1999). As a diagnostic tool, plant analysis improves the chances of making a correct diagnosis and can be particularly useful in identifying hidden hunger or pseudo deficiencies.

Conclusions

Nutrient deficiencies and toxicities cause crop health and productivity to decrease and may result in the appearance of unusual visual symptoms. Understanding each essential nutrient`s role and mobility in the plant can help determine which nutrient is responsible for a deficiency or toxicity symptom. When in excess, many nutrients will inhibit the uptake of other nutrients, thus potentially causing deficiency symptoms to occur as well. According to the results obtained in this investigation we can conclud that soil contained sufficient amount of available nutrients, except the potassium content which was deficient in the second and third stage of growth. So, higher amount of potassium fertilizer could be applied.

Abstract

The paper presents results of examination of various red clover seed lots of the process of cleaning on the seed processing equipment. The experiment was carried out at the seed processing center of the Institute for Forage Crops Kruševac. In the Republic of Serbia, among the perennial fodder leguminous plants, red clover (*Trifolium pratense* L.) occupies the second place immediately after the alfalfa. The seed for planting red clover crop must have high purity, germination and genetic value. These properties of red clover seeds are accomplished by processing, i.e. by removing all impurities and seeds of poorer quality. In order to achieve optimum results during seed processing, each seed lot needs to be carefully analyzed and the machines should be appropriately adjusted. The aim of the study was to show the effectiveness indicators of seed processing in the red clover seeds. The basic indicators of the efficiency of machines in seed processing were the quality and quantity of the seed obtained at the end of the seed processing. The relevant parameters that define the characteristics of seed processing machines were: pure seed (%), weed seed (%), seed of other crops (%), inert matter (%), amount of processed seed (kg), seed losses (%) and processing output (%). On the basis of the obtained results it is possible to select the appropriate equipment, as well as their correct adjustment in the seed processing, depending on the quantity and type of weeds and other ingredients found in the natural red clover seeds. Machines and devices used for seed processing were: intake pit with belt conveyor, belt conveyors, bucket elevators and the fine-cleaning machine. For the separation of weeds used a magnetic separator with rollers.

Keywords: *Relevant parameters, Machines, Red clover, Processing, Impurities.*

Introduction

In the Republic of Serbia, red clover (*Trifolium pratense* L.) occupies the second place in the areas where it is grown, right after alfalfa (*Medicago sativa* L.). Red clover (*Trifolium pratense* L.) is most grown in the area of Sumadija and Western Serbia where it is harvested on an area of 33.883 ha with an average hay yield of 3.0 t ha^{-1} (Statistical yearbook of the Republic of Serbia, 2018). For animal, red clover is used as green fodder plants; as a single crop or as a mixture; for grazing or conservation as hay, silage, or dehydrated as flour, in the form of pellets and briquettes (Vučković, 1999). Red clover is characterized by high yield of biomass, high feed quality and rapid regeneration after mowing. In particular, the leaves are rich in proteins (about 25% in the phase of butonization). It has a high content of provitamin A, vitamin C, D, E, K, B1, B2, B3, as well as microelements - molybdenum, cobalt, boron, copper and manganese (Marković et al., 2007). In comparison with lucerne (*Medicago sativa* L.), red clover (*Trifolium pratense* L.) is better tolerated by acidic soil. It is recommended to cultivate on neutral to slightly acidic soils with low pH (5.5-7), and the soils with worse structure. It can be grown on different types of soils: medium heavy, wet, with medium fertility – brown earth, alluvial and smonitza (Lugić et al., 2000).

The natural seed for seed processing is a very complex mechanical mixture in which there are large and small weeds, parts of organic and inorganic matter and broken seeds. Seed processing, as a part of seeds production, is a very hard work with high energy consumption (Orobinskij at al., 2017). For the seed processing and storage, the physical characteristics of the seed are very important. The most important physical characteristics of the seeds are: humidity, shape, dimensions, sphericality, mass of 1000 seeds, seed volume, porosity of the seed, volume-hectolitic mass, density, static and dynamic angle of internal friction - free fall angle, static coefficient of friction on known surface (Copeland et al., 2004; Black et al., 2006, Đokić and Stanisavljević, 2012; Đokić et al., 2012; Baskakov et al., 2018). The right combination of seed processing equipment is necessary to achieve the best quality of processed seed in the shortest possible time, where the quality of the seed corresponds to the standards for seed (Đokić et al., 2017; 2018; 2019). In red clover, weed species contaminate seeds and can make difficult processes of harvest and seed processing. In particular, there is a detrimental presence of quarantine weed, Dodder (*Cuscuta* sp). This weed belongs to the most dangerous and economically most damaging quarantine weeds in the red clover crop. If it can not be prevented, it causes enormous crop damage (Karagić et al., 2007). Seeds must be of high purity, germination and moisture. The Law of Seeds and Planting Material prescribes all conditions related to the production, processing, use, trade, import and testing of seeds of agricultural plants (Gazette of the Republic of Serbia, No. 45, 2005). The quality of the red clover seeds should correspond to the Rule on the Quality of Seeds of Agricultural Crop Seeds (Official Gazette of SFRY, No. 47/87). The red clover seeds must have a minimum purity of 95%, 2% of other seeds, less than 0.5% of weeds (without *Cuscuta* sp and *Rumex* sp), up to 2.5% inert matter, minimum germination of 70% and maximum moisture of 13%.
The aim of this study was to show the effectiveness indicators of seed processing in the red clover seeds. The basic indicators of the efficiency of machines in seed processing are the quality and quantity of the seed obtained at the end of the seed processing. In the process of seed processing, it is necessary to get as much quality seeds for the shortest possible time, and with the least losses.

Materials and methods

The test was carried out at the seed processing center of the Institute for Forage Crops Kruševac. In three replications, the natural seed of the red clover of seven seed lots with different purity was processed. The content of the weed species was different for each seed lot. The seed processing equipment was manufactured by Danish manufacturers Kongskilde and Damas. Machines and devices used for seed processing were: intake pit with belt conveyor, belt conveyors, bucket elevators, and the fine-cleaning machine type Alfa - 4. In the upper and lower shaker shoe on the fine-seeding machine Alfa-4 there were six sieves arranged in two levels. In the upper shaker shoe were sieves with round openings of diameter: 2.75 mm; 2.5 mm; 2.25 mm; 2.2 mm; 1.9 mm and 1.9 mm. In the lower shaker shoe were sieves with longitudinal-cut openings of width: 1.3 mm; 1.2 mm; 1.1 mm; 0.6 mm; 0.5 mm and 0.5 mm. For the separation of weeds we used a magnetic separator of the German manufacturer Emcek Gompper-type 4. During the test, the steel powder of Nutra Fine was used.
An analysis of the content of basic seed and other ingredients in the red clover seeds was done in a Laboratory for the sample analysis of the Institute's seed processing center. For the analysis of the content of the other matters in the seed samples, a magnifying glass and a precision electronic scale was used. Seed samples for analysis were weighing 5 g (working) and 50 g (average). An electronic scale of measuring range up to 300 kg was used to measure the mass of the natural and processed seeds. During the process of seed processing, the following parameters were measured: quantity of pure seed (%), seed of other species (%),

inert matter (%), weed (%), and amount of processed seed (kg). After seed processing, the processing output (%) and seed losses (%) were calculated. The obtained results were processed by statistical analysis of variance (ANOVA), and the significance of the difference of the mean was tested with the Tukey test. The statistical program Minitab 16.1.0 was used for data processing (statitics software package).

Results and discussion

The purity of the red clover natural seed of seven different lots is shown in Table 1. The smallest seed purity (52.0 %) was for seed lot II, and the highest (88.0 %) was for seed lot V. The purity of seed lot I was 81.0 %. For seed lots III and VI, the seed purity was 78.0 %. Seed lots IV and VII were seed purity of 86.0 %.

Table 1. The average purity of the natural red clover seed

Lot	I	II	III	IV	V	VI	VII	*F test*
Seed structure	%	%	%	%	%	%	%	
Pure seed	81.0 ab	52.0 c	78.b	86.0 a	88.0 a	78.0 b	86.0 a	***
Other species	-	-	-	-	grass		0.6 alfalfa	
Inert matter	19.0 bc	48.0 a	22.0 b	14.0 c harvest residues, empty seed	12.0 c harvest residues, soil	22.0 b harvest residues	13.4 c harvest residues	***
Weed	in 5 g 5 *Cuscuta* sp	in 5 g 4 *Cuscuta* sp	-	Barnyard grass in 5 g 2 *Rumex* sp	in 5 g 2 *Cuscuta* sp, in 5 g 2 *Rumex* sp	in 5 g 40 *Cuscuta* sp, in 5 g 5 *Rumex* sp	barnyard grass in 5 g 40 *Cuscuta* sp	
Total	100	100	100	100	100	100	100	-

Tukey test statistical significance levels: p≤ 0.05, differences in row marked in small letters a, b, c...

Inert materials in the form of harvest residues (stems, leaves, pods), sickly, damaged seeds and soil were from 12.0 % for seed lot V; to the highest values of 48.0 % for seed lot II. In seed lot VII seed of other plant species (grass and seed of alfalfa) was discovered. In the working sample (5 g), the highest presence of the quarantine weed Dodder (*Cuscuta* sp) was founded in seed lots VI and VII (a total of 40 seeds of *Cuscuta* sp). In the seed IV, V and VI there were also seeds of curly dock (*Rumex* sp). In the samples of seed lots IV and VII, there were also Barnyard grass (*Echinochloa crus-galli*).

The purity of the red clover seeds after seed processing is shown in Table 2. During the cleaning, the seed passes through a system of machines that separate impurities such as dry stems, weeds and broken seeds (Uhlarik et al., 2018; Baskakov et al., 2018). After seed processing on the fine- cleaning machine, the seed is processed on a magnetic machine to remove weeds. Seed samples for quality analysis are taken after processing the seed on a magnetic machine (Đokić et al., 2019). The purity of the red clover after passing through the magnetic separator was high and ranged from 98.4% for seed lot I, to 99.0% for seed lots II, V and VI. The content of other plant species, inert materials in the form of sickly seeds and weeds, were within the legally prescribed limits. In the seed lot III three seeds of curly dock (*Rumex* sp) were found in the average sample of 50 g, which is less than the legally prescribed amount (maximum 4 seeds in a sample of 50 g).

Table 2. The average purity of processed red clover seeds

Lot	I	II	III	IV	V	VI	VII	*F test*
Seed structure	%	%	%	%	%	%	%

The quantities of natural red clover seeds at the beginning of the seed processing, as well as the amount of processed seeds at the end of the processing are shown in Table 3. Processing output and seed losses on the processing machines, also calculated and displayed (%). The highest utilization of seed yield (82.59%) was found in the seed lot VII (with initial purity of 86%) with losses on the processing machines of 3.8%. Đokić et al. (2018) obtained the highest red clover seed yield of 80.56%, with at least losses of 7.4% on processing machines (purity 87%). In the examined material, the minimum seed utilization of 46.64% was found for seed lot II. This seed lot, also, had the lowest initial purity of natural seed (52.0%) with the highest content of inert substances (48.0%). The highest seed losses during seed processing (17.34%) were found in seed lot I.

Table 3. Amounts of proceseed red clover seeds on the processing machines

Seed structure	Lot (kg)							*F test*
	I	II	III	IV	V	VI	VII	
Natural seed	1150.0 a	268.0 c	1027.0 a	663.0 b	593.0 b	896.0 b	293.0 c	***
Processed seed	770.0 a	125.0 c	700.0 a	520.0 b	473.0 b	655.0 a	242.0 c	**
Processing output (%)	66.96 b	46.64 c	68.16 b	78.43 a	79.76 a	73.1 ab	82.59 a	**
Losses **(%)**	17.34 a	10.3 bc	12.62 b	8.8 c	9.36 bc	6.28 c	3.8 d	***

F test, statistical significance levels: *p≤ 0.05, **p≤ 0.01, ***p≤ 0.001, ns – not significant (p ≥0.05)
Tukey test statistical significance levels: p≤ 0.05, differences in row marked in small letters a, b, c...

Quantities of natural seed (p≤ 0.05) were significantly higher in the seed lots I and III. For processed seed significantly higher quantity were in lots I, III, and VI. The processing output were statisticaly signifficant in part IV, V and VII, while seed losses were significantly higher the in seed lot I (Table 3).

Conclusions

Based on the obtained research results, it can be concluded that the effectiveness of the seed processing machines depends on the purity of the natural seed, the content and the type of quarantine weeds, as well as the correct adjustment of the finishing machines in the processing of red clover seeds. By increasing the content of weeds and impurities in the natural seed, the technological process of processing is longer, the consumption of energy is higher, and therefore the cost of the harvested seeds are high. The purity of natural red clover seeds ranged from 52% to 88%. The content of inert materials ranged from a minimum of 12% for seeds lot V to a maximum of 48% for seeds lot II. The most seeds of quarantine weeds were found in the seeds of the VI and VII. There was a total of 40 seeds of *Cuscuta* sp in each seed lot. Any defects and failures in the technological process can lead to large losses of seeds, or large economic losses. The quality of the processed seed must comply with the legislation on seed material.

Abstract

There are more than 7.7 billion of humans at the moment. It seems unavoidable that, if it weren't any calamity, our population would be about to reaching 10 billion mouths by the mid-century. The crop production increment in developing countries relies on agricultural production intensification per area unit by 80% and the remainder on arable land expansion. Hence, the part of strategy is to seize the soil degradation and to enhance or restore productivity to degraded soils. Solonetz is a less productive alkaline soil, with high sodium content, covering about 2.1% of agricultural land in Serbia. Bread wheat, one of the main sources of plant generated energy for humans, is moderately tolerant to alkaline soil. Long term trials for studying the wheat reaction to solonetz growth conditions, has been established. The results of 11 wheat varieties and 1 triticale are given. Analyses of grain yield, its components, as well as macro and microelements storage in plants has been conducted. Varieties showed considerable variation in grain yield, plant height, spike length and weight, grain weight and number per spike. The content of selected elements (Ca, Cd, Co, Cr, Cu, K, Mg, Mn, Na, Ni, Pb, and Zn) varied in harvested plant material, as well. Pearson correlation coefficients were used to study interrelationship between observed sources of variation. Low positive correlation coefficients between grain yield and plant height were in consequence of the genetic variation generated in plant breeding program under similar selection criteria. The mutual influence within the yield components, the spike traits, was considerably higher. Away from K and Na, the variation of elements had weak to negligible influence on grain yield variation. Further analysis using ridge regression and cluster analysis showed more complex relationship..

Keywords: *wheat, yield, components, elements, solonetz.*

Introduction

Though gradually slowing in rate, the human population is still exponentially growing (UN DESA PD, 2019). Hence, using up resources is closely related to the demand for food increment, particularly targeting those energy sources like key cultivars for global food security, that wheat and cereal, as a whole, surely are (Mondal *et al*., 2016). The crop production increment in developing countries relies on agricultural production intensification per area unit by 80% and the remainder on arable land expansion (Alexandratos and Bruinsma, 2012). The part of this strategy is to seize the soil degradation and to enhance or restore degraded soils productivity. An inventory of the soils of Serbia and their degradation revealed that solonetz which is a class of a less productive alkaline soil, with high sodium content, covers 2.1 - 2.6% of 3.4 million hectares of agricultural land in Serbia (Ličina *et al.*, 2011; Belić *et al*., 2012). In Vojvodina, there is approximately 80,000 hectares of this type of soil, mostly in the Banat (Belić *et al.*, 2006). This soil type belongs to alkaline class with high sodium content, occurring as a result of extensive irrigation, or could be spontaneously formed in a lowland steppe arid climate. Solonetz covers about 150 million hectares in the World, about 0.5% i.e. 20 million hectares of Europe is solonetz covered soil, mainly in Russia, Ukraine, Hungary, Bulgaria, Romania, and Kazakhstan (ESBN, 2005; Spaargaren, 2008). This type of soil is known as alkaline, clay and sodium reach land, deficient for nitrogen (N), phosphorus (P), potassium (K), zinc (Zn), cuprum (Cu), manganese (Mn) and iron (Fe), after Blum (2018). There are 118 elements that have been discovered (Karola *et al.*, 2016). However, 98 of them occurred in nature, 90 among them could be found in appreciable amount, and 6 of them, namely, carbon (C), hydrogen (H), N, oxygen (O), P and sulphur (S) are essential for life entering the protein and nucleic acid structure. Other 12 are very important for organism activities, chlorine (Cl) and iodine (I) from halogen family of elements (non-metals) and bio-metals sodium (Na), K, magnesium (Mg), calcium (Ca), Fe, cobalt (Co), Cu, Zn, Mn and molybdenum (Mo). Elements that play an essential role in the living world could be divided into 4 groups: 1. *The main or bulk elements* (C, H, N, O, P, S); 2. *Macrominerals and ions* Na, K, Mg, Ca, Cl, phosphate ion (PO_4^{3-}), sulphate ion (SO_4^{2-}); 3. *Trace elements* (Fe, Zn, Cu) and 4. *Ultratrace elements* comprises of: a. *Non-metals* fluorine (F), I, selenium (Se), silicon (Si), astatine (As), boron (B) and b. *Metals* Mn, Mo, cobalt (Co), chromium (Cr), vanadium (V), nickel (Ni), cadmium (Cd), tin (Sn), lead (Pb), lithium (Li) (Giribabu and Narayanan, 2015). Essential mineral elements for plants could be classified in four groups: *Macronutrients - major* (N, P, K), *Macronutrients - secondary* (Ca, Mg, S), *Micronutrients - essential* (Fe, Mn, Zn, Cu, B, Mo, Cl, Ni), and *Micronutrients - beneficial* (Na, Si, Co, Se), Ronan (2007). The increasing demand for food pushes primary agricultural production toward the increment of cultivation intensity, not only in a sense of getting a higher yield, but also in obtaining higher quality. To reach this goal, a better understanding of plant nutrient acquisition, complex interaction between genotypes, environment and chemical elements is required (Etienne *et al.*, 2018). Solonetz is commonly utilized for extensive pasture, but some crops and remedial measures can raise the productive value of this land. Salt tolerance is an inherent trait existing in plants in order to adapt to various environments. Small grains including bread wheat are generally regarded as moderately tolerant to alkaline soil (Dimitrijević *et al*., 2012; Zafar *et al*., 2015). Phenotypic variability of yield studied in trials established *in situ* in abiotic stress conditions of solonetz soil agro-ecological environment could provide valuable informations in creating desirable wheat variability in order to put less productive land in more intensive use for food production (Petrović *et al*., 2016). However, in stressful production conditions, some Green Revolution ways do not apply in full. Firstly, that means that individual plant contributes more to overall grain yield than in normal intensive production environment, where the main contributor is population per area unit. Consequently, individual plant trait variation, the yield components like plant height, and generative part traits influencing individual plant productivity (spike length and weight, grain number and weight per spike), gain in importance in final yield formation.

Hence, the aim of this work is to examine and analyse varietal variation of grain yield and the yield components in wheat grown on solonetz soil, as well as, to get an insight in complex interrelations in these variations.

Material and Methods

There were 12 genotypes included in the experiment, where 11 were 6X bread wheat varieties (*Triticum aestivum ssp. vulgare* L), all created within a Cereal Breedeing Program of the Institute of Field and Vegetable Crops in Novi Sad, namely Renesansa, Pobeda, Evropa 90, NSR-5, Dragana, Rapsodija, Simonida, Cipovka, Banatka, Bankut 1205 (winter types), Nevesinjka (facultative) and winter type triticale variety Odisej. The trial is a part of broader research experiment conducted for about two decades parallel in normal, chernozem i.e. black soil, (pH = 6.86) experimental conditions at the test field of the Institute of Field and Vegetable Crops - near Novi Sad (latitude: 45.3249360N, longitude: 19.8428830 E), and in solonetz soil (pH = 9.86) abiotic stress conditions at the experimental field in Kumane village (latitude: 45.5219940N, longitude: 20.1949190 E). The experimental plant sample was chosen according to previously accumulated experience of varietal behaviour in harsh environmental conditions that solonetz soil is. Varieties Renesansa, Rapsodija, Pobeda, NSR-5 and Evropa 90 are selected as particularly adaptable genotypes. Varieties Nevesinjka and NSR-5 are particularly tolerant to less productive soil conditions. All the genotypes express tolerance to low temperatures. Varieties Renesansa and Rapsodija are particularly resistant to drought conditions. Varieties in study are grown not only in Serbia, but also at the Balkans. Variety Rapsodija is grown in the EU and Ukraine, as well. Triticale Odisej was included as a control genotype, because triticale as a synthetic species has been created to withstand abiotic stressful growth environments. Moreover, two varieties Pobeda, and Renesansa were followed parallel on chernozem and solonetz as control genotypes, too. The raw data were collected in one vegetation period, to diminish environmental variance in total phenotype variation. The variation observed in the experiment was analyzed using descriptive statistics, as well, as Analysis of variance (ANOVA) and direct and indirect correlations. Additional analysis of trait interrelations and variation was conducted using Cluster analysis as non-parametric method. The content of macro and micro chemical elements was followed by atomic absorption spectrophotometry in dry plant material. The data were standardized in order to be comparable in statistical models. All the statistical calculations were done according to Microsoft Excel procedures. The experiment was set up by Randomized Complete Block Design in three replications. Each variety was sawn in eight 12.5cm spaced rows, 155m of length. Fifty kilograms of NPK 15:15:15 fertilizer was applied with sowing.

Results and Discussion

The analysis of grain yield variation shows that abiotic stress caused mainly by sodium rich solonetz soil influenced grain yield decrement by about 40%, comparing yield to control varieties Pobeda and Renesansa grown in normal conditions of chernozem at the locality of Rimski Sancevi. Local population Banatka, and old variety Bankut 1205 were expectedly the tallest genotypes, however modern varieties did not exhibit no significant loss in plant height (PH) on solonetz comparing to cernozem, including varieties Pobeda and Renesansa. Hence, the immediate cause of the grain yield decrement is to be searched in mass property parameter variation, including grain weight and grain number per spike (GWS, and GNS, respectively), which were affected by solonetz stressful growth conditions by lowering its average values about 30% comparing to control averages. Triticale Odisej exhibited the best performance on solonetz soil (tab. 1). According to visual screening from the field, the other reason of the grain yield decrement on solonetz was canopy that suffered more in a harsh conditions of Kumane part of the trial. Concerning chemical elements that were found in plant dry material by atomic-absorption spectrophotometry, varietal variation in content has been denoted. Wheat varieties in trial absorbed chemical elements differently, exhibiting variation that could be meaningful in wheat breeding program for special purposes i.e. higher salinity tolerance, or remediation of soil burdened with toxic elements. There is a significant difference in absorbed cobalt (Co), chromium (Cr), sodium (Na), nickel (Ni), and lead (Pb) comparing plant material samples gathered on solonetz, and chernozem soil. Sodium richer solonetz soil caused higher absorption of this element. The higher absorption of Co, Cr, Ni, and Pb, on solonetz soil, could be the result of prolonged effect of phosphogypsum application as an ameliorative measure, in the past (tab. 2). Pearson's correlation coefficients varied between none to very high, graded after Akoglu (2018). The relation between the grain yield and the yield components varied from weak ($r = 0.21$ to 0.28) to moderate ($r = 0.31$ to 0.33). In a whole, yield components under study were quite evenly related to grain yield, and no one stood out as an early phenotypic marker of higher yield (tab.3)

Table 1. Grain yield, and the yield components (plant height – PH, spike length – SL, spike weight – SW, grain weight per spike – GWS, and grain number per spike – GNS) variation in wheat varieties grown on solonetz and control varieties grown on chernozem at R. Sancevi.

The mutual relation between the grain yield and chemical elements content, predominantly varied from none to weak at r = -0.03 to 0.23. However, higher sodium content of solonetz caused higher content in plants as well, resulting in moderate to strong (r = -0.42) negative correlation between Na content and grain yield. The effect of regular and usual application of fertilizers reflected in moderate to strong positive correlation between K and yield (tab. 3).

Table 3. Pearson’s correlation coefficients giving interrelationship of examined biological traits, and chemical elements content in wheat sample of 11 wheat and one triticale varieties.

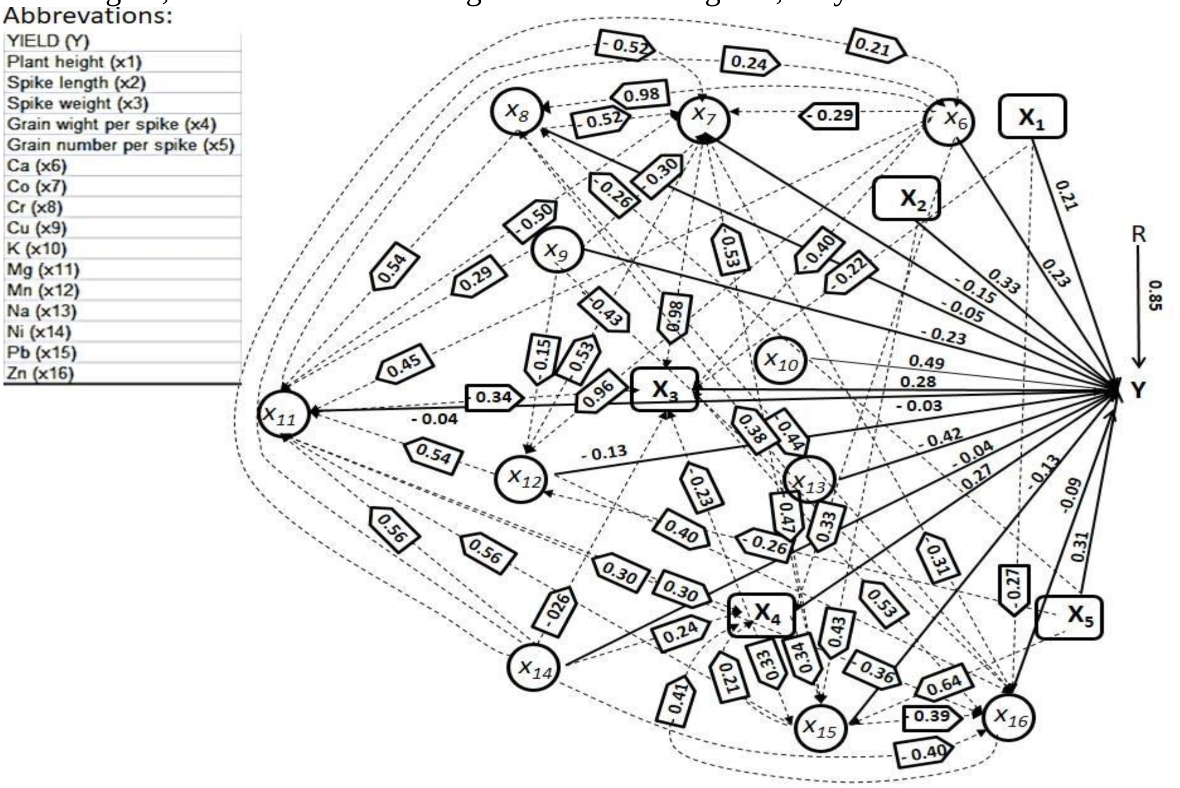
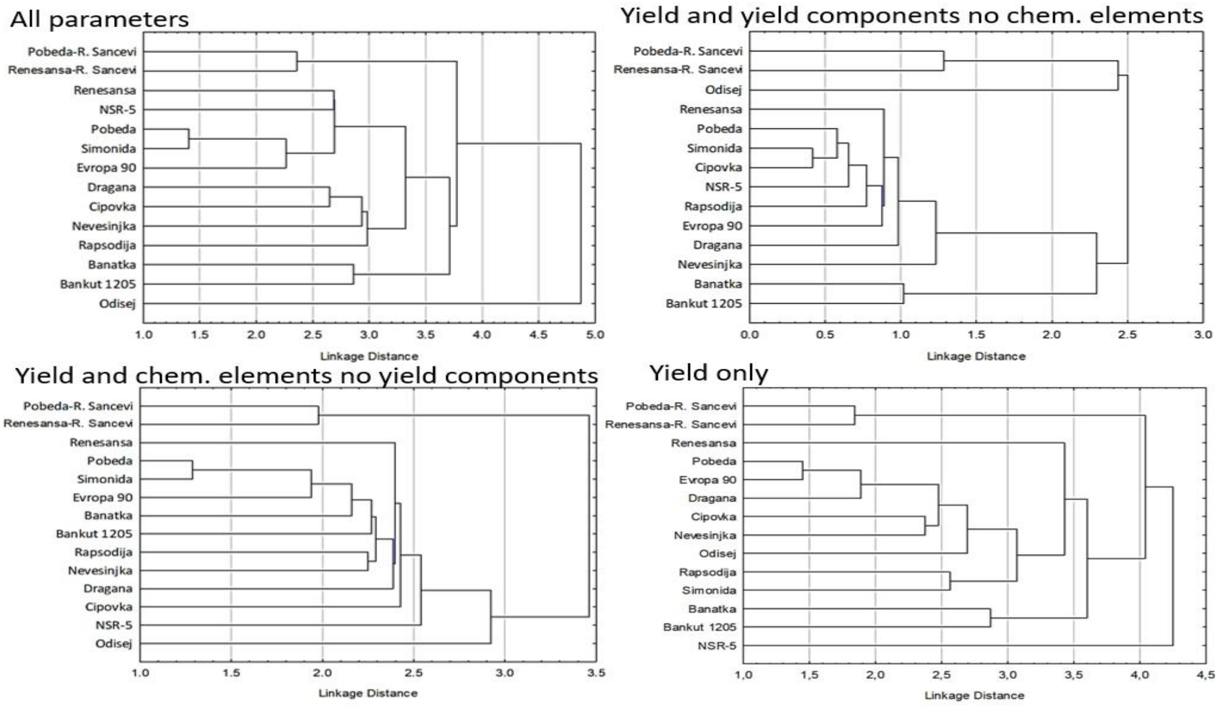
Path coefficient analysis was conducted on normalized data by subtracting varietal averages from the grand mean, and dividing by standard deviation, in order to weight values. Since, there is no room for detailed analysis, the sample figure given illustrates very complex indirect relations to grain yield, that were observed (fig. 1)

Figure 1. Path coefficient analysis giving closer analysis of direct effect of yield components and chemical elements on grain yield, through indirect effects screening. Due to complexity of the figure, indirect coefficients higher than 0.20 are given, only.



Clusterization of genotypes in trial was conducted as a non-parametric evidence of the influence of the yield components and chemical elements content as a whole in plants on grain yield formation. By drawing a comparison between genotype array in cluster grouped using all parameters – yield, yield components, and chemical elements content in plant material, and other three clusters it is evident that all the examined biological traits, as well as, chemical element content had an influence on the yield. The effect of soil stress absence on chernozem led to the grouping of control wheat varieties, Pobeda and Renesansa at the locality of Rimski Sancevi, in all the clusters. Triticale Odisej was genotype for itself, as expected. All the other varieties more or less differed in grouping depending on clusterization criteria. Although the grain yield had its influence on genotype grouping, the variation of the yield components, as well as, chemical element content variation exhibited its strength to rearrange the genotype grouping to some extent (fig. 2).

Figure 2. Cluster analysis for 11 wheat and 1 triticale varieties grown on solonetz soil and two wheat varieties grown on chernozem as control.



Conclusions

This is a pilot report of the results obtained on two localities for 12 genotypes in one year, so there are indications and trends in order, rather than hard conclusions. The inferiority of sodium reach solonetz soil in wheat production is well illustrated, once more. However, the existing genetic variability created for intensive agricultural practice in favourable growth conditions, could withstand abiotic salinity stress giving up to 60% of grain yield comparing to chernozem environment, without any additional investment. Moreover, analysing some tiny influences of chemical element content in plants, we could find genetic variability not only for grain yield increment, but also for phytoremediation of soil with higher content of adverse chemical elements. The higher zinc content in varieties grown on solonetz soil comparing to control varieties grown on chernozem, as well as, other macro, and micro nutrients varietal variation observed in this investigation, points out the existence of variability that could be utilized in fighting the "hidden hunger" of malnutrition. Anyway, the further research is required for analysing deeper a complex structure of phenotype variation in order to cultivate genetic variability adequate for drastic climate changes, and higher, and higher demands in food production the humanity is facing.

Abstract

The Green Revolution had great, but ambiguous impact on food production. Though it has increased agricultural output dramatically, the loss of a third portion of arable land due to erosion or pollution has been going on, as well. Moreover, the similar selection preasure, as it seems, has led to nutritionally inferior crops, engendering malnutrition, and even a stand that we live in a toxic food culture. The narrowing of genetic variability, and industrialized, unsustainable food system, made a modern diet as a leading risk factor for diseaes development. Increased demand for nutrients and health-safe food in the situation of the exponential growth of human population represents a some of heavy challenges to agriculture. The utilization of less productive soil in wheat production, as well as, the studies of nutritional and toxic elements dynamics in vegetative and generative wheat plant parts is given in the article. The trial has been conducted on solonetz soil. The phenotypic varietal variation of the yield and yiels components (plant height, spike length and weight, grain weight and number per spike) in 11 bread wheat and the one triticale genotypes was followed, as well as, the source to sink dynamics of 13 selected elements (B, Ca, Cd, Co, Cr, Cu, K, Mg, Mn, Na, Ni, Pb, and Zn). The varietal ability to endure abiotic stress growth conditions of solonetz was estimated through the relative tolerance index obtained by comparing a phenotypic variability of particular trait for each genotype in sample with corresponding phenotype variation of two standards, wheat varieties Renesansa and Pobeda, grown in normal, intensive production conditions of the experimental fields of the Institute of Field and Vegetable Crops in Rimski Šančevi. Notable variation has been found and commented in the article.

Keywords: *wheat, solonetz, yield components, tolerance index, chemical elements.*

Introduction

Starting in the middle of previous century, two phenomena have label our past, present and future – The Green Agricultural Revolution and Human Population Geometric Growth. World's food production per-capita increased about 25%, and the yield of cereals, substantial for securing human energy supply, has grown 3-5 times for the four decades since 1960s. In the same period, the human population has more than doubled (Roser and Ritchie, 2019). Parallel processes, however, have been the loss of a third portion of arable land due to erosion or pollution has been going on, biodiversity and dietary diversity narrowing, as well as, ongoing overall erosion of the environment. The soil, as well as total environmental pollution, largely depends on micro and macro elements content and flow. High concentrations of heavy metals, as a special group of elements, for example, could exhibit a toxic effect on plants. However, from 1970s there has been a rising perception of the preventable influence of dietary micronutrient deficiency on human health and mortality (Dubock, 2017). In the same time, the growing level of environmental awareness has started. In order to find adequate pathways toward food production sustainability, stability and increment, complex and multidisciplinary scientific programs are needed. Within this strategy the research of chemical elements in biosphere and food is of relevance. Chemical elements influence environmental pollution, food nutritive value, healthcare, and is fundamental for cell and genetic and epigenetic processes. There are 11 heavy metals - lead (Pb), cadmium (Cd), mercury (Hg), cuprum (Cu), tin (Sn), vanadium (V), chromium (Cr), molybdenum (Mo), cobalt (Co), and nickel (Ni) and three metalloids - antimony (Sb), arsenic (As), and selenium (Se) listed as the most hazardous elements. (Vodyanitskii, 2016). Because of water and soil pollution, metals in the environment should be considered as environmental contaminants that represent a permanent threat to mankind. Hence, there are some serious concerns over their potential health effects on humans (Jan *et al.*, 2015). In fact, there are 118 elements discovered up to 2016 (Karola *et al*., 2016). In fact, there are 118 elements discovered up to 2016 (Karola *et al.*, 2016). Six of them - carbon (C), hydrogen (H), nitrogen (N), oxygen (O), phosphorus (P) and sulphur (S) are essential for life building the protein and nucleic acid structure, while twelve are of remarkable importance for organism activities, chlorine (Cl), iodine (I) as non-metals and sodium (Na), potassium (K), magnesium (Mg), calcium (Ca), iron (Fe), cobalt (Co), cuprum (Cu), zinc (Zn), manganese (Mn) and molybdenum (Mo), as bio-metals. According to Ronan (2007), there are four groups of elements having an essential role in organisms: I. the main or bulk elements (C, H, N, O, P, S); II. Macrominerals and ions Na, K, Mg, Ca, Cl, phosphate ion (PO_4^{3-}), sulphate ion (SO_4^{2-}); III. Trace elements (Fe, Zn, Cu) and IV. Ultratrace elements comprises of: IVa. Non-metals fluorine (F), I, selenium (Se), silicon (Si), astatine (As), boron (B) and IVb. Metals Mn, Mo, cobalt (Co), chromium (Cr), vanadium (V), nickel (Ni), cadmium (Cd), tin (Sn), lead (Pb), lithium (Li) (Giribabu and Narayanan, 2015). Essential mineral elements for plants could be classified in four groups: Macronutrients - major (N, P, K), Macronutrients - secondary (Ca, Mg, S), Micronutrients - essential (Fe, Mn, Zn, Cu, B, Mo, Cl, Ni), and Micronutrients - beneficial (Na, Si, Co, Se). As it could be seen from above classification, the effect of particular element depends of its nature i.e. chemical properties and its concentration. Consequently the role of plants could be double-natured. Plants, through food, bring these elements to our diet and plants through elements mobilization could be utilized in phytoremediation i.e. cleaning up contaminated soil using the ability of plants to uptake pollutants from the environment (Ali *et al*., 2013). Solonetz is sodium reach soil, of higher pH value, being considered as a stressful environment for cultivar growing, and is commonly used as extensive pasture. The genetic group at the Faculty of Agriculture, University of Novi Sad has been running long term parallel trials on solonetz and chernozem soil, in order to study usable variation among the existing genetic variability in wheat, wheat adaptation to abiotic stress, and the possibility of novel superior variability selection (Petrović *et al.*, 2016). Through these studies the experience and knowledge is to be gathered to respond to more and harsher food production conditions brought by climatic changes. The aim of this article is to follow genetic variability of salinity stress tolerance, as well as, varietal variation in chemical elements translocation from source to sink in wheat.

Material and Methods

A sample of 11 bread wheat varieties (*Triticum aestivum ssp. vulgare* L), - Renesansa, Pobeda, Evropa 90, NSR-5, Dragana, Rapsodija, Simonida, Cipovka, Banatka, Bankut 1205 (winter types), Nevesinjka (facultative) and a winter type triticale variety Odisej, was pulled out from the larger multiyear experiment. All 12 genotypes where creations of Breedeing Program of the Institute of Field and Vegetable Crops in Novi Sad, Serbia. The parallel trial was established in normal, chernozem soil, (pH = 6.86) at the test field of the Institute of Field and Vegetable Crops - near Novi Sad (latitude: 45.3249360N, longitude: 19.8428830 E), and in solonetz soil (pH = 9.86) at the experimental field in Kumane village (latitude: 45.5219940N, longitude: 20.1949190 E). Varieties Renesansa, Rapsodija, Pobeda, NSR-5 and Evropa 90 were choosen as very adaptable genotypes. Varieties Nevesinjka and NSR-5 are more tolerant to less productive production conditions. All the genotypes were tolerant to low temperatures. Varieties Renesansa and Rapsodija are more tolerant to water deficiancy. Varieties Pobeda, and Renesansa were analyzed both on chernozem and solonetz as control genotypes. Data were gathered in one year, to eliminate the influence of multiyear environmental variance in total observed variability, and to underline genotype differences. The data were analysed using statistical measures of central tendency and dispersion (Hadživuković, 1973). The content of macro and micro chemical elements was followed by atomic absorption spectrophotometry in dry plant material in the National Institute of Field and Vegetable Crops (NIFVC), Novi Sad, Serbia. Relative tolerance to solonetz abiotic stress production condition was calculated as follows: T = Ti /T1 x 100 [%], where Ti represents the mean value of a trait at solonetz soil, and T1 is mean value of average performance of control varieties Pobeda and Renesansa on chernozem soil. All the statistical calculations were done according to Microsoft Excel procedures. The experiment was set up by Randomized Complete Block Design in three replications using standard spacing (eight 12.5cm spaced rows, 155m of length), and plant feeding (50kg of NPK 15:15:15 fertilizer) was applied during sowing.

Results and Discussion

The varieties exhibited statistically significant variation in reaction to abiotic stress growth conditions of solonetz soil. The grain yield was on average 27% lower than in control part of the trial, except 17% decrement denoted for triticale variety Odisej, and the highest RTI of 0,82. The relative tolerance index for grain yield in wheat varieties varied from 0.55-0.58, for varieties Renesansa, Banatka, and NSR-5, respectively, to 0.65, 0.66 and 0.67 for varieties Evropa 90, Pobeda, and Dragana. Variety Banatka is and old local wheat population, instinctively bred, with good dough quality, but lower grain genetic potential in general. Variety NSR-5 is an early genotype. Abbreviation NSR stands for "Novi Sad's Early". Early varieties their "earliness" commonly pay with lower yield potential. Moreover, the clay fraction in the Bt horizon of solonetz, that Belić *et al.* (2012) reported, could cause the accumulation of excessive amount of water, that commonly greatly affect the yield, and plant development as a whole, beside exchangeable sodium and a high alkaline reaction. A higher tolerance index of varieties Evropa 90, Pobeda and Dragana was in accordance to previously reported results (Dimitrijević *et al.*, 2011; Dimitrijević *et al.*, 2012; Petrović *et al.*, 2016). The RTI for the yield components revealed significant genotype variation, as well. Plant height showed RTI nearly to 1, meaning high tolerance of genotypes for that trait in this experiment. Weight spike parameters exhibited RTI of about 0.80, in general, whereas local population Banatka had lower RTI, while triticale Odisej was with the highest RTI in trial. Triticale Odisej was compared with bread wheat control, so triticale as a synthetic plant species exhibited superior variation of tolerance to abiotic stress of solonetz growth environment comparing to 6x wheat varieties Pobeda and Renesansa as control. According to coefficient of variation as a relative parameter of phenotypic variability, mass traits SW and GWS exhibited the highest varietal variability. Hence, CV was the highest for RTI of these two traits, as well. Bread wheat varieties Evropa 90, Renesansa, Nevesinjka, Simonida, Pobeda, Rapsodija and Pobeda with overall RTI of 0.80, and higher. Variety Nevesinjka is facultative wheat variety, especially bred for harsh growing conditions in special purposes wheat breeding program established in the IFVCNS in cooperation with former Yugoslav People's Army in S.F.R. Yugoslavia, proving its value in this trials, as well, almost half of century later (tab. 1).

Table 1. Mean values of 11 wheat, and 1 triticale (Odisej) varieties for PH - plant height [cm], SL – spike length [cm], SW – spike weight [g], GWS – grain weight per spike [g], GNS – grain number per spike, and YIELD – grain yield [t/ha]. All the varieties were grown on solonetz soil. Varieties Pobeda and Renesansa were parallel grown on chernozem soil at the

Experimetal Field of NIFVC in Rimski Sancevi (R.S.) as control varieties. Relative tolerance index (RTI) was calculated, as well, for each variety in trial. Basic statistic was calculated – Se (standard error of the average), STD (standard deviation), CV (coefficient of variation), and LSD – Least Significant Differences at the 5% and 1% levels.

Trace microelements showed different dynamics among themselves and genotype variation, as well. Cobalt was not detected in control varieties grown on chernozem, while on solonetz translocation from vegetative to generative plant parts was not observed. Mean content indicate accumulation of Zn in generative parts of varieties Renesansa, Pobeda, older Banatka, Bankut 1205, and facultative Nevesinjka (tab. 2). The higher Na content in plants grown on solonetz than in control varieties was expected due to solonetz chemical properties. However, the Na translocation from vegetative to generative parts was the same on solonetz and on chernozem, according to source to sink content variation. Genotype variation was exhibited for Mg content variation. Magnesium is an important element in plant physiological processes, photosynthesis in particular, important for enzyme activities, and plant tolerance to stressful environmental conditions. The content of Mg was higher in varieties grown in stressful solonetz conditions, than in control varieties grown on chernozem (tab. 3).

Heavy metals are widespread and dramatically increased environmental pollutants. They require particular attention because being non-degradable they could persist in the environment as constant environmental and health threat. The results obtained, are encouraging for phytoremediation of heavy metals in soil. No translocation of Cr, and particularly of Pb, from vegetative to generative wheat parts, has been denoted. Moreover, the Ni content in grain has been considerably lower than in vegetative part. Genetic variability in heavy metal presence is observed, as well (tab. 4).

Conclusions

The analysis could be considered as a pilot study of the variation denoted in larger multiyear research of wheat genetic variation in abiotic stress caused by chemical and physical properties of solonetz soil, as well as, harsh environmental conditions of western Banat area. Observed genetic variability in bread wheat, reflected through phenotypic variation followed using RTI, relative tolerance index for grain yield, and its components, provides basis for further wheat improvement for withstanding abiotic stressful growing conditions, salinity stress in particular. Triticale variety Odisej was superior to wheat varieties in durability under abiotic stress. The variation in chemical elements variability has been denoted not only through genotype variability, but also depending on localities in the experiment, predominantly due to solil properties and agricultural practice. Further investigation in this direction is required because of phytoremediation, the enhancement of nutritional properties in wheat, searching for special purpose food production on less favorable soil. Moreover, epigenetic pathways are very important in plant reaction to the environmental stress (Pikaard & Mittelsten, 2014). The plant responsiveness is highly depending on balance between enzyme activities, small RNA gene expression regulation, long non-coding RNAs regulation etc. All these processes have in their core the dependency on chemical elements dynamics in plant. The study of micro- and macro-elements variability in source, and particularly in generative plant parts is of rising importance in epigenetic pathways comprehension.

THE EFFECTIVENESS OF SOIL TILLAGE SYSTEMS IN MAIZE CULTIVATION UNDER VARIABLE METEOROLOGICAL CONDITIONS OF CENTRAL SERBIA

Abstract

Soil tillage system is a basic in maize crop production. Under variable climatic conditions and frequent occurrences of dry years, soil tillage adjusted to the soil type, agro-ecological conditions and the crop, can contribute to the achievement of the maximum yield potential. Systems of reduced tillage, particularly direct sowing, have been widely used in Europe. Under agro-ecological conditions of central Serbia, the highest maize yields have been achieved by using conventional soil tillage with 20-25-cm deep autumn ploughing and a single pass land preparation in spring as 10-12-cm shallow tillage. In the Maize Research Institute, Zemun Polje, the long-term experiment was conducted (2005-2016) in order to test the efficacy of zero-, reduced and conventional tillage together with the application of different rates of mineral fertilisers in maize cultivation. The experiment was performed under rainfed and irrigation conditions. The data were processed by four factorials ANOVA and differences were analysed by the LSD-test. Based on the precipitation sum in the investigated period, three years were extremely dry, four were moderately dry and five were favourable for maize production. Under irrigation conditions, the 12-year maize grain yield average was higher by 2.1 t ha^{-1} than under rainfed conditions. Under rainfed conditions, differences between conventional and reduced or zero-tillage were 1.7, and 1.3 t ha^{-1}, respectively, while under irrigated conditions conventional tillage was more productive by 1.4 t ha^{-1} than reduced and zero-tillage, respectively. In some dry years, such 2012, the maize grain yield was higher under conditions of reduced tillage than conventional tillage.

Key words: *Maize, Tillage system, Meteorological conditions, Yield.*

Introduction

Tillage contributes to the formation of a loose soil layer and the accumulation and moisture preservation, which leads to the improvement of the air-temperature regime of the soil (Kovačević, 2010). Appropriate soil tillage provides more efficient water use, prevents erosion, changes CO_2 concentration, reduces soil compaction and enables better soil structure. It ensures the introduction of organic residues of the preceding crops and fertilisers, increases crop competitiveness, influences weed presence and biomass of rhizomes, provides better efficacy of the applied herbicides, etc. (Stefanović et al., 2011). Under variable climatic conditions and frequent occurrences of dry years, soil tillage adjusted to the agro-ecological conditions and the crop, can contribute to the achievement of maximum yield (Bodner et al., 2015). Yield potential of maize hybrids developed in Serbia is much higher than an actual yield (Videnović et al., 2013) and, except soil tillage, irrigation and the fertiliser application are very important for maize yield increase (Simić et al., 2018).

The highest yields of maize are recorded on loose and well-permeable soils with high water capacity. Soils containing great moisture reserves, easy available nutrients and at the same time if well-aerated, are favourable for the maize cultivation. Such properties are characteristic for soils with a medium texture/mechanical composition (medium and light clay) and soils rich in organic matter (chernozem and brown forest soil and similar). Maize grown on well-permeable soils with good physical properties can utilise moisture from the depth of 1.5 to 2 or more meters because maize has great demands for water, which is a decisive factor for its production in Serbia (Pejić et al., 2009). A necessary precipitation sum during the maize growing season amounts to approximately 570 l/m^2. It is also important that maize plants are well supplied with moisture in the second part of their growing season (July and August) during the ear formation, flowering and until the end of grain filling (Pejić et al., 2009). In the regions with insufficient precipitation sums and irregular distribution of precipitation, water should be provided by irrigation (Kresović et al., 2013). The maize root system was better developed under irrigated (76.7 g) than under conditions of soil water deficit (46.5 g). The water intake from the 80-cm soil layer was higher, as well as, the maize grain yield under irrigation (442 mm and 13.7 t ha^{-1}, respectively) than under rainfed conditions (304 mm and 8.4 t ha^{-1}, respectively), (Pejić, 2000). Maize plants can use the stored water during periods of drought. It is well known that accumulated water increases maize yield. In the majority production areas, the different measures should be taken to collect and store moisture in the soil (proper tillage and fertilisation, autumn ploughing, summer ploughing, snow retention).

Systems of reduced tillage, particularly direct sowing, are entered in widespread use in North America (Fulton, 2010), Australia (Llewellyn et al., 2012), South America and in Europe (Morris et al., 2010). Direct sowing also means saving energy, labour and machinery and helps prevent erosion and increases the efficiency of water and fertiliser utilisation. However, the use of these soil cultivation systems requires the implementation of measures for intensive weed control (herbicides). Under irrigated conditions, soil tillage greatly increases maize yield, because it enhances positive effects of beneficial soil micro-organisms and fertilisers. Under conditions of a higher water supply in the soil, 80– 85% of field water capacity, the maize yield was the highest (15.08 t ha^{-1}), and also mobility of soil N and accumulation of nitrates in the upper soil layers were increased (Kresović et al., 2012).

Conventional tillage mainly includes autumn ploughing (20-25 cm) and a single pass land preparation in spring - shallow tillage (10-12 cm). In such a way a good soil structure is provided, moisture is maintained, the soil is not trampled, weed seedlings are destroyed, which is all of a particular importance for the efficient herbicide actions (Stefanović et al., 2011). Conventional soil tillage should be conducted in autumn to the depth of 20-30 cm, depending on the soil type, the amount of harvest residues, etc. At the same time, organic and mineral fertilisers containing phosphorus (P) and potassium (K) should be incorporated. The soil over winter remains with open furrows to be exposed to the frosts, which contribute to a better soil structure and reduction in the number of pests. Immediately after harvest of small grains, crop residues should be ploughed to the depth of 10-15 cm. In such a way the water regime of soil is improved, while a portion of elements removed by harvest is returned.

The effectiveness of conventional, reduced and zero-tillage system of chernozem soil in the central part of Serbia (Zemun Polje) together with the application of mineral fertilisers in three rates, on maize grain yield were investigated under rainfed and irrigated conditions in twelve meteorologically different years, 2005-2016.

Material and Methods

The study was conducted in the experimental field of the Maize Research Institute, Zemun Polje, Belgrade, Serbia, during the 2005-2016 period. The soil was slightly calcareous chernozem with 47 % clay and silt, and 53 % sand. The 0–30-cm layer contained 3.3 % organic matter, 0.21 % total N, 1.9 % organic C, 14 and 31 mg per 100 g of soil available P and extractable K, respectively and 9.7 % total $CaCO_3$, and pH of 7.8.

The experiment was performed under rainfed and irrigation conditions as a split-plot design with four replications. The main plots were soil tillage systems: zero soil tillage or direct

sowing - ZT, reduced soil tillage system - RT and conventional soil tillage system- CT and subplots were the levels of N fertiliser applied in the following rates: F0 – without fertilisation; F1 - 180 kg N ha^{-1} and F2 - 240 kg N ha^{-1}. The elementary plot size was 21 m^2. Fertilisers in the amount of 50 kg P ha^{-1} and 50 kg K ha^{-1} were applied in the autumn, while N fertiliser was incorporated in the spring, prior to sowing. Winter wheat was the preceding crop to maize in each year. The irrigation was applied to maintain 75% of field water capacity (FWC).
Maize grain yield was measured from two inner rows within the elementary plot and calculated to 14% moisture at the end of a growing cycle. The data were processed by two factorial ANOVA and differences were analysed by the LSD-test.
Meteorological conditions. Based on the precipitation sum in the investigated period, four years were very dry – 2008, 2012, 2013 and 2015, while the extremely dry with a highest average temperature was 2012; four were moderately dry – 2007, 2009, 2011 and 2016 and four years were favourable for maize production – 2005, 2006, 2010 and 2014 (Table 1). The highest average temperature, i.e. precipitation sum during the growing season (April-September) was recorded in 2012, i.e. 2014, respectively (the year with extreme floods).

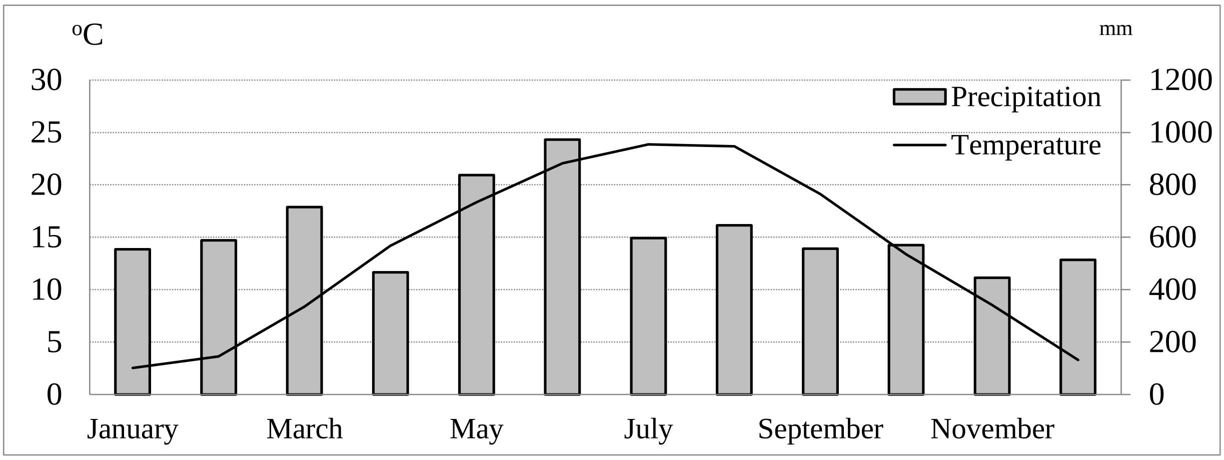

Figure 1. The average monthly temperatures and precipitation sum (2005-2016)

Table 1. Meteorological data for the growing season of maize (April-September) in the years of investigation, 2005-2016

	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015	2016
°C	18.8	18.0	20.7	20.3	21.1	19.8	20.8	22.1	20.2	19.3	21.1	20.3
mm	387.4	417.1	290.1	224.6	321.0	453.9	301.6	174.8	245.4	652.5	285.4	320.1

In average for all years within a period of investigation, 2005-2016, April was a month with the insufficient amount of precipitation as well as July, August and September (Figure 1).

Results and Discussion

The long-term experiment results showed considerable differences in maize grain yield in dependence on the applied soil tillage system, as well as, on the fertilisation level and their interactions. Maize grain yield was higher under irrigated conditions especially in some years - 2007, 2012 and 2013 (Table 2). In 2012, the average maize yield was 5.5 t ha^{-1} (63.2%). It was higher under irrigated conditions (8.7 t ha^{-1}) than in the rainfed treatment (3.5 t ha^{-1})

because of extremely unfavourable meteorological conditions. In total, maize yield was, on average, higher by more than 2 t ha^{-1} in the irrigation treatment. The highest yield was obtained in 2005, under irrigation and CT (14.5 t ha^{-1}). In both water regimes, the conventional soil tillage system significantly contributed to the achievement of higher maize yield (10.0 and 11.9 t ha^{-1}) than reduced tillage system (8.3 and 10.5 t ha^{-1}) and direct sowing (7.0 and 9.1 t ha^{-1}). In some dry years, such 2012, the reduced tillage system was advantageous over the conventional system regarding to maize grain yield, even though differences were not significant. Bescansa et al. (2006) and Fernández-Ugalde et al. (2009) reported the same trend for a clay loam and a silt loam soil, respectively, in a semi-arid climate in Spain, leading to better crop performance in the reduced tillage systems during dry years.

Table 2. The effects of soil tillage on maize yield under rainfed and irrigated conditions,

$LSD_{0.05}$ soil tillage x water regime = 2.821**								

Tillage system is important soil and plant management practice which has both, short- and long-term impacts on a yield limiting processes (Bodner et al., 2015). In the long term, soil water and air performances and plant physiological limitations may be overcome by altering tillage systems and cultivating new varieties that are a more resistant to stresses. Interactions between plant and soil, particularly in the rhizosphere, are a way towards better crop water supply. Kell (2011) pointed to the unexploited potential of breeding for deeper rooted crops to substantially improve resource uptake efficiency in deep rooted cropping systems. Deeper root systems can be achieved either by cultivar selection (Wasson et al., 2012), tillage system (Pietola, 2005) or crop stand establishment (Sharratt and McWilliams, 2005).

Another important measure, which can significantly contribute to higher yield of maize is fertilisation. Results show that the application of mineral fertilisers (F1 and F2) increased maize grain yield especially under rainfed conditions (Table 3). In average for 12 years, maize yield was higher by 1.1 t ha^{-1} in F1 and by 1.8 t ha^{-1} in F2 than in F0 in rainfed variant, while differences were 2.2 and 2.8 t ha^{-1} in irrigated conditions. The highest maize yield was achieved in CT-F1 under irrigation (12.7 t ha^{-1}) and it was higher by 2.3 t ha^{-1} than yield in CT-F1 and rainfed conditions (10.4 t ha^{-1}). Higher amounts of fertilisers, F2, did not increase maize yield significantly in comparison to F1, neither in rainfed nor irrigated conditions.

Turner (2004) reviewed measures for sustainable crop production under drought in Mediterranean climates and attributed half of yield improvement over the last decades to agronomic measures, mainly advanced sowing time and fertilisation both leading to higher early vigour and better match of water availability with crop demand.

Table 3. The effect of tillage systems and fertiliser application on maize grain yield, long-term average 2005-2016, Zemun Polje

$LSD_{0.05}$ fertilization x water regime = 2.856**							

Conclusion

The conventional tillage system including the application of fertilisers is the most suitable maize cropping system for achieving high yields on high-quality soil, such as chernozem, under agro-ecological conditions of central Serbia. In dry years, reduced tillage system could be more appropriate, while the fertilisation level should be adjusted to crop demands. In order to maintain the optimum plant water supply, irrigation is the most important factor, which together with conventional soil tillage system and fertilisation may increase maize yield by more than 2 t ha^{-1}.

Abstract

In this research an influence of the strong source restriction meaning cutting off the whole plants at the first internodes 5 (5DAPt), 10 (10DAPt) and 15 (15DAPt) days after pollination on grain yield and its corresponding traits in maize were tested. Control represented plants harvested at full maturity. Four inbred lines were used, two historical ones (Mo17 and B73) and two commercial ZP inbreds (ZPL and ZPB). The experiment was conducted at Zemun Polje, Serbia, in 2014 and 2015. The trait of particular importance was the number of kernels per ear and its average values were 37.73 at 5DAPt, 115.14 at 10DAPt and 175.20 at 15DAPt, being sufficient for planting next generation of breeding. According to the results obtained, ZPL represented an improved Lancaster line over Mo17 regarding drought tolerance, that could not be stated for ZPB over B73. Hybrid among these two lines is drought tolerant due to heterosis (epistatic effects) or dominant origin of ZPLs good response to drought stress. Values for seed set and eventually for grain yield per plant were 0.00 for line B73 at 5DAPt in 2015. An improved breeding scheme for increased drought tolerance could be proposed, namely self-pollination of border plants on high density sown selfing progenies or dihaploid (DH) lines, cutting off selfed plants at 15 DAP and evaluating their kernel properties. Open-pollinated progeny would serve to estimate other important traits for selection. From the chosen progenies kernels of selfed and cut-off plants should be used for the next generation of breeding.

Keywords: *drought, grain filling, Zea mays L.*

Introduction

Drought is one of the most important limiting factors in maize production, and new methods for increasing drought tolerance in maize are searched for. Maize plants are most susceptible to drought at the flowering time, resulting in low kernel number and grain yield per plant (Grant *et al.*, 1989). Following in sensitivity is grain filling phase, while the vegetative phase is the least sensitive (Fereres and Villalobos, 2016). Some researchers have suggested that the early grain filling phase is very suitable for breeding for drought tolerance (Grant *et al.*, 1989; Nesmith and Ritchie, 1992). However, kernel number is highly correlated with grain yield under drought stress (O'Neill *et al.*, 2004).

The source-sink interaction in plants represents the connectivity between the source of assimilated material and the pathway of this material to the sink, a region where carbon-based products are metabolized and energy (in the form of ATP) is synthesized. Source-to-sink ratio is very important in all cereals in determining grain yield. The supply of assimilates from mother plant (source) or the capability of the reproductive ear (sink) to accumulate assimilates limits growth of maize kernels (Gambín *et al.*, 2006). Assimilate supply can be increased by the environment (nitrogen N supply) and genotype. Under normal growing conditions maize yield is mostly sink limited (Borrás *et al.*, 2004). Drought and/or deficiencies in N supply decrease grain yield by reducing kernel number per plant (poor synchronization between silking and pollination) and greater kernel abortion (poor grain filling). The same authors denoted maize as source-limited crop under stress conditions. Maize plants set sink potential early during grain filling, indicating importance of studying first stages of this phenophase.

Yield responses of major crops to different source-sink manipulations were often studied. Usually, this was done in five ways: 1) stand density manipulations (Hernández *et al.*, 2014; Solomon *et al.*, 2017); 2) induced drought stress at flowering time (Oveysi *et al.*, 2010; Siahkouhian *et al.*, 2013); 3) pollination treatments during seed set (Borrás *et al.*, 2003a, 2003b), 4) seed removal (Jones and Brenner, 1987) or truncation of the ear (Seebauer *et al.*, 2010), and 5) manipulation of N supply in the soil (D'Andrea *et al.*, 2008).
The objective of our research was to estimate the effects of cutting off the whole maize plants at the first internodes at different days after pollination (DAP) on grain yield traits. This procedure would provide a high source restriction, and make an impact on grain filling and other kernel traits. Finally, it could serve as a tool for estimating drought tolerance in maize.

Materials and Methods

The four maize inbred lines were used: two historical ones (Mo17 of Lancaster and B73 of BSSS origin) and two commercial ZP inbred lines (ZPL of Lancaster and ZPB of BSSS origin) which are components of the commercial late maturity drought tolerant ZP hybrid. The trial was conducted at Zemun Polje, Serbia, in 2014 and 2015 according to the Split-Plot Randomized Complete Block Design (RCBD) in two replications. Three treatments (sets) were applied: cutting off plants at first internodes at 5 (5DAPt), 10 (10DAPt) and 15 (15DAPt) days after pollination. Plants harvested at full maturity were used as control set. Each genotype was sawn in two rows 0.75 m apart, five plants per row and 0.3 m between plants. Rows were overplanted (three kernels per hill) and thinned to one plant per hill at 5-7 leaf stage. Only border plants were cut, providing the same environmental conditions to the all plants measured, and also only border control plants were measured. Cut-off plants were put into the shed house, away from direct sunlight.
A total of 15 traits were tested on both cut-off and control plants. Morphological traits were: anthesis-silking interval (ASI) in days, ear (EH, cm) and plant height (PH, cm), total number of leaves (NL), number of leaves above the uppermost ear (LAE), length (LL, cm) and thickness (LT, cm) of the ear leaf. Average chlorophyll content (CL, SPAD units) was measured by a SPAD (Minolta) chlorophyll meter, and duration of chlorophyll content (CD) in days from silking till SPAD values reached units beneath 10. Ear and kernel traits were: number of ears per plant (EP), seed set (SS, %) - visual estimate of the percent of pollinated kernels on the ear, grain filling (GF, %) - visual estimate of the percent of filled kernels from the total of pollinated kernels, number of kernels per ear (KE), grain yield per plant (GP, g) and 100 kernel weight (KW, g).
Statistical analysis was done by threre-way analysis of variance (ANOVA) for genotypes combined over sets and years for each trait. Significances of differences among years, genotypes and treatments were determined by LSD test at 0.05 probability level. Pearson's correlation coefficients were calculated for CL, CD, EP, SS, GF, KE, GP and KW for three cut-off treatments and control in order to estimate prediction ability of the treatments on the final values of control plants.

Results and Discussion

Highly significant differences between years ($p<0.001$) were found for ASI, EP, ES, EH, PH, NL, LL, LT, CD, SS, KE and GP, and significant ($p<0.01$) for CL and KW (data not shown). These was expected, since climate conditions in 2014 and 2015 were drastically different at Zemun Polje. Namely, 2014 was highly favorable in comparison with 2015, as sum of precipitation was higher for 56.3%. The largest difference was observed in July, during maize pollination, with precipitation of 187.4 mm in 2014 and only 7.2 mm in 2015. On the other hand, more rainfall occurred in August (time of grain filling) in 2015 than in 2014 (56 and 41 mm, respectively). In south-east Europe the first part of maize vegetation is most often sufficient in rainfall, but about two to three weeks before or at the flowering time drought frequently occurs. The consequence is poor development of root system in the first part of vegetation that remains inefficient to compensate drought stress for rest of vegetation. The second peak of drought occurs during grain filling, when uptake of soil assimilates by maize plants is poor (Anders *et al.*, 2014). Our experiment was designed to simulate this common situation - by cutting off the plants at the first internodes assimilates from the soil became unavailable, thus imitating poor development of the root system.

Genotypic differences were highly significant ($p<0.001$) for all traits except KW (non-significant), which is in accordance with review given by Borrás and Vitantnonio-Mazzini (2017). Year × genotype interaction was significant for ASI, EH, CD, EP, SS, GF and KE. Differences among sets were non-significant for all the morphological traits, indicating they were fully developed before time of stress (Abrecht, 1999). Induced stress provoked significant differences in all other traits ($p<0.001$ and for CL $p<0.01$). Minimal, maximal and average values for these traits are given in Tab. 1. The trait of particular importance is KE and the average values were 37.73 at 5DAPt, 115.14 at 10DAPt and 175.20 at 15DAPt. From breeding standpoint these KE are sufficient for planting the next generation. In the previous pilot experiment with gene bank material, kernels obtained in this way were viable and had good emergency (data not published). The minimum values for SS, GF, KE, GP and KW were 0.00 for B73 at 5DAPt in 2015. This line has passed ear formation (V10) successfully, but the severe drought stress during pollination caused the absence of seed set.

Table 1. Minimal, maximal and average absolute values of the analyzed traits

Trait	Treatment (DAP)					Checks

	Aver.	6.31	14.27	14.49	↑	27.07

ʌ - maximum value of the particular parameter is at 10 DAP; ↓ - decreasing value trend of the trait from 5 towards 15 DAP; ↑ - increasing value trend of the trait from 5 towards 15 DAP

All three values (min, max and av.) for CL were highest at 10DAPt, although still smaller than for control plants. This was unexpected, since plants cut-off at 10DAPt had five days less for photosynthesis than those at 15DAPt. Probably photosynthesis continued for some time on the cut-off plants of this treatment. These results are in accordance with Borrás *et al.* (2004), who found that maize kernel growth is highly source-dependent when tested in drastic reduction of assimilates during grain feeling. Minimum CD values showed the same trend, but maximum and average values decreased from 5DAPt to 15DAPt, and for all three treatments values were higher than for checks. As a response to stress, leaf tissue probably shrunk more than in checks, so the relative chlorophyll concentration in the leaves was higher. For EP erratic values and trends were obtained, presumably due to differences between the genotypes tested. For all other traits mostly increasing trends were obtained and in almost all instances values of the treatments were smaller than those of the checks.

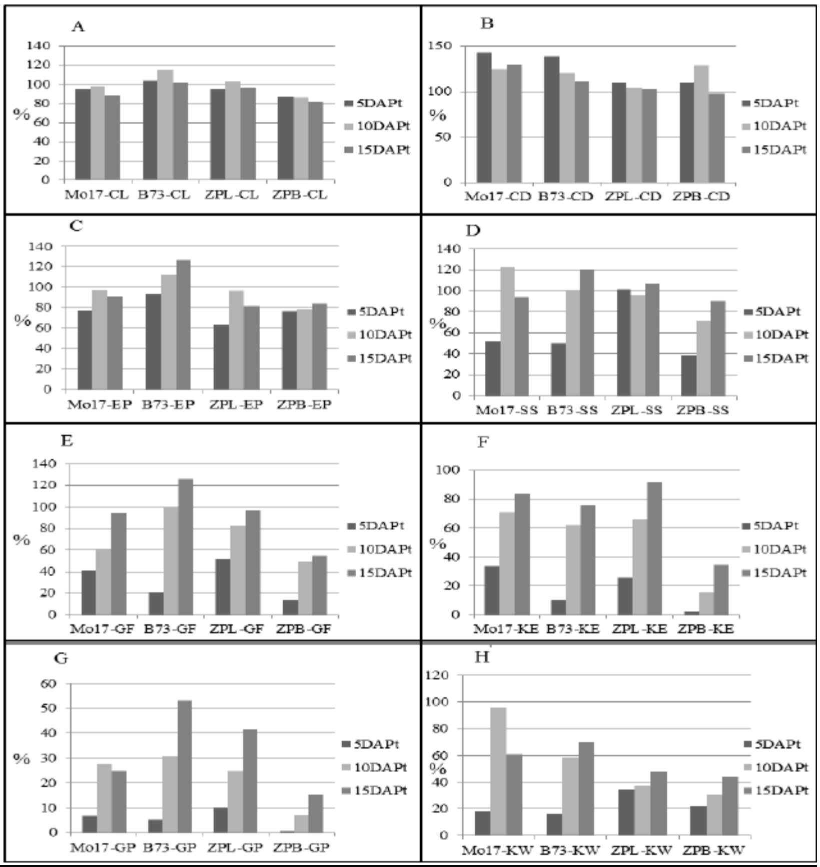

Figure 1. Values for CL (A), CD (B), EP (C), SS (D), GF (E), KE (F), GP (G) and KW (H) are presented in percent of the control for four lines and three cut-off treatments.

LSD values at 0.05 level for genotypes over years were calculated (data not shown). For all analyzed traits, ZPL was significantly better or at the level of Mo17, indicating that it is an improved Lancaster line regarding drought tolerance. On the other hand, B73 and ZPB had, in most cases, non-significant differences between trait averages, except for GF at 15DAPt and KE at 10DAPt where B73 was superior, but only overall both seasons. Therefore, ZPB showed better stability of drought tolerance over B73, but it is not significantly improved for this trait considering both years of research.

If pollination occurs 3-8 days after first silk exposure maximal seed set is expected (Carcova *et al.*, 2000; Anderson *et al.*, 2004). According to this, plants would be adequately pollinated already at the first treatment in our experiment (5DAPt). The results for SS, however, showed that pollination was not sufficient. Namely, SS was less than 33.00% for three lines and 76.25% for ZPL. SS in our experiment raised with number of DAP. This trait, however, remained constant in the review presented by Borrás and Vitantnonio-Mazzini (2017). Regarding GF the experiment was efficient, since there was a growing trend from 5DAPt to 15DAPt. The least values were obtained for ZPB. In maize and other cereals there are three phases of grain filling: a lag phase, a linear phase and a phase of slowing down approaching the physiological maturity (Johnson and Tanner, 1972). The first phase lasts 15-18 DAP and during this time very little dry weight is accumulated. In our experiment normal grain filling was stopped at 5DAPt and 10DAPt since the lag phase was not finished. KE was particularly low at 5DAPt for all lines and again ZPB was the poorest one. The most jeopardized trait was GP with maximum value of 53.2% in comparison with the control for B73 at 15DAPt. KW showed increasing trend from 5DAPt to 15DAPt, except for Mo17 at 10DAPt, and smaller values for all treatments were obtained for ZPL and ZPB. Middle leaves have essential role in photosynthesis and deriving grain yield (Siahkouhian *et al.*, 2013). Defoliation in mentioned research produced many immature and small kernels on ear tips. Similar phenomenon occurred in our experiment. Premature death of leaves induced by cutting off the stalks resulted in yield losses and plants most probably remobilized stored carbohydrates from the leaves and/or stalks to the developing ears, but yield potential was already lost. Death of all plant tissues, occurring about 15 days after cutting off the plants, stopped any further remobilization of stored carbohydrates into the ears.

Pearson's correlation coefficients between treatments and checks were significant only for 15DAPt and checks for KE (0.681; $p<0.01$) and GP (0.543; $p<0.05$), and we could assume that at 15DAPt our experiment became feasible for predicting final grain yield under uncontrolled environmental conditions.

Conclusions

In the literature we could not find cutting off plants as a way of source-sink manipulation in plants. High plant density is often used during inbreeding or double haploid breeding for obtaining new, drought tolerant maize inbred lines. An improved breeding scheme for increased drought tolerance could be proposed. The new approach would include self-pollination of border plants on high density progenies, cutting off selfed plants at 15 DAP and evaluating their kernel properties. Besides for SS and GF, open-pollinated progeny could be used for estimating other important traits (ASI, stay green, tolerance to plant and stalk lodging, diseases and pests). From the chosen progenies kernels from selfed and cut-off plants should be used for next generation of breeding. One of the advantages of such approach might be shortening of vegetative period of late materials, thus allowing more generations per year.

TROPHIC STRUCTURE OF THE NEMATODE COMMUNITY IN MONOCULTURES OF CARROTS (*DAUCUS CAROTA SUBSP. SATIVUS*)

Lilyana KOLEVA*, Deria ADEM

University of Forestry, Sofia, Bulgaria
*Corresponding author: liljanamarkova@abv.bg

Abstract

The carrot (*Daucus carota* L.) has been used as food since ancient times. Despite of the nutritional importance of carrots, their production in small farms is stagnant or declining. The main reason is the monoculture of the carrots, where the risk of attack and damage from pests is high. The carrots change their shape and appearance under the influence of a number of biotic stress factors such as bacteria, fungi and plant-parasitic nematodes which affect their quality. Plant-parasitic nematodes are long known to cause significant damage to carrots. The results of the present work have been obtained on the basis of conducted field and laboratory studies, as for the research were used agricultural areas in the region of Targovishte. The aim of the present work was to assess the phytosanitary status of the areas in the monocultures of carrots on the basis of the trophic structure of the nematode communities. A total of 11 genera of plant parasitic nematodes were found in the analyzed samples. The genus *Pratylenchus* was found in 92% of the samples tested. The genus *Meloidogyne* was found in 53% of the samples. In addition to plant parasitic nematodes, entomopathogenic nematodes of the genus *Steinernema*, omnivorous nematodes of the genus *Dorylaimus* and bacterial-feeding nematodes of the genus *Cephalobus* were also found. The knowledge of the trophic structure of nematode communities in monoculture is a key to deciding on a crop rotation that will effectively reduce plant-parasitic populations.

Key words: *carrots, nematodes, monoculture.*

Introduction

The carrots (*Daucus carota* L.) are widespread in all countries of Europe, Asia, Africa and America because of their high plasticity, adaptability to environmental conditions, keeping edible and good taste quality. However, irrespective of the nutritional importance of carrots, their production on small farms is stagnant or declining. Some of the major problems are technological, related to the quality of the seed, germination and germination energy, which leads to low yields (Lada et al., 2004). Despite the application of chemical and organic fertilizers that guarantee the successful production of carrots, yields are often low on these farms. The main reason is undoubtedly the monoculture cultivation of carrots, where the risk of attack and damage by pests is greatest. The carrots change their shape and appearance under the influence of a number of stress biotic factors such as bacteria, fungi and plant parasitic nematodes. The plant-parasitic nematodes have long been known to cause significant damage to carrots (Fitzgerald 1950). They feed on the root system (with both root, lateral roots and root hairs) as a result, the nutritional value decreases and the root deformations are observed (Pretorius & Engelbrecht 2009, Tangvik 2017). Deformed carrots do not meet the market criteria

Many of the farmers' questions refer to clarifying the causes that lead to distortions and poor quality of production. All this is leading to finding ways of reducing the negative effects while ensuring plant health and the potential of the crop.

The purpose of the present work is to evaluate the phytosanitary status of the areas in monoculture cultivation of carrots on the basis of the trophic structure of nematode communities.

Materials and Methods

Characteristics of the region, experimental area and plant material

The results of this work were obtained on the basis of field and laboratory studies. For the purposes of the study, agricultural land was used in the area of Targovishte (Vasil Levski village, GPS: 43°15'48.4"N 26°37'36.9"E). In the region, the soil in mechanical composition can be classified as heavily sandy-clayey. It is are characterized by good water-physical properties, with medium to low water permeability, good water holding capacity and relatively favorable air regime.

Carrots (*Daucus carota* subsp. *sativus* (Hoffm.) Schübl. & G. Martens, variety Nantes 2 were used for the experiments. The investigations were conducted during the growing season in 2015-2018. The experiments were carried out in the first half of March, on an area where carrots have been grown for 10 years ,with an area of 180 m^2, with a total number of plants 1200, with planting scheme: 0.06 m in-row and 0.25 m in-row distance, rows oriented east-west. The soil tillage was done manually. During the growing season, plant protection products were not used.

Sampling methods

The plant health condition of the fields has been satisfactory; there were zones of reduced plant growth and plant damage. Soil samples were taken to evaluate the quantitative and qualitative composition of the migrating root nematodes.

According to the meteorological data, abiotic factors, which could cause these symptoms, are excluded. The period of sampling of plant and soil samples was consistent with that recommended by Knuth et al. (2003). In order to determine the increase or decrease of density of the populations, the samples were taken depending on the season, before sowing and repeatedly during the growing season. The soil samples were taken randomly from 15 – 25 cm depths and then transferred in plastic bags to the laboratory. After mixing the samples, the average samples of 100 cm^3 were determined by means of a measuring cylinder. The resulting quantitative and qualitative data was related to this volume.

Samples from the root system of healthy and diseased plants were also taken for analysis. The root systems and roots were harvested at the same time as the soil and placed in the same bag. A simple amount of 500 g of root was sufficient for the pooled sample.

Extraction of the nematodes

The methods for the extraction of the nematodes from the soil and roots and their subsequent mounting on permanent slides for identification are according to the Baermann pan method described by Townshend (1963). In addition, the samples were examined for the presence of cyst nematodes by flotation methods.

Quantitative and qualitative assessment of nematodes

The liquid nematode suspension was filled to 100 ml with water to include the number of extracted individuals. The suspension was transferred (5 times per 1 ml) into Bogorov Modified Counting Chamber. Initially, all nematodes were counted under stereomicroscope and the plant parasitic nematodes were separated at recount. The average number of live nematodes in the sample (100 cm^3) in the starting suspension of 100 ml was determined by Peters (2013). Species characterization and identification were based on morphology of various life stages [1. Andrassy 1998, Holovachov et al., 2017). Due to the complexity of the process of identification, the some extracted nematodes were determined up to genus level.

The dominant genera were described by using Engelmann's method (Engelmann, 1978). All individuals were subdivided into trophic groups based on the classification of Yeates et al. (1993). The number of nematodes in the various trophic groups was calculated by the relative density of taxa (in 100 cm^3) included in the group.

Results and Discussion

Trophic structure and analysis of nematode communities

A total of 11genera of plant parasitic nematodes were detected in the analysed samples. In the table 1, lists the identified genera and species of plant-parasitic nematodes. The number of samples tested is also indicated.

Table 1. Plant-parasitic nematodes in soil and plant samples

Genus	Speies	number of individuals [n=67]
Aphelenchoides	*Aphelenchoides saprophilus*	2
Ditylenchus	*Ditylenchus dipsaci*	1
Geocenamus		17
Helicotylenchus	*Helicotylenchus sp.*	11
Meloidogyne	*Meloidogyne hapla*	36
	Meloidogyne naasi	8
Paratrichodorus	*Paratrichodorus sp.*	2
Paratylenchus		41
Pratylenchus	*Pratylenchus neglectus*	61
	Pratylenchus penetrans	13
	Pratylenchus crenatus	81
Rotylenchus	*Rotylenchus sp.*	5
Trichodorus	*Trichodorus similis*	21
Tylenchorhynchus		142

The genus *Pratylenchus* with the species *P. crenatus*, *P. neglectus* and P. *penetrans* was detected in 92% of the tested samples. The genus *Meloidogyne* with *M. hapla* and *M. naasi* species was found in 53% of the samples.

Other plant-parasitic genera were *Paratylenchus*– 56% and *Trichodorus/ Paratrichodorus,* which were represented in 41% of the samples. *Ditylenchus* was observed in only 5% of the samples. The nematodes of genus *Ditylenchus* were difficult to detect in soil. A significant number of plant analyses were required to accurately identify them. The Pratylenchus species during sampling may be in the root rather than in the soil and thus have lower values. Also, values in the Meloidogyne genus could be higher, as Meloidogyne nematodes can hardly be covered by the sampling. Therefore, nematodes of this genus may not be found in soil samples from areas with typical *Meloidogyne* damage (root knotting). The widespread genus *Tylenchorhynchus* is irrelevant to carrot production. The relative frequency of genera is shown in Fig. 1.

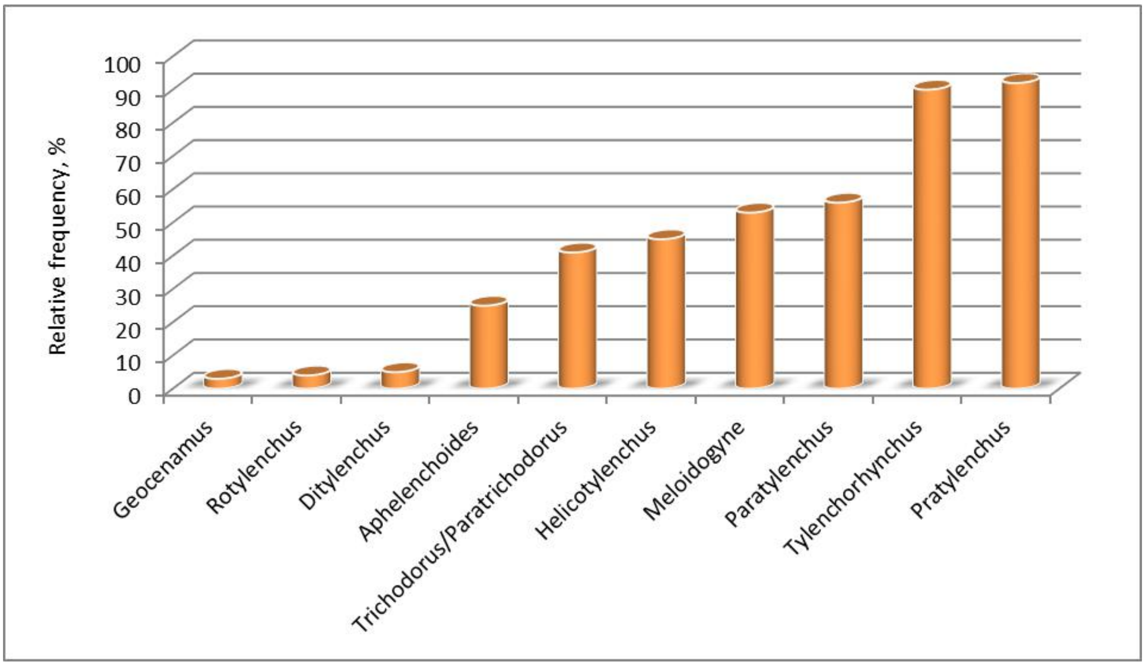

Figure 1. Relative frequency of plant parasitic nematodes in the tested samples (n = 67)

In addition to plant-parasitic nematodes, entomopathogenic nematodes of the genus Steinernema were detected in 14% of the tested samples. Saprophagic nematodes of the genus Dorylaimus were detected in 19% and in 3% of the samples found the genus Cephalobus, which feeds on bacteria. Predatory nematodes of genus Mononchus were found in only 1 sample (Fig. 2).

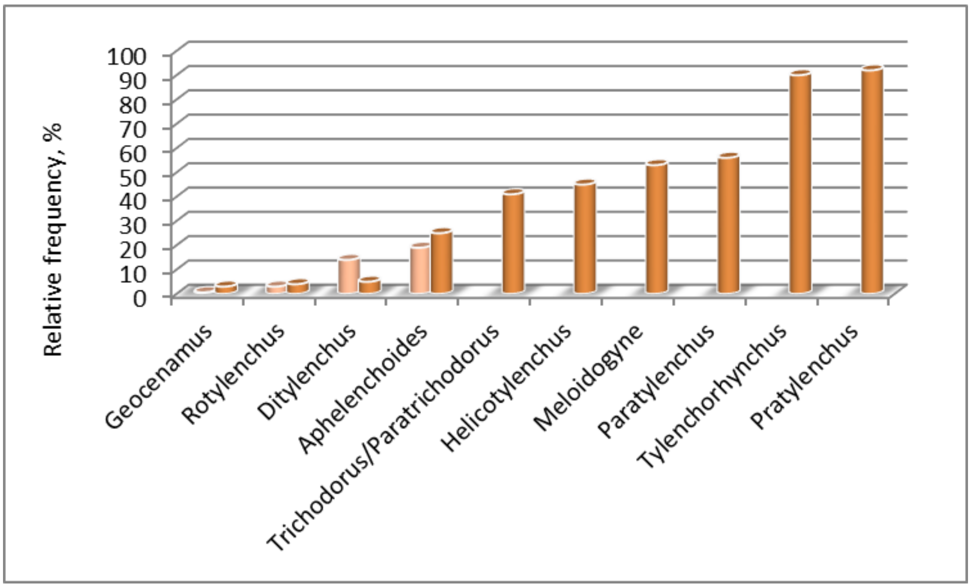

Figure 2. Relative frequency of beneficial and indifferent nematode species in the samples tested (n = 67**)**

Depending on the relative share of individuals in the nematode community, the genera *Pratylenchus*, *Meloidogyne*, *Paratylenchus* were dominant; eudominant - *Tylenchorhynchus*, and subdominants *Helicotylenchus*/*Rotylenchus* (Engelmann 1978) (Fig. 3).

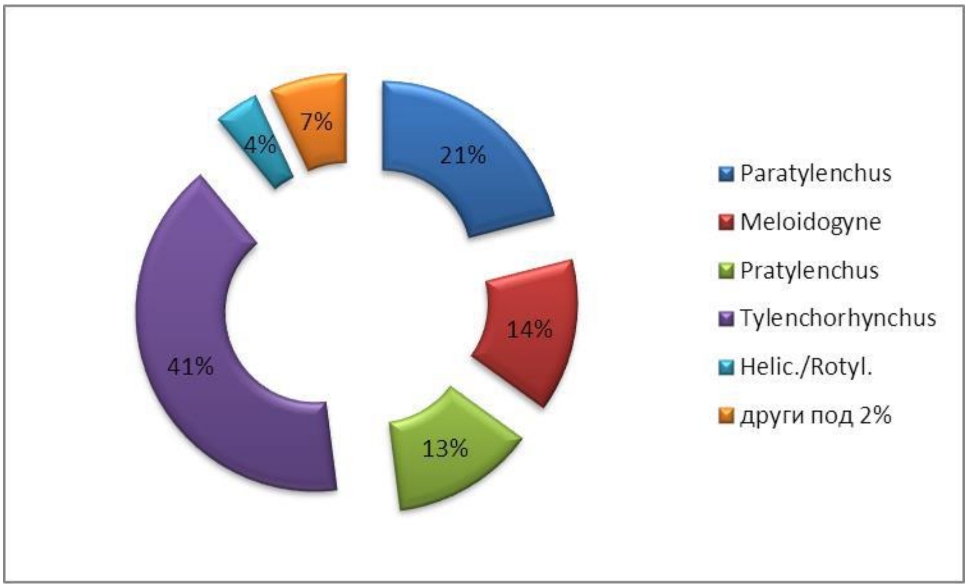

Figure 3. Dominant structure of plant-parasite genera in the tested samples (n = 67)

Figure 4 shows that more than 3 genera/sample were detected in most samples.

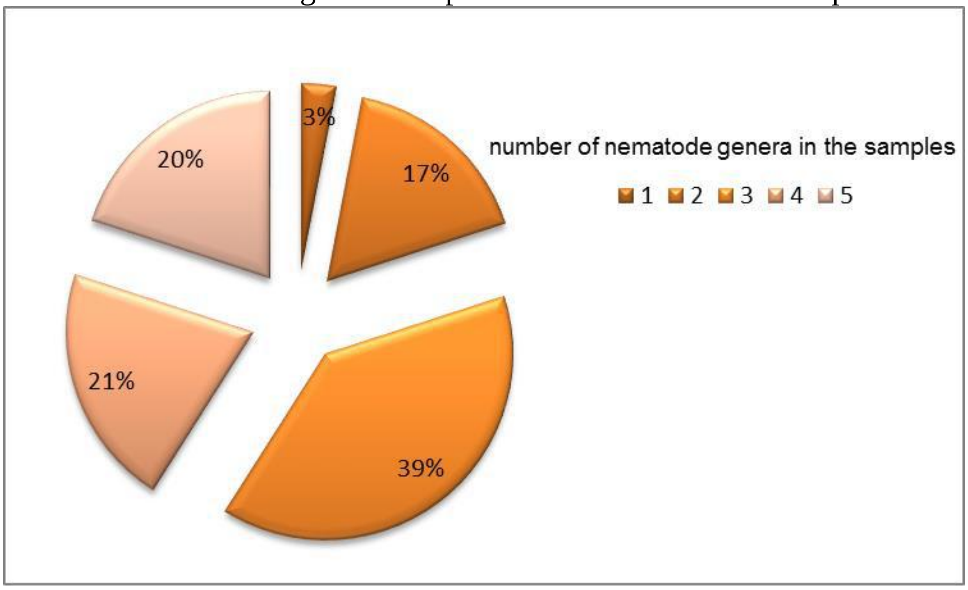

Figure 4. Relative share of the jointly founded plant-parasite genera in the tested samples (n = 67)

In more than 28% of all samples, the 3 genera Meloidogyne, Pratylenchus and Paratylenchus were found together (Tab. 2). Joint populations of the genera *Pratylenchus* and *Paratylenchus* as well as *Meloidogyne* and *Pratylenchus* have been proven. *Meloidogyne* spp. alone were detected in only 4 soil samples.

Table 2. Occurrence of genera (n = 195)

Genus	Number of individuals in the samples	Relative share,%
Meloidogyne	4	2
Pratylenchus	39	19
Paratylenchus	3	2
Meloidogyne Pratylenchus	40	20
Meloidogyne	5	3

Paratylenchus		
Pratylenchus Paratylenchus	50	26
Meloidogyne, Pratylenchus Paratylenchus	54	28
total	195	100
number of samples	67	93

Table 2 shows that nematode genera that cause significant damage are often found together. Therefore, their regulation through crop rotation becomes more difficult as each species has a different range of hosts. The nematodes in the soil were of low numbers (between 1 and 20 nemotodes in 100 cm3 of soil) most often. The genus Pratylenchus shows proportionally higher levels of infection than the genus Meloidogyne (Fig. 5). There are various factors affecting the number of the nematodes, such as the sampling time and phenophase of the carrots during sampling.

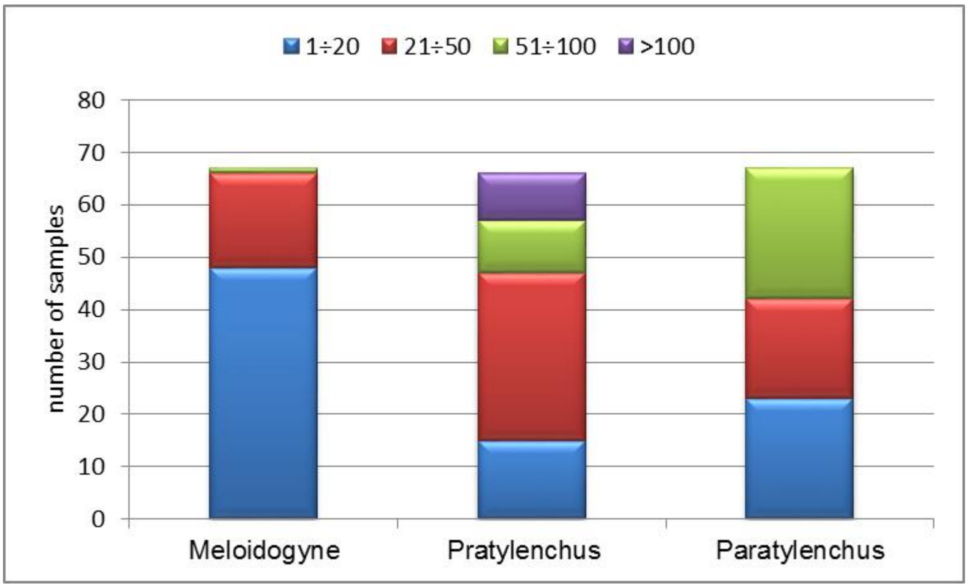

Figure 5: Number of dominant genera in nematode communities)(nematodes / 100 cm3 soil) divided into 4 different classes (n = 67)

During all time points in the study, an average of 5-6 species of plant-parasitic nematodes were identified. The main plant- prasitic nematodes in our research were *Meloidogyne hapla* and various species of *Pratylenchus*, mostly *P. crenatus*, *P. neglectus* and *P. penetrans*. Since several Pratylenchus species always appeared simultaneously in the samples, they can be assembled in *Pratylenchus* spp. Other authors also point out that main plant-parasitic nematodes on carrots are species of the genera *Meloidogyne*, *Pratylenchus*, *Paratylenchus* and (*Para*-) *Trichodoru*s (Hallmann & Meressa 2018; Sikora et al. 2018). Significant yield losses can be observed even at low levels of nematode infection on carrots of (Hay et al. 2004).
As the application of nematocides in small farms is economically unjustified, the control of plant-parasitic nematodes is based mainly on non-chemical methods. Knowing about the trophic structure of nematode communities in monoculture cultivation is a key factor leading to decisions of applying crop rotation, which will effectively reduce plant-parasitic nematode populations. Further studies are needed to determine causes of species damage, to improve the prognosis, and to develop easily a practically applicable control measures**.**

Conclusions

In the analysed samples were detected a total of 11 genera plant-parasitic nematodes. Eudominant was the genus Tylenchorhynchus; dominant - genera Pratylenchus, Meloidogyne, Paratylenchus, and subdominants Helicotylenchus and Rotylenchus. The genus Pratylenchus with the species *P. crenatus*, *P. neglectus* and *P. penetrans* was detected in 92% of the samples tested. The genus *Meloidogyne* with the species *M. hapla* and *M. naasi* was found in 53% of the samples. Nematode genera, which cause significant damage to the carrots, were common together. Joint populations between the genera *Pratylenchus* and *Paratylenchus* as well as *Meloidogyne* and *Pratylenchus* have been proven. *Meloidogyne* spp. In more than 28% of all samples, the three genera *Meloidogyne*, *Pratylenchus* and *Paratylenchus* were found together. In addition to plant parasitic nematodes, entomopathogenic nematodes of the genus Steinernema were detected in 14% of the tested samples. Saprophagic nematodes of the genus Dorylaimus were found in 19% and in 3% of the samples the genus Cephalobus was found to feed on bacteria. Mononchus predatory nematodes were only found in 1 sample.

Abstract

Aromatic and medicinal plants are a natural source of volatile oils studied for the antimicrobial, insecticidal or antioxidant activity. The composition of volatile oils of the same species may vary depending on the geographical origin. The purpose of the present research was to acquire new Scanning Electron Microscopy (SEM) images on secreting tissues of *Mentha x piperita* L. plants (Romanian ecotype originated in Ulmeni, district Teleorman) and to identify the main organic compounds from biochemical composition of volatile oil, underlining their importance for utilization in pharmaceutical, alimentary or cosmetics industry. The study of secretory tissues was performed using electronic microscopy at the Research Center HORTINVEST, U.A.S.M.V. Bucharest. Separation and identification of the compounds in volatile oil was carried out by gas chromatography. NIST spectral library was utilized to identify the essential compounds and verified using Kovat's indices. Micromorphological and anatomic analysis of SEM images of leaf tissues revealed secretory structures represented by hairs with unicellular and multicellular glands. Chemical composition of volatile oil of the Romanian ecotype of *Mentha x piperita* L. included 23 compounds, most important proportion being recorded for the next compounds: alpha-terpinolene (29.80%), terpinen-4-ol (23.33%), gamma-terpinene (9.84%), alpha-terpinene (6.40%), sabinene (4.26%), cis-p-terpineol (3.97%). These volatile compounds, generally recognized as safe (GRAS), are known to confer the character of medicinal and aromatic plant and recommend its utilization in pharmaceutical industry, plant protection, food industry and perfumery.

Keywords: *Mentha, volatile oil, scanning electron microscopy, secreting tissue, chemical composition.*

Introduction

Aromatic and medicinal plants are a natural source of volatile oils studied for the antimicrobial, insecticidal or antioxidant activity (Pandey and Tripathi, 2011). The composition of volatile oils of the same species may vary depending on the geographical origin (Al-Bayati, 2009). Originating in the regions around the Mediterranean Sea, cultivated peppermint has spread worldwide in regions with favorable thermic climate, including countries from Europe, Asia and America. Taxonomy studies based on phylogenetic analysis, morphology, the number of chromosomes and the main chemical constituents of volatile oil (Cantino *et al*., 1992) redefined the genus *Mentha* (from Family *Lamiaceae*, order *Lamiales*). In present, 18 species and 11 hybrids grouped in 4 Sections are included in this genus (Tucker and Naczi, 2007). Of these, 6 species of *Mentha* (with varieties) and 6 hybrids have been described in Romanian flora (Beldie,1979; Ciocârlan, 2009). *Mentha x piperita* L. requires cultivation on well aerated, permeable, fertile and humid soils (humidity around 80-90%).

Plants cultivated on sunny fields produce volatile oils rich in menthol and poor in menthone. These properties warranty a superior quality of mint volatile oil (Păun,1975). The hybrid *Menta x piperita L.* is frequently met in spontaneous flora but varieties of the taxa are cultivated for their special properties, presenting economic importance (Tucker and Naczi, 2006). It is cultivated on large areas in USA, Russia, Bulgaria, Italy, France. In Romania, this hybrid can be found especially in districts Bistriţa-Năsăud, Sibiu, Argeş and Ilfov (Oprea, 2005). Plants of this hybrid are resistant to -10 ºC unprotected or even until -25 ºC – 30 ºC under the snow layer or protected with various materials. They can grow in shadow but a high light intensity is more favorable for obtaining higher yields. The plants content in volatile oil and its quality are also influenced by soil characteristics, such as good aeration, permeability, drainage and fertility. The purpose of the present research was to acquire new Scanning Electron Microscopy (SEM) images on secreting tissues of *Mentha x piperita* L. plants (Romanian ecotype originated in Ulmeni, district Teleorman) and to identify the main organic compounds from biochemical composition of volatile oil, underlining their importance for utilization in pharmaceutical, alimentary or cosmetics industry.

Materials and Methods

***Mentha x piperita* L. plants** (Romanian ecotype originated in Ulmeni, district Teleorman) were sampled in flowering stage.

Micromorphological analysis of leaf and stem tissues (the study of secretory tissues) was performed using electronic microscope Inspect S50 (FEI) at the Research Center HORTINVEST, U.A.S.M.V. Bucharest.

Chemical composition of volatile oil: Volatile oil was extracted from plants by hydrodistillation using a Clevenger-type apparatus. Heating was carried out with Bunsen burner, with precaution to avoid overheating of distillation recipient. Generally, the vegetal mass and water ratio was 1:3 (w/v). Separation and identification of the compounds was carried out by gas chromatography (Agilent 7890B-MSD 5977A apparatus with sample introduction system GC 80, HP-5 MS Ultra inert column of 30 m, Ø = 0,250 mm and fill of 0,25µm). Chromatographic conditions were: injecting temperature: 250 °C; detector temperature: 150 ºC; initial temperature of the oven: 50 °C, programmed to grow gradually until 150 °C. Helium was utilized as carrier gas to a linear flow rate of approximately 0,6 ml min. Retention time and peaks were processed using Agilent 7890B-MSD 5977A software. NIST spectral library was utilized to identify the essential compounds and was verified using Kovat's indices.

Results and Discussion

Micromorphological analysis of SEM images of leaf and stem tissues of *Mentha x piperita L.* revealed secretory structures represented by hairs with unicellular and multicellular glands (Figures 1, 2, 3).

For most species in this family there are two types of secretory hairs: peltate and capitate (Fahn, 1988). The results obtained are similar to those obtained by Svoboda et al. (2001) and Andro (2012) in *Mentha* spp. or in *Thymus pannonicus* (Boz *et al*., 2009).

Chemical composition of volatile oil of the Romanian ecotype of *Mentha x piperita* L. determined by GC-MS analysis (Figure 3) included 23 compounds, the most important proportion being recorded for the next compounds: alpha-terpinolene (29.80%), terpinen-4-ol (23.33%), gamma-terpinene (9.84%), alpha-terpinene (6.40%), sabinene (4.26%), cis-p-terpineol (3.97%).

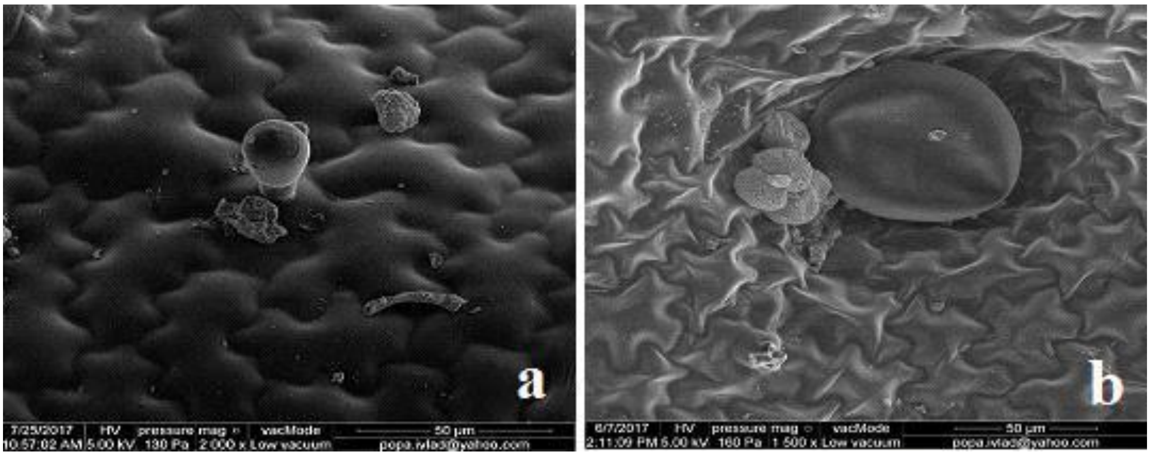

Figure 2. The scanning electron - microscopy image of upper (adaxial) epidermis of *Mentha x piperita L.* leaf (a) and (b). Secretory hair with unicellular (a) and multicellular glands (b).

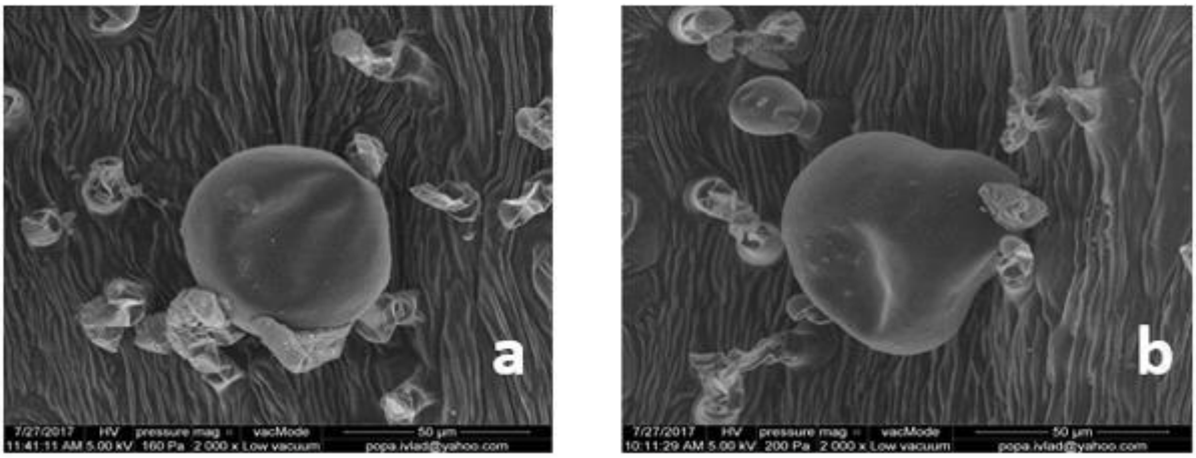

Figure 3. The scanning electron - microscopy image of stem - Secretory hair with unicellular and multicellular glands of *Mentha x piperita* L.

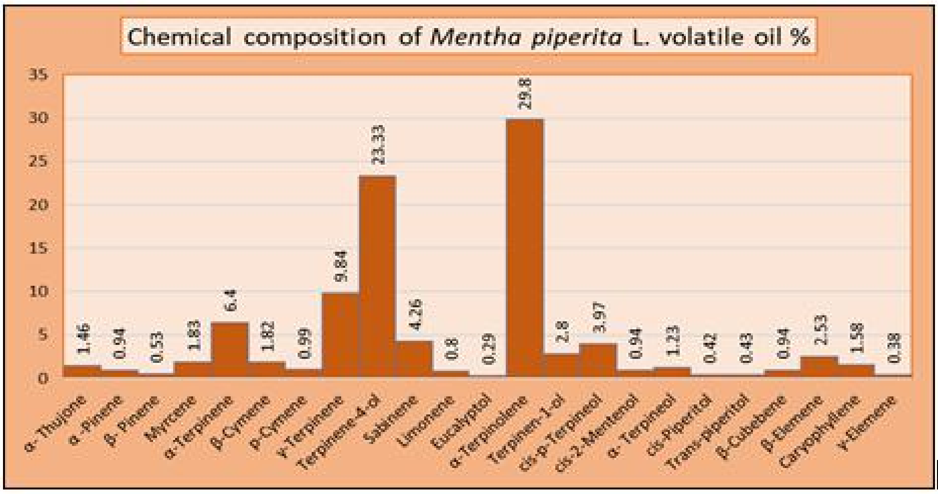

Figure 3. Chemical composition of *Mentha x piperita* volatile oil (%)

These volatile compounds, generally recognized as safe (GRAS), are known to confer the character of medicinal and aromatic plant and recommend its utilization in pharmaceutical industry, plant protection, food industry and perfumery. α -terpinolene (29.80%), belongs to the group of terpenoids, also known as terpenes, a category of phytochemical products which provide a wide range of therapeutic benefits. These substances can present sedative and antioxidant properties as well as antimicrobial activity. Terpinolene is commonly used to improve the odor of various industrial and household products, like mixing paints and varnishes. Terpinolene is found in citrus, allspice, peppermint, juniper, and parsnip essential oils. Terpinolene is used as an input in soap, detergent, creams, lotions, perfume, fragrances, flavoring ingredients, and laundry and dishwashing products. In certain cannabis varieties, terpinolene can be the predominate terpene (https://praxis-laboratory.com/terpene-analysis). α – terpinene (6.4%) is a flavoring and fragrance chemical used in the personal care and cosmetic and food industries, also used in the pharmaceutical and electronics semi-conductor manufacturing industries (https://foreverest.cn/products/turpentine-derivatives/99-alpha-terpinene.html). Like other terpenes, α -terpinene is commonly used in essential oils and in the production of perfumes. α-Terpinene is often used to synthesize other products and reagents (https://praxis-laboratory.com/terpene-analysis/). Terpinen-4-ol (23.33%) is utilized in perfumery for its flavor (smells like lemon). It has strong anti-allergenic, anti-asthmatic, antiseptic, antibacterial, diuretic and fungicidal effect (http://www.alegesanatos.ro/cautare/).
γ -terpinene (9.84%) is a terpene with acaricide, insect repellent and antioxidant properties. γ-Terpinene is colorless, oily terpene with an odor that resembles turpentine. γ -Terpinene exudes a tropical, lemon-lime, woody scent and has a bitter taste. γ-Terpinene is an insectifuge, a compound that repels insects non-lethally, and can also be an irritant. γ -Terpinene is also an antifeedant, a naturally occurring substance that adversely affects creatures that feed upon plants that produce it. γ-Terpinene is found in a variety of foods, including allspice, carrots, cinnamon, oregano, sage, and thyme. Commercially, γ -terpinene is used as a flavor and a production input in perfumery (https://praxis-laboratory.com/terpene-analysis/). Sabinene (4.26%) presents antimicrobial, antiseptic, bactericide properties (www.ars-grin.gov) and is utilized in perfumery (Burzo, 2015). Andro (2012) found: α -pinene, sabinene, β -pinene, β -myrcene, 3-octanol, β -ocimene, limonene, eucalyptol, cis- β -ocimene, menthone, iso -menthone, menthol, terpinen-4-ol, α -terpineol, pulegone, piperitone, menthyl -acetate, β -burbonene, β -caryophyllene, β -cubebene, mint furanone, germacrene D, caryophyllene oxide, ledole as main chemical compounds of essential oil from stems, leaves, flowers of *Mentha x piperita*. According to Burzo (2015), the volatile oil extracted from peppermint during flowering period had the following composition: 61.42% piperitone oxide,

7.56 % eucalyptol, 3.57 % beta-cubebene, 2.26 % beta-caryophyllene, 2.24 % piperitone oxide, 2.08 % beta-pinene, 2.01 % alpha-caryophyllene, 1.68 % trans-beta-ocimene, 1.44 % mint-furanone, 1.16 % 3-octanol, 1.15 % myrcene, 1.08 % alpha-pinene, 1.16 % sabinene, 0.79 % octil acetate, 0.76 % cis-beta-terpineol, 0.59 % carvacrol, 0.47 % hydro-piperitone, 0.40 % burbonene, 0.34 % cubenol, 0.29 % alpha-cadinol, 0.29 % germacrene D and 0.27 % calamenen. Research carried out on the composition of essential oils from *Mentha x piperita* L. reported menthol (53.28%), methyl-acetate (15.1%), menthofuran (11.18%) as main constituents of the total 17 compounds identified and significant antimicrobial activity against human pathogenic species of *Candida* (Saharkhiz et al., 2012). Other studies found menthone, neomenthol, menthol and carvacrol as compounds of peppermint essential oil from Brazil responsible for antifungal activities in postharvest deteriorating species of *Aspergillus*, *Colletotrichum* and *Fusarium* (Freire et al., 2012). In peppermint essential oil from Romanian ecotype, menthol was not detected, as also reported for essential oil from Portugal (Martins et al., 2004). Strong antimicrobial, insecticidal and antioxidant activities in essential oils from different species of the genus *Mentha* offer the prospective of their use as natural, environmentally friendly products with commercial value ((Rahnama et al., 2017; Singh and Pandey, 2018).

Conclusion

Micromorphological analysis of SEM images of peppermint leaf tissues revealed open stomata and secretory structures represented by hairs with unicellular and multicellular glands. Chemical composition of volatile oil of the Romanian ecotype of *Mentha x piperita* L. from Ulmeni, district Teleorman, included 23 compounds, most important proportion being recorded for the next compounds: alpha-terpinolene (29.80%), terpinen-4-ol (23.33%), gamma-terpinene (9.84%), alpha-terpinene (6.40%), sabinene (4.26%), cis-p-terpineol (3.97%). These volatile compounds, generally recognized as safe, are known to confer the character of medicinal and aromatic plant and recommend its utilization in pharmaceutical industry, plant protection, food industry and perfumery.

Abstract

In the Black Sea subtropical zone, the reservs to assimilate the new areas for the citriculture has been exhausted and further development of the sector is mainly possible with the introduction of modern technologies, while increasing the cost of the plant should be carried out by replacing biologically amortized plants by arranging sedimentation nurseries, raising soil fertility, timely conduct of agro-techniques and plant pest control measures and correctly organizational-practical issues. Since our region belongs to the extremely northern subtropical zone, it is necessary to select varieties that are suitable for our zones, which are distinguished by early ripening and high yield. In 2011, with the initiative of the Ministry of Agriculture of Adjara for solution of this problem, 11 varieties of tangerine were imported from Japan: Nichinani, Iura-Vase, Taguchi - Vase, Miagava - Vase, Kavada, Nankani-20, Ohotsu-Vase, Ueno-Vase, Aoshima, Okitsu-Vase, Mukaiama, which was planted in the Kobuleti municipality, the plants are planted with nutritional air of 4 × 2.5 meters, at 35-40 meters above sea level, the soil is red. We had ten plants in each variant that we have studied: - The formation of buds, the beginning and end of vegetation, the massive flowering, setting, the beginning of the ripening of the fruit and the full ripening, high yielding (piece, kg), the average weight of one fruit (g), the color of the fruit, the nature of the skin removal from the flesh, number of seals in flesh and organoleptic characteristics. We received fruit from different expositions of the plant and explored biochemical indicators at the University Laboratory. The novelty of the research is that we have examined the first phonological, agro-ecological and agro-technological characteristics of eleven varieties of introductive tangerins, from which only three varieties: Nichinani, Iura-Vase, Taguchi - Vase identified the best characteristics for our zone and were recommended to be a super early sorts, which are 40-45 days prior to the local in breeding. We recommend the cultivation of such plants by growing citrus areas and therefore productivity. The novelty of the research is also that the intensive technological complex also includes organizational and economic measures and economic issues that will be directed to improve organizational management and management of the sector.

Keywords: *Citrus, fruit, subtropical, varieties, phenology, vegetative growth*.

Introduction

The problems of development of citriculture in Georgia can not be considered only in terms of the characteristics of the market economy. It needs special approaches and support from the state, and the manufactured products will meet the requirements and standards of the world market. After the collapse of the Soviet Union, due to the breakdown of old economic ties and market relations, export was significantly reduced and import increased. Currently, harvesting of citrus cultivars is 10 times lower, but the quality of harvest is reduced and the export is

difficult. For example, in 1995 citrus exports comprised 7 million US dollars, and in 2000 the export volume decreased to 2.3 million, and in 2018 only $ 1.1 million (Jabnidze, 2018).
Plants in our citrus garden in the age of eighty years and more. Theoretically and practically it is proven that citrus fruits are highly productive until the age of 50-55, then the harvest is gradually decreasing, and any agronomic activities do not give the desired result.
One of the effective measures for solving this issue is the rejuvenation of plants in the citrus plantations, namely, the biologically aged plants should be replaced by the abundant and stablely fruit-bearing, early ripening varieties and forms of species, which are better adapted to the local conditions. The replacement of amortized trees with young plants will increase yield and decrease the timing of harvesting. This will increase economic efficiency and in a few years we will get completely rejuvenated plantations (Lamparadze, 2014).
In order to solve this problem, it is necessary to arrange new nurseries and gardens from district and collective gardens. At the same time, it will be essential to establish such ratio of the varieties of breeds, which provide the prolonged period of harvest and relatively early adoption of harvest, which is unimaginable without early ripening breeds at different times, which have already been tested and approved in many foreign countries, which produce citrus. From the financial point of view, the event will be economically advantageous, our calculation confirms it. In the amortized gardens averaging 10-11 tons of fruit per hectare, younger (25 years) up to 30 tons, which can bring extra income for farmers and private owners annually (Beridz, 2010).

Material and Methods

The plant material included 11 varieties of tangerine (Nichinani, Iura-Vase, Taguchi-Vase, Miagava-Vase, Kavada, Nankani-20, Ohotsu- Vase, Ueno-Vase, Aoshima, Okitsu-Vase, Mukaiama) which were imported from Japan in 2011, with the initiative of the Ministry of Agriculture of Adjara, Our experiment was conducted on the south-eastern slopes of the 25-35 degrees in the Chakvi citrus collection of the Kobuleti municipality, where the plants are planted at 4 × 2.5 meters, at an altitude of 35-40 meters above sea level. Under the plants, the soil is red, we had ten plants in each variant, and we had tested and examined about 110 plants. Studies were conducted according to the preliminary draft and methodology. All trial plants were numbered, labeled, obtained data was written in a special journal where all the data of each plant was envisaged for research.
On each varieties we did the phenological monitoring: the formation of buds, the beginning and end of vegetation, the massive flowering, setting, the beginning of the ripening of the fruit and the full ripening, yield (piece, kg.), the average weight of one fruit (g.). In 2011-2018 we also studied biometric indicators on tangerine varieties, thus determining the height of the plant in cm, the base and bot diameter in mm for grafting (table 3).

Results and Discussion

Observations have shown that the following varieties of tangerine are distinguished with the early ripening, quality and productivity: Nichinani, Iura-Vase and Taguchi – Vase.
As shown in the 1-2 table, the blossoms, vegetation and massive blossoming on the above-mentioned plants almost coincide with each other. The fruit setting was begun in the third decade, the second vegetation in the second decade of August.
Nichinani - The massive ripening of the fruit began in the second decade of October. On average one tree has produced 415 pieces of fruit, resulting in an average of 24.3 kg. The average weight of one fruit is 57.7 g. The number sections in the flesh is 12 (Table 1-2). The leaves are oval, the average size is 12 × 6 cm, the length of stem is 2 cm. Attached with the sharp angle. The size of the plants in the range was 223 cm, the diameter of the base and the bot for grafting is 62-52 mm (Table 3).

Iura-Vase - The massive ripening of the fruit began in the first decade of September, and the mass of ripening phase in the third decade of September, on average, 458 pieces of fruit was gathered per tree, which reached averagely of 20.1 kg. The average weight of one fruit is 52.3 grams. In comparison with breed Nichinani, the fruit is smaller in size, the number of sections in the flesh is 11 (Table 1-2). The leaves are rhombic-oval, the average size is 13X7 cm, attached with the sharp angle. The length of the stem is 2,5 cm. The size of the plants in the range was 171 cm, the diameter of the base and the bot for grafting is 60-58 mm (Table 3).

Taguchi – Vase - The second vegetation beginning was at the first decade of August. The massive ripening of fruit began at the second decade of September, averagely, 425 pieces of fruit was gathered per tree, which reached averagely of 28,5 kg. The average weight of one fruit is 62,4 grams. The number sections in the flesh is 10 (Table 1-2). The plant is well-leafy, the leaf is attached with the sharp angle and is of the dark-green color, the length of the stem is 2.0 cm. The average size of the leaf was 13.5X5 cm. The size of the plants in the range was 198 cm, the diameter of the base and the bot for grafting is 56-48 mm (Table 3).

Table 1. Basic phenological pbservation pata on pifferent species of tangerine (2011-2018 average)

	Variety	Waking buds	The first vegetation	Massive flowering	The second vegetation
1	Nichinani	II decade of March	III decade of April	I decade of May	II decade of August
2	Iura-Vase	II decade of March	III decade of April	I decade of May	II decade of August
3	Taguchi-Vase	II decade of March	III decade of April	III decade of May	II decade of August
4	Miagave-Vase	III decade of March	III decade of April	II decade of May	II decade of August
5	Kavada	III decade of March	III decade of April	III decade of May	III decade of August
6	Nankani-20	III decade of March	III decade of April	III decade of May	III decade of August
7	Ohotsu-Vase	I decade of April	I decade of May	III decade of May	III decade of August
8	Ueno-Vase	III decade of March	III decade of April	II decade of May	II decade of August
9	Aoshima	I decade of April	I decade of May	III decade of May	III decade of August
10	Okitsu-Vase	III decade of March	II decade of April	I decade of May	II decade of August
11	Mukaiama	III decade of March	III decade of April	I decade of June	II decade of August

Table 2. Basic phenological, productivity and fruit weight observation data on different species of tangerine (2011-2018 average)

N	Species	End of 2nd growth	Beginning of ripening fruit	Massive ripening of fruit	Productivity		Average weight of one fruit (gr)	Number of particles in the pulp (units)
					Pieces	In Kg		
1	Nichinani	II decade of August	I decade of September	III decade of September	415	24.3	57.7	12
2	Iura-Vase	I decade of August	I decade of September	III decade of September	458	20.1	52.3	11
3	Taguchi-Vase	I decade of August	II decade of September	I decade of October	425	28.5	62.4	10
4	Miagave-Vase	II decade of August	I decade of October	III decade of October	355	23.5	54.2	11
5	Kavada	II decade of August	III decade of September	II decade of October	252	21.5	49.2	10
6	Nankani-20	I decade of August	III decade of September	II decade of October	265	21.8	63.2	11
7	Ohotsu-Vase	III decade of August	II decade of October	I decade of November	231	22.4	62.1	11
8	Ueno-Vase	II decade of August	II decade of September	I decade of October	371	24.2	51.3	10
9	Aoshima	III decade of August	I decade of October	I decade of November	81	8.4	84.2	10
10	Okitsu-Vase	I decade of August	III decade of September	I decade of October	347	25.2	68.4	12
11	Mukaiama	II decade of August	III decade of September	III decade of October	297	21.3	65.2	13

Table 3. Results of biometric observations on tangerine varieties based on 2018 data on 3 plants in the variant

N	Variety	2018		
		Height cm	Rootstock dm/mm	Grafted dm/mm
1	Nichinani	223	62	52
2	Iura-Vase	171	60	59
3	Taguchi-Vase	198	56	48

Conclusions

Following our experiment and analyzing the results of scientific research data we have made following conclusions:

Among the 11 varieties of tangerine, which was imported from Japan, three varieties of tangerine; Nichinani, Iura-Vase and Taguchi – Vase are distinguished with the early ripening, high yielding, productivity.

These plants are well adapted to soil-climatic conditions of humid subtropical zones and we can recommend them for planting on agriculture farming.

With the cultivation of early ripening, high-yielding breeds, the citrus areas will intensively be increased and therefore, the productivity as well, which will help to improve the economic condition of the population.

Abstract

General combining abilities (GCA) is an important biometric parameter for maize that can be used to predict the contribution that the investigated genotype can give to its progeny. The purpose of this study was to determine GCA values in six elite maize inbred lines, components of commercial hybrids of Maize research institute „Zemun Polje“ and belonging to different heterotic groups. Field trials were set on three locations (Zemun Polje, Becej and Pancevo) during two years (2011 and 2012). GCA was calculated for eight different trait the most important being grain yield. Significant values of GCA for examined traits with positive and negative sign, were evaluated in both years of trials and differences were recorded both between different years and genotypes. GCA estimates for grain yield ranged from -0.870 t ha-1 for ZPL3 line in 2011, to 0.909 t ha-1 for ZPL6 inbred line. Significant values of GCA for plant height (cm) were evaluated for each inbred line except for ZPL1 in 2012 with ZPL 5 being the best general combiner for that trait in both years: 19.4 cm in 2011 and 18.55 cm in 2012. Traits that were in correlation exhibited GCA values of similar significance. Inbred ZPL6 had significant GCA values for most of the wanted traits making this inbred line a valuble source of desirable alleles for maize breeding programs. This GCA analysis provided a better insight and understanding of the inbred lines chosen in this study as breeding material.

Key words: *maize, general combinig ability, grain yield, morphological traits*

Introduction

Maize as an important crop was subject of intensive breeding practices resulting in the increase of areas under cultivation and constant increase in yield (Troyer i Hendrickson, 2007) with the discovery and explotation of heterosis has had a great impact on modern agriculture and was a milestone in maize breeding (Lamkey and Edwards, 1998). The performance of a hybrid and expressed heterosis is related to the general (GCA) and specific (SCA) combining abilities of the inbred lines involved in the cross with SCA being more important in elite breeding material due to a greater importance of dominance and epistasis (Hallaur and Miranda, 1988; Gama et al., 1995; Nass et al 2000). Therefore general combining abilities (GCA) is an important biometric parameter for maize that can be used to predict the contribution that the investigated genotype can give to its hybrid progeny and the expressed heterosis for the investigated traits (Sharareh et al, 2018).

The concepts of general combining ability (GCA) and specific combining ability (SCA) was first explained by Sprague & Tatum (1942), defining GCA as an average performance of a line in a hybrid combination. They interpreted GCA largely as a indication of genes having mostly additive effects. Its predominance can be useful to a breeder in increasing selection efficacy in segregating populations (Bocanski et al., 2009). The value of any cultivar in breeding programes depends on its potential *per se* and its combining ability in crosses (Vacaro *et al*., 2002).

Different mathematical modeling were proposed to estimate the GCA and SCA values for specific traits: diallel crosses (Griffing ,1956), topcross (Jenkins i Brunson, 1932), line x testers analysis (Kempthorne ,1957; Singh and Chaudhary, 1976), principal component biplot technique for diallel analysis (Yan and Hunt, 2002)... Most commonly used is the Griffing's method (1956), which partitions the total variance to GCA variance of parents and SCA variance of crosses. The diallel is simple to manipulate in maize and supplies important information about the studied populations, as general and specific combining ability, genetic variances, heritability and maternal effects, among others. This analysis also permits an evaluation of the populations *per se* (Vacaro *et al*., 2002).

Material and methods

For this study, six maize inbred lines belonging to the elite core of „Zemun Polje" institute gene bank were chosen. Inbred ZPL1 is of unknown heterotic origin, lines ZPL2, ZPL3 and ZPL4 are sharing a common BSSS origin, while ZPL5 and ZPL6 belong to a Lancaster heterotic group. Crossings according to a incomplete diallel design (Griffing model II) were performed among the inbred lines in order to obtain 15 of their F_1 progenies. Inbreds and their crosses were tested in field trials set at 3 locations (Zemun Polje, Becej and Pancevo) during two years (2011 and 2012). While the 2011 had average temperatures and precipitation, 2012 is considered arid with significantly lower precipitations especially during critical phases of maize growth. The trials were sown according to a RCB experimetal design in 4 repetitions. The size of the elementary plot was $7.5m^2$ and the sowing was done mechanicly with a 0.75m spacing between rows. Traits that were evaluated in this trial are grain yield (t/ha), plant height (cm), ear height (cm), total number of leaves, number of leaves above main ear, ear lenght (cm), number of kernel row and number of kernel in a row.

Estimates of general combining abilities (GCA) for the investigated traits were evaluated according the method 2 by Griffing (1956). The following formula was used for the calculation of general combining abilities (GCA):

$$Sij = \frac{1}{p+2}\left[(Ti+ii) - \frac{2}{p}GT\right]$$

Tj + ii = total i- row + average value of parent i

Results and Discussion

Estimation of GCA for investigated traits were calculated for each year of the trials (2011 and 2012) and they're presented in table 1 and table 2.

Grain yield is the most important and most complex agronomic trait of maize, which represents the ultimate, although not the only goal of most selection programs (Duvick, 2005). Therefore, the determination of the inbreds with high positive values of GCA for grain yield and their inclusion in the breeding programs is very important. GCA estimates for grain yield ranged from -0.870 t ha^{-1} for ZPL3 line in 2011, to 0.909 t ha^{-1} for ZPL6 inbred line. In 2011, four lines showed statistically significant values of the GCA for grain yield. Inbred lines ZPL2 and ZPL3 had negative values (-0.393 t ha^{-1} and -0.870 t ha^{-1}) while ZPL5 and ZPL6 had positive GCA values of for this trait. In the more unfavorable year of 2012, significant GCA for grain yield were evaluated for all tested lines with only inbreds ZPL2 and ZPL4 having a negative value. Lines ZPL6 and ZPL5 emerged as best combiners for grain yield in both years, while ZPL1 had highest GCA value in arid 2012 but insignificant in the rainy 2011, indicating that this line is a potential source for drought tolerance.

Table 1. Estimates of GCA for grain yield (YI), plant height (PH), ear height (EH), total number of leaves (TNL), number of leaves above main ear (NLE), ear lenght (EL), number of rows of kernel (NRK) and number of kernel in a row (NKR) in 2011.

In maize breeding , plant height and in particular the height of the upper ear are considered undesirable agronomic traits in which the tendence is to obtain lower values (Duvick et al., 2004, 2005). All investigated lines had statistically significant values of GCA for plant height in both years of testing, except for the ZPL1 line in 2012. It can be noticed that all BSSS lines (ZPL2, ZPL3, and ZPL4) had negative values of GCA for plant height in both years, while the Lancaster lines ZPL5 and ZPL6 had significant positive values for plant height GCA. ZPL 5 is the best general combiner for that trait in both years with GCA estimates of 19.4 cm in 2011 and 18.55 cm in 2012. Inbred lines that were recognised as best general combiners for grain yields have also significant positive GCA values for plant height which is in accordance with results by Čamdzija (2014).

Table 2. Estimates of GCA for grain yield (YI), plant height (PH), ear height (EH), total number of leaves (TNL), number of leaves above main ear (NLE), ear lenght (EL), number of rows of kernel (NRK) and number of kernel in a row (NKR) in 2012.

0.01	0.167	2.303	1.708	0.165	0.083	0.394	0.248	0.903
0.05	0.125	1.732	1.284	0.124	0.062	0.296	0.186	0.679

*,** Significant at the 0.05 and 0.01 probability levels, respectively

The estimates and direction of GCA for ear height show a compatibility with GCA estimates for the plant height, which is in agreement with numerous authors who examined the correlation between these two traits (Bello et al., 2010; Pavlov et al., 2012). Four inbred lines in 2011 (ZPL1, ZPL3, ZPL4 and ZPL5), and three lines in 2012 (ZPL3, ZPL4 and ZPL5) had statistically significant values of GCA for ear height raging from -6.128 cm (ZPL3) to 9.557 cm (ZPL5).

The total number of leaves, and especially the number of leaves above the upper ear is in a positive correlation with the yield and maize yield components (Jalilian and Delkhosh, 2014) making these traits highly desirable in maize breeding. For the total number of leaves, significant GCA values in both years were estimated in four lines: ZPL1 and ZPL3 with negative GCA values, versus ZPL4 and ZPL5 lines with positive.

Ear lenght is an important yield component trait correlated to grain yield in maize (Rafiq et al, 2010; Pavlov et al, 2012). The results of the study in both years pointed to statistically significant values of GCA for this trait for all inbred lines. Inbred ZPL6 had greatest positive GCA values for ear lenght in both year 1.486 cm in 2011 and 1.514 cm in 2012, which is consistent with the said line being the best general combiner for grain yield.

Greatest positive GCA estimates for number of rows of kernel were found in ZPL4 inbred (1.094 in 2011, 0.776 in 2012), while inbred ZPL 6 had highest negative values of GCA for this trait in both years. The fact that the ZPL6 line is the best general combinator for yield, despite being the worst combiner for the number of rows of grains, is in agreement with the results of the research that came from Zarei et al (2012) and Camdzija (2014), which found poor correlation of grain yield and number of grain rows in hybrids.

As expected, the values of the GCA for the number of kernel in a row are have the same sign and high correlation with the values of GCA for ear lenght. The ZPL5 and ZPL6 lines are particularly distinguished as positive general combiners for this trait.

Conclusions

In this study inbred lines with significant GCA values for each of the analysed trait have been idetified. Inbred ZPL6 had significant GCA values for most of the wanted traits and can be considered as such as a source of desirable alleles for maize breeding programs. Interestingly, inbred line ZPL1 has emerged as the best general combiner for grain yield in the arid 2012, although its values for the same trait in 2011 were without significance. In this regard, it can be estimated that inbred ZPL1 is a carrier of the drought tolerance genes and should be included as a source material in breeding programs having for purpose the creation of drought tolerant maize hybrids. Inbred lines ZPL2 and ZPL4 having significant negative GCA values for grain yield would be of limited usability and therefore not recomended in breeding programs with a purpose of creating high yielding maize lines and hybrids. Although been great general combiner for grain yield, inbred lines ZPL5 and ZPL6 had significant positive GCA values for undesirable traits of plant and upper ear height so it would be advisable to cross them with inbred lines with significant negative GCA values for these unwanted traits. This GCA analysis provided a better insight and understanding of the inbred lines chosen in this study as breeding material, allowing a greater precision and efficiency of its use in breeding programs.

Abstract

Eight ZP maize hybrids, belonging to FAO 300-400 maturity groups, were tested during the 2018 year at six different environments in Serbia. All examined hybrids have been recently registered in Serbia. The aim of the study was to identify hybrids with the highest grain yield, as well as with high yield stability over different environments. The experiment was conducted according to Randomized Complete Block Design in three replications. For the estimation of yield stability, different statistical analyses were done: regression coefficient (bi), deviation from regression (S^2di), Shukla stability variance (ri^2), and cultivar superiority measure (Pi). Maize hybrids ZP 4540 and ZP 4077 showed the highest yield potential, but they also had high moisture content in harvest. Hybrid ZP 4567 had above average yield and also high stability, while hybrid ZP 3536 had average yield, good stability and the lowest moisture content in the harvest. Although hybrid ZP 4540 obtained the highest grain yield in trial, it performed unstable according to the results of stability analysis. Based on the results obtained in the experiment, hybrids ZP 4567 and ZP 3536 are recommended for further testing in 2019 and initial commercialization.

Key words: *maize hybrids, grain yield, yield stability*

Introduction

Maize is the most important field crop in Serbia. Traditionally, late maturity hybrids were dominant in maize production, but in the last decade medium-early hybrids are becoming more popular, due to better stability and lower harvest moisture content compared to late maturity hybrids. The main challenge for maize breeders is to create hybrids with high yield potential, but also with stable yield under different seasons and environments. The presence of genotype by environment interaction is of major concern for breeders, because large interaction can reduce yields and complicate identification of superior cultivars (Rasul et al., 2005). There are genotypes that have similar performance regardless of the productivity level of the environment, while there are others whose performance is directly related to the productivity potential of the environment, clearly indicating the importance of stability analysis (Babu et al., 2017, Kaya et al., 2014). Stability of expected grain yield is one of the most desirable properties, in order to recommend hybrid for use (Čvarković et al., 2009).

Multi environments trails play an important role in selecting the best cultivars to be used in future years at different locations and in assessing cultivars stability across environment before its commercial release (M.A.A. Hassan, 2015, Vargas et al., 1999).

Gauch and Zobel (1996) reported that if the number of new genotypes to be evaluated were large, five different environments would be adequate to determine different stability parameters and/or optimize the amount of GE interaction. The objective of this research was to identify hybrids with high yield potential, low moisture content in harvest and good stability.

Material and methods

Eight maize hybrids, belonging to FAO 300-400 maturity groups were tested during the 2018. year at six different locations in Serbia. Hybrids included in this trial have recently been registered in Serbia and also three check hybrids were included in trial. Trials were set up in three repetitions and each hybrid was sown in eight rows. In order to avoid the effect of border rows, only grain yield from four middle rows was used for statistical analysis. Sowing and harvesting were done mechanically. The experiment was conducted according to Randomized Complete Block Design in three replications. For the estimation of yield stability, different statistical analysis was done: Eberhart and Russell (1966) regression analysis, Shukla (1972) stability variance and cultivar superiority measure, proposed by Lin and Binns (1988). According to joint regression model developed by Eberhart and Russell (1966), a stable variety is one with a high main yield, regression coefficient close to one (bi = 1) and deviation from regression close to zero (S^2di = 0).

Shukla method (1972) is based on variance components. A genotype is stable if its stability variance (ri^2) is equal to environmental variance ri^2, which mean that ri^2= 0. A relatively larger value of ri^2 indicates higher instability, while stable genotypes are those having minimum stability variance ri^2. Lin and Binns (1988) proposed cultivar performance measure (Pi) as the mean squares of distance between genotypes i and 'i' where 'i' is the genotype with maximum response over all locations. The smaller the value of Pi, the smaller the distance to the genotype with maximum yield, the better the genotype. Pi values were measured on overall location means and it represents superiority in the sense of general adaptability (wide adaptation).

Results and discussion

Average grain yield obtained at six different locations, as well as average moisture content in harvest are shown in Table 1.

Table1: Grain yield (t/ha) and average moisture content (%) obtained at six locations in Serbia

Grain yield (t/ha) per locations								Moisture %
Hybrid	Z.Polje	Bečej	Bajša	S.Mitrovica	Pančevo	Požarevac	Average	
ZP 3536	12.81	13.97	10.89	11.72	14.28	14.54	13.04	14.4
ZP 366	12.71	13.76	9.85	10.87	14.43	14.45	12.68	18.4
ZP 4007	11.62	14.09	10.09	10.94	12.43	13.09	12.04	16.8
ZP 4073	13.12	14.15	10.36	12.22	14.24	15.22	13.22	17.6
ZP 4077	14.42	14.51	11.20	12.38	15.25	14.59	13.73	17.4
ZP 427	13.87	14.95	10.31	11.53	14.47	12.45	12.93	15.7
ZP 4540	11.42	15.42	12.22	11.91	16.26	15.23	13.74	17.3
ZP 4567	13.69	14.65	11.37	11.69	14.82	15.22	13.57	15.5
Average	12.96	14.44	10.79	11.66	14.52	14.35	13.12	16.6

Grain yield of hybrids included in this trial was in the range from 12.05 to 13.75 t/ha. The highest grain yield was observed for hybrids ZP 4540 (13.75 t/ha) and ZP 4077 (13.73 t/ha), but both hybrids had higher moisture content and they could be proposed for further testing in FAO 500 maturity group. Hybrid ZP 4567 had above average grain yield and moisture content was lower than the average, which is desirable, while ZP 3563 achieved grain yield which is slightly lower than the average of the trial, but at the same time it had the lowest moisture content in harvest. Stability parameters are presented in Table 2. In present study, the regression coefficient values (bi) ranged from 0.84 (ZP 4007) to 1.19 (ZP 366). According

to joint regression model developed by Eberhart and Russell, a stable variety is one with a high main yield and regression coefficient equals to one (bi = 1) Hybrids with the bi value close to 1 were ZP 4567 (bi = 1.02) and ZP 4073 (bi = 1,03) and those two hybrids could be considered as a most stable, according to the bi values. According to the deviation from regression values, the most stable genotypes are those with the S^2di values close to zero. In our experiment hybrids ZP 4077 and ZP 4073 could be considered as a most stable with the S^2di values 0,02 and 0,07 respectively. The most stable genotypes based on the values of Shukla stability variance were ZP 3536 (ri^2 = 0) and ZP 4567 (ri^2 = 0.06), while the most unstable were ZP 427 (ri^2 = 1.18) and ZP 4540 (ri^2 = 1.76).
Finally, values of superiority index (Pi), proposed by Lin and Binn's ranged from 0.27 (ZP 4077) to 2.95 (ZP 4007). Beside ZP 4077, which had the lowest Pi value, hybrids ZP 4567 and ZP 4540 had also low values of Pi (0.37 and 0.77 respectively).
Hybrid ZP 4567 had above average grain yield, low moisture content and performed very stable, according to the majority of used stability parameters. Those results are in accordance with the results published by Crevar et al. (2011) and Kaya et al. (2014), who also identified hybrids with high yield and good stability. On the other side, hybrid ZP 4540 had the highest grain yield, but performed very unstable. Similar results were reported by Stevanović et al. (2018).

Table 2: Values of stability parameters for investigated hybrids

Hybrid	bi	Rank	S^2di	Rank	ri^2	Rank	Pi	Rank
ZP 3536	0.92	5	-0.22	6	0.00	1	0.94	5
ZP 366	1.19	8	-0.18	5	0.15	3	1.46	7
ZP 4007	0.84	7	0.12	3	0.43	6	2.95	8
ZP 4073	1.03	2	0.07	2	0.28	5	0.90	4
ZP 4077	0.93	4	0.02	1	0.24	4	0.27	1
ZP 427	0.96	3	0.91	7	1.18	7	1.32	6
ZP 4540	1.10	6	1.42	8	1.76	8	0.77	3
ZP 4567	1.02	1	-0.15	4	0.06	2	0.37	2

Conclusions

Hybrids ZP 4540 and ZP 4077 had the highest grain yield in trial, but at the same time both of them had higher moisture content in harvest, so they could be proposed for further testing in FAO 500 maturity group. Although hybrid ZP 4540 obtained the highest grain yield in trial, it performed unstable according to the results of stability analysis.
Taking into account obtained grain yield as well as harvest moisture content, hybrid ZP 4567 is the most desirable genotype for further testing in FAO 400 maturity group. It also showed very good stability estimated by different stability parameters.
Hybrid ZP 3536 had average grain yield, but the lowest harvest moisture content and good stability. Based on obtained results, it can be proposed for further testing in FAO 300 maturity group.

EFFECT OF DIFFERENT SIZES OF (PRE BASIC SEEDS) MINITUBER ON PLANT GROWTH AND SEED YIELD OF POTATO

Shyama Nadeeka HETTIARACHCHI*, Nilusha AMARASINGHA, George Chandra BABU, Kanagarathnam DAYANI AND RATHNAKUMARA

Agriculture Research and Development Centre, Sita-Eliya, Nuwara-Eliya, Sri Lanka
*Corresponding author: shyamanadeeka@gmail.com

Abstract

Potato (*Solanum tuberosum*) is one of the major stable foods in the world. Worldwide, potato minitubers are used at initial stage of seed multiplication. Minitubers are the progeny tubers produced from *in-vitro* derived plantlets. Field performance of different size minituber can vary and it is important to plant optimum size minituber in order to get higher seed yield. Hence, a study was conducted at Agriculture Research and Development Centre, Sita-Eliya to investigate the effect of different sizes of potato minituber on yield and growth performance. Potato variety granola was used and four grades of potato minituber (<10 mm, 10-15 mm, 15-20 mm, >20 mm) were taken for the study. Plant emergence percentage, number of main stems and plant height were measured as growth parameters and there was no significant effect ($p<0.05$) observed in plant emergence with different sizes of mintubers. But, a significant influence on number of main stems due to different minituber size was recorded. Plant height was also, significantly affected by minituber size. Total yield was also, significantly affected by planted minituber size. But, seed tuber yield (28 - 55mm) was not significantly affected by different minituber sizes. It was found that mini tuber size >10 mm was most suitable for the field planting in order to obtain high seed yield.

Keywords: *Different size, Minituber, Potato.*

Introduction

Potato (*Solanum tuberosum*) plays significant role in developing countries with its high yield potential and high nutritional productivity compared to rice, wheat and maize. Potato is introduced to Sri Lanka in 1850's by the British rulers and at present successfully cultivated in Nuwara-Eliya, Badulla and Jaffna Districts. Average potato productivity in 2017 is 16.46 t/ha in Sri Lanka (Agstat, 2018). Non availability of good quality disease free seeds of desirable varieties at the correct time for planting is considered as the main constraint for increasing productivity of potatoes in Sri Lanka (Nugaliyadde *et al*., 2005). In 2017, 151,438 tons of potatoes were imported for consumption at a cost of Rs million 5,440,129 (Agstat, 2018). This emphasizes the importance of increasing local potato production and productivity. Potato cultivation still depends on imported seed potatoes which amount to about 1611 t in 2017. The total annual seed potato requirement in Sri Lanka is about 16,000 tons and out of which 750-1000 t/year seed is produced formally. Rest of the seed potato requirement of about 80% is met by farmers own seed production. Since the quality of farmer produced seed is not assured, productivity is also low. Thus there is a high potential for increasing productivity of potato with high quality seeds. It was realized that the quality of farmer produced seed should be increased to improve the productivity. *In-vitro* mother plant production, rapid multiplication and production of pre basic seeds (mini tubers / G_0) through aeroponic, hydroponic and geoponic are the main consecutive steps of potato seed production techniques. Minitubers are the progeny tuber produced by *in-vitro* derived plantlets (Struik, 2007). Repeated harvesting method is practiced under these three technologies, in order to maximize the G_0 production. During harvesting different sizes of minitubers are harvested.

The size of minitubers may range from 5-25 mm and sometime it grows even bigger. Larger size minituber also demanded by farmers.
Even though sufficient information is available on the performance of minitubers under protected houses, a little information exists on the field performance of minitubers of potato. A massive programe is launched in Nuwara-Eliya and Baddulla districts to improve the seed quality produced by the farmers in order to achieve higher productivity and intern lower the cost of production. It has been realized that suitable size of minitubers should be identified to streamline the field multiplication of G_0 tubers. This study is therefore intended to evaluate the effect of different sizes minituber on growth and yield of potato under field condition and identify the best size of minituber for increasing the seed tuber yield of potato.

Materials and methods

This study was conducted at the Agriculture Research and Development Centre Sita-Eliya, Sri Lanka in the up country wet zone during 2015 *yala* and 2016 *yala*. Potato minituber seeds were divided in to four different diameter classes and tested in this experiment as T_1 seed diameter below 10 mm, T_2:10 -15mm, T_3:15-20 mm and T_4:20-25 mm. Treatments were arranged in a randomized complete block design and replicated three times during two seasons.
Before planting pre basic seeds of potato variety Granola was harvested and stored for 3 and 1/2 months for sprouting. Uniformly sprouted seeds with 3-4 sprouts were selected and planted in plots (2.25 m^2) contained 50 plants at the spacing of 30‹15 cm. All crop management practices were performed as per the DOA recommendations. Number of plant emerged at 20 days after planting, number of main stems and plant height at 30 days after planting was recorded. Harvesting was done at physiological maturity i.e. 105 days after planting and number of tubers/m^2 and tuber yield/m^2 were recorded. Harvested yield were graded according to seed diameter (i.e. <28 mm, 28-55 mm and >55 mm) and seed weight and seed number were recorded.
The analysis of variance and mean separation were done for the experimental data using SAS statistical package.

Results and discussion

Plant emerge percentage

There was no significant difference ($p<0.05$) in plant emerging percentage among mini tuber sizes at 20 days after planting (DAP) (Table 01). Dimante and Gaile (2015) also reported that minituber size had no effect on emergence. In contrary, Hossain *et al.*, (2015) and Kawakami and Iwama (2012) reported that minituber size had significant effect on plant emergence.

Number of main stems

There was a clear effect of minituber size on number of main stems. With increasing of minituber size, number of main stems was also increased (Table 1). This is due to the presence of more eyes and reserve food in large size tuber and it help for rapid growth of stems. Dimante and Gaile (2015) also reported that main stems depend on both cultivar and mini tuber size.

Plant height

Plant height also significantly higher in bigger tubers than that of small tubers except in 2015 *yala* (Table 01).This finding also is in agreement with the findings of Hossain *et al*. (2015). This also could be attributed to presences of more reserve food in tubers, which support rapid growth of plant during initial stages.

Tuber yield (Kg /m^2) and tuber number (m^2)

The maximum tuber yield was recorded from the 15 -20 mm size minituber during 2015 *yala*. But, during 2016 *yala* maximum yield was obtained from the >20 mm size minituber. During two seasons, the lowest yield was recorded in < 10 mm seed size (Table 2). However there was no significant difference observed between seed size of 15-20 mm and of >20 mm (Table 04).

>20 mm	19 ab	61 a	5 ab	13 a	98 a	11 a
CV	19.2	6.7	47.5	50.5	18.6	35.3

The result shows, that there was no significant difference on tuber numbers during 2015 *yala* and 2016 *yala*. With increasing size of minituber, number of tubers wasn't shown clear increasement during 2015 *yala* and 2016 *yala* (Table 3).
Mahmoudpour (2014) reported that the size of minituber has an impact on tuber yield, but not in the tuber number. However, Hossain *et al*. (2015) observed that minituber size and planting distance interacted significantly on tuber weight and tuber number.
Highest seed size category (28-55mm) was recorded from minituber of 10-15 mm size planted during 2015 *yala* seasons, whereas during 2016 *yala* season more seed size tubers were harvested from mini tubers diameter 15-20 mm and there was no significant differences (Table 5). Dimante and Gaile, (2015) also found tuber yield at >25 mm was significantly affected only by the cultivars, but not by seed size.

Conclusions

It was found that mini tuber size had a positive effect on tuber yield, tuber number, number of main stem and plant height. However, mini tuber size did not influence the amount of seed size tubers produced in the next progeny. Considering the growth parameters and seed yield G_0 minitubers of size >10 mm are most suitable for open field multiplication.

Abstract

At the mouth of the Tamis into the Danube there is a complex of alluvial forests that represents a separate ecological unit within the Managment unit „Donje Potamišje". In unchanged natural conditions, there were favorable ecological conditions for the development of forest vegetation, defined by the periodically high water levels of the Danube and Tamis, as well as moistening of groundwater. The construction of Hydropower plant "Djerdap" changes the regime of the Danube and Tamis waters, which implies the process of degradation of land and vegetation, that is, the formation of ponds and wetlands on the entire surface of the forest management unit. By raising the embankment towards the Danube and Tamis, as well as by building ameliorative canals and evacuating excess water, more favorable ecological conditions for the development of forest vegetation were created. In addition, the area, called "Gradska Suma", is used as a source for the city's water supply, which affects groundwater levels, whose impact on forest vegetation should not be neglected.

Keywords: *hygrophilic forests, habitat, ecological unit, water regime, forest and swamp ecosystems, forest management class, levees, melioration*

Introduction

Spacious alluvium at the mouth of the Tamis into the Danube, edged with earth embankments, which protect it from the large waters of these rivers and it represents a special ecological unit on the territory of the municipality of Pancevo (Serbia). This area, designated as "City Forest" - GJ "Donje Potamišje" under the unchanged conditions of the humidification regime, which was occasionally flooded by large waters of the Tamis and the Danube, represented, under the existing climate and soil conditions, the natural habitat of hygrophilic species. The construction of HPP "Djerdap" in 1972 created a slowdown in the Danube and even the Tamis, which floods the alluvial plain for most of the year and causes the existing habitat of forest species to decay, turning it into a swampy and grazed area. This area is inhabited by hydrophilic species, that is, represents the habitat of numerous species of swamp birds and other aquatic organisms, which excludes it from forest production by decaying of hygrophilous forests. In addition, one part of the city of Pancevo has the need for drinking water from the aquifer from the site. Protective embankments, built since 1998, create special environmental conditions with controlled humidity. In the conditions of the so-called melioration section, floods are excluded, and the precipitation water is collected and transferred to the Tamis by constructed pumping system and a system of reclamation canals. The aim of this paper is to analyze the changes of habitat characteristics, conditioned by changing the basic ecological factor and humidification regime to establish the possibilities of biomass production in accordance with the use of water resources of the source "City Forest".

Material and methods

A number of different methods were used in the preparation of this paper, based on the available database of which:

- Descriptive method, used to familiarize with the basic characteristics of the ''Gradske Sume'' area, the potentials and limiting factors of the natural environment for the use of water and forest resources, as well as the mutual influence of water and forest vegetation;
- analysis of data collected using available literature, planning documents, scientific and professional papers, made it possible to explore and identify key elements of the use of available resources of the ''Gradske Sume''.
- The synthesis method was used to draw an appropriate conclusion based on the descriptions and analyzespreviouslyused.

The analysis will use the data on the forest management units for characteristic periods of changes in the habitat conditions of the study area: natural conditions (1953), the period of influence of the Danube slowdown (1983) and controlled wetting regime (2015), which is achieved by protective embankments and drainage network channels. The area of research of the Donje Potamišje Unit is mainly located on the left bank of the Danube and is a homogeneous spatial unit that extends along a river flow, with various widths, from several hundred meters to 2.5 km. Part of the management unit ''Gradske Sume'' has been separated into a separate ecological unit, due to the erection of a protective embankment near Tamis, as this area is no longer flooded.

Figure 1. View of the ecological unit "Gradska Suma", GJ "Donje Potamišje", Forestry Holding "Banat" Pancevo

The ecological unit "Gradska Suma" covers an area of 348.55 ha, bordered on the north by an old protective embankment, from the bridge over Tamis to the embankment, which connects the old road with the new E-94, on the south side by the embankment on which the E-94 road lies and from the east side with the right coast of Tamis, Figure 1. The terrain of the ecological whole, "Gradske Sume", is mostly flat with characteristic elevations, beams, along the bed of old Tamis, Sibnica and Tamis itself. The highest elevation in the area of the City Forest is 74.5 m (Lugarnica), the lowest is 69.0 m, the bed of old Tamis and the pits along the old Pancevo - Belgrade road. Analyzing the relief by altitude zones, it can be seen that the largest surface area between the 70.0 and 70.5 m elevation is about 142 ha, the smallest area of only 2.0 ha is in the height zone above 73.5 m. Altitude zones that still stand out are: zone with an altitude below 70.0 m, with an area of 87 ha and an altitude zone from 70.5 m to 71.0 m, with an area of 49 ha. The hydrographic network of the study area is primarily represented by the Danube and Tamis Rivers, which, as typically plain rivers, have a large number of branches, meanders, sections of old streams and still waters. In addition to these two rivers, smaller tributaries of the Danube such as Sibnica, Galovica and Nadela, as well as a number of melioration canals should be noted.

An analysis of the land profiles in the "Gradska Suma" area revealed the remains of the Chernozem that are typical of this area. The presence of sand and alluvium indicates the same origin of these lands with the formations of the large belt of the Danube coast. The fact that the Danube and Tamis flooded this terrain at high water levels and at low water drained both surface and groundwater, which was very suitable for growing soft and hard deciduous trees. The application of fertile sludge brought about by each flood wave had very positive effects on the processes of pedogenesis and forestry.

Table 2. Distribution of land types in the area of "Gradska Suma" before the rise of the Danube ("Energoprojekt", Belgrade, 1983)

Types-subtypes of soil	**Area**	
	ha	**%**
Chernozem	48.99	14.09
Swamp-gley soil-epigley	11.50	3.3
Swamp-gley soil on chernozem	117.35	33.76
Hydromorphic (gley) alluvium	4.25	1.2
Hydromorphic (gley) alluvium on chernozem	157.02	45.17
The unexplored surface of the Tamish meander	8.52	2.45

According to the European classification (FAO-UNESCO), Škorić et al., (1985), the following types of land have been identified in the surveyed area of the Gradska Suma according to the European classification (Table 2).

Results and discussion

According to the available data on the isolated forest management classes for characteristic periods of time, the area of the ecosystem under study can be observed, "Gradske Sume", their very uneven representation, table 3, diagram 1. According to these data the following forest management classes (gk) are separated: AB-Euro-American Poplar, Black and White Poplar and American Ash; C-white willow, black and white poplar and American ash; D-American ash and oak; E-gullies (1983 only) and G-forest openings and paths.

During the period of natural humidity conditions (1953), the area under study is dominated by forest management class C, which comprises 60.18% (from Salicetum albae to Populeto-Fraxinetum angustifoliae), and forest clearings and paths are the least represented, forest management class G with 6.40% of total area, Table 3, Diagram 1, Figure 2.

The period of the impact of the Danube slowdown (1983) on the surveyed areas of the Gradske Sume is characterized by a drastic decrease in the areas under forest and an increase in forest clearings, forest management class G at 53.77% (with predominant aquatic and swamp vegetation) and isolation of special forest management class E, thinning out of old forest, which increased the woodless level by an additional 3.51%, Figure 3.

Table 3. Share of forest management classes in ecological unit "Gradska Suma" of GJ "Donje Potamišje" (Matijević, 2016)

FOREST MANAGEMENTCLASS	PERIOD OF TIME					
	1953		1983		2015	
	ha	%	ha	%	ha	%
AB	52,43	15,50	36,56	10,81	188,01	55,59
C	203,52	60,18	34,33	10,15	14,17	4,19
D	60,60	17,92	73,57	21,75	99,17	29,32
E	0,00	0,00	11,87	3,51	0,00	0,00
G	21,63	6,40	181,85	53,77	36,83	10,89
Σ	338,18	100	338,18	100	338,18	100

Institute of Topology of Novi Sad, (1976), in the newly created habitats of "Gradske Sume", along with the channel network, vegetation units of Salicetum triandrae and Salicetum albae will survive; on the Chernozem and swamp gley areas, the sets of pedunculate and field ash will be expanded; deep sandy soils will be occupied by white poplar and European oak, and the sets of peduncle and hornbeam will replace the sets of black poplar and oak with fluvisols and humofluvisols, Figure 4.

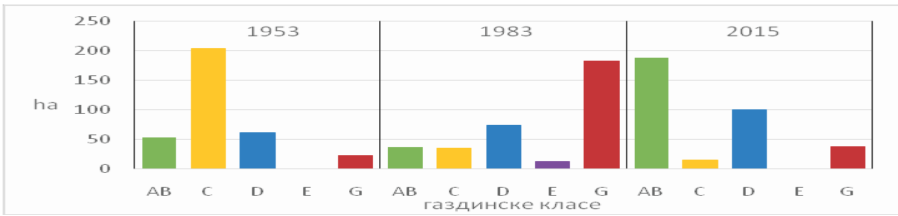

Diagram 1. Separate forest management classes in the ecological unit "Gradska Suma" GJ "Donje Potamišje"

The controlled wetland period (2015) of the eco-unit under study (protected from external and inland waters) is characterized by an increase in areas with forest management class AB at 55.59%, as well as a significant decrease in forest management class G to only 10.89% with the absence of forest management class E. According to the available data (Table 3, Diagram 1), there is a significant increase in the area of forest management class D, non-coniferous wood species, which ranges from 17.92% in natural conditions to 29.32% in controlled humidity conditions, is especially emphasized, which is confirmed by the above forecasts of the Institute in Novi Sad. The ecological conditions of the ''Gradske Sume'' were dictated by the water regimes of the Danube and Tamis, as the area is influenced by these rivers and was exposed to flooding and wetting of groundwater. Depending on the relief, or hydrographic position, soil moisture in this area was different and directly depended on the water level, its duration and frequency. According to the available data, before the construction of HPP "Djerdap", the Danube level ranged between 66.5 m and 73.9 m above sea level, while groundwater oscillation amplitude ranged from 2.0 to 3.5 m. The existence of favorable ecological conditions (Herpka, I., 1979) is confirmed by isolated forest management classes where the indigenous vegetation of the field, as well as artificially raised plantations occupy about 94% of the area of the ''Gradske Sume''.

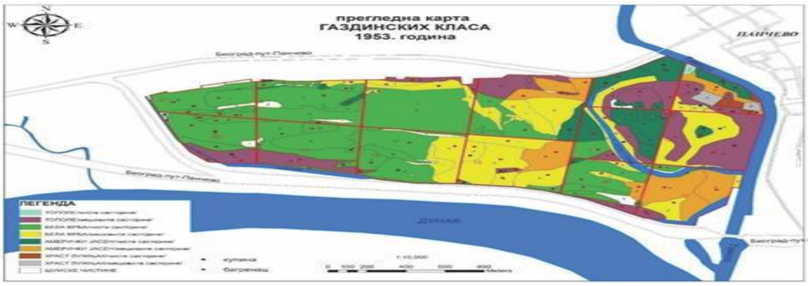

Figure 2. Overview map of the forest management classes of the "Gradska Suma" in 1953 - Natural Conditions ("Energoprojekt", Belgrade, 1984)

Figure 3. Overview map of the forest management classes of "Gradska Suma" in 1983. - Period of influence of slowdown ("Energoprojekt", Belgrade, 1984)

Changing the regime of the Danube waters, after the construction of HPP "Djerdap", in this area, the regime of soil moisture as well as the intensity of wetting was changed, which led to permanent appearance of ponds and swamps. As a result of the pronounced ecological changes (the impact of the basic ecological factor changed), land degradation occurred and forests were prevented from restoration as well as any kind of forest economic activity. Separate forest management classes indicate numerically the previously exposed ones, so that over 50% of the area is covered with clearings and paths.

Hydrological indicators of the flow regime of the Danube in slow conditions indicate significant changes, the most important of which are in small waters and the amplitudes of their oscillations. In the 68/63 m low water regime, they increased by an average of 2.0 m, especially in the period July - September, did not go below 68.5 m. In the 69.5 / 63 m regime, small waters were 3-3.5 m higher than in natural conditions (Energoprojekt, 1984). Median waters also increased, more in the vegetation than in the non-vegetation period, with the regimes for both periods approaching each other. The mean waters for the regime of 69.5 / 63 m were at an elevation of 71.1 m above sea level. All regimes have acquired characteristics of lake - river regimes (Nikolić, V. et al., 2012).

Figure 4. Overview map of the "Gradske Sume" forest management classes in 2015

The large waters of the Danube and Tamis previously flooded the study area, until defense embankments were built along these rivers and a canal system in the ''Gradske Sume''. The construction of the canal system drained many ponds and wetlands. The water regime in them depends on the height of the atmospheric precipitate as well as the water level of the surface currents. Rainfall is particularly dominant in June and July. During such periods, these channels accept excess water and from the water to the pumping station, which transfers to Tamis. The controlled soil moisture regime provides more favorable ecological conditions for cultivation of both the softwood species and the extension of the surface of forest management class AB and hardwood ones, as indicated by the increase in forest management class D, (Matijevic, 2016).

Conclusions

The natural conditions of the alluvial surfaces at the mouth of the Tamis into the Danube are established by the wetting regime, characterized by the appearance of flood-meadows in the first half of the vegetation period and their withdrawal in the second part of the period. Such a regime of wetting, depending on the position and type of soil, establishes an adequate vegetation of hygrophilic species, soft and hard deciduous forest, as indicated by the layout and participation of the separated forest management classes with dominant C class.

The impact of anthropogenic factors is hampered by the natural regime of surface and groundwater (slowdown by HPP "Djerdap" since 1983, "Nera" regime 69.5 m and more), which leads to degradation and decay of forest habitats and the creation of ponds and wetlands. Deforestation and degradation of forest habitats defines the relationship of forest management class G, especially singled out E, whose participation exceeds the other forest management classes;

Improved ecological conditions for the cultivation of forest species are achieved by protection against external and internal waters, that is, by controlled soil moisture in the analyzed area of the ''Gradska Suma''. Larger participation, over half the surface, separated by forest management class AB, as well as a significant increase in forest management class D, refers to the process of raising the production capabilities of the habitat of the analyzed area;

Excessive pumping of water for the purposes of water supply has negative consequences, reducing groundwater level below the reference level, which in specific conditions is 1.5 to 2.0 m;

The prognosis of cultivation of hygroviline species, softwoods and hardwoods in the area of such ecological units, is achieved by providing optimal conditions for their cultivation. Under current conditions, these are mainly habitats: A-white willows, B-white and black poplars and C-field ash and European oaks on different types of land.

In general, the land of the ''Gradske Sume'', despite its degradation forms, is a solid basis for the cultivation of characteristic forests of inundation. Although the pedogenetic processes in such land melioration areas differ from the flood-meadow zones of the alluvial planes, where the precipitated sludge allows optimal biomass production in short time cycles;

It can be generally stated that forest vegetation in the "Gradska Suma" area has a production function (production of biomass) and a protective function of forests (special purposes), which is for the time being rare to use water and wood from the same area as a resource.

EFFECT OF NITRIC OXIDE (NO) APPLICATION ON THE DEVELOPMENT OF PEPPER PLANT UNDER DROUGHT STRESS

Fikret YASAR*, Ozlem UZAL

Van Yuzuncu Yıl University, Faculty of Agriculture Department of Horticulture, 65080 Van, Turkey
*Corresponding author: fyasar@yyu.edu.tr

Abstract
The study was carried out in the Physiology Laboratory, Faculty of Agriculture, Van Yuzuncu Yıl University, in a climate room where normal atmosphere was provided. The main purpose of the normal atmosphere in the experiment was to ensure that salt stress effects occur under normal conditions. The study was carried out under controlled conditions in a light / dark photoperiod of 16/8 hours, climate room of 25^{o}C and 70% humidity. The aim of the study was to determine the possible role of NO (nitric oxide) as a precursor molecule in some metabolic changes occuring under the effect of drought stress in plants and to try to determine its effects on plant growth. Demre pepper variety was used as a test material. Tested plants in the controlled climate were cultured in cups containing Hoagland nutrient solution. For drought stress application, 10% polyethylene glycol (PEG 6000), equivalent to the osmotic potential of -0,40 MPa, was added to the nutrient solution. Different doses of sodium nitroprusside (SNP) and potassium salt (carboxy-PTIO) (SNP 0,01, SNP 1, SNP 100 and SNP 0,01 + cPTIO, SNP 1 + cPTIO, SNP 100+ cPTIO) were applied to the pepper seedling before drought stress was applied. On the 10th day of drought application, the root, stem and leaf weights, leaf counts and inter-node distances of the plants were examined as growth parameters. In terms of plant growth parameters, it was determined that the growth and growth of plants pretreated with 0.01 and 1 doses of SNP were better.

Keywords: *Capsicum annum, Carboxy-PTIO, Drought stress, Nitric oxide, SNP*

Introduction
One of the abiotic stress conditions affecting the plant growth and development is drought (Farooq *et al.,* 2009; Yasar *et al.,* 2013; Yasar *et al.,* 2014). This change in growth depends on the duration and severity of the drought. In the early stages of arid conditions, the plant slows the body's elongation and triggers root development to reach more water. On the contrary, if arid conditions last long enough to cause damage to the plant, both stem and root growth will be halted, leaf area and number of leaves will decrease and even some leaves will be poured out with yellowing (Ozpay, 2008; Kose, 2010; Yasar *et al.,* 2013; Yasar *et al.,* 2014). The decline in plant growth is due to the division of cells in the shoot and root meristems and the arrest of the expansion of the cells. The disruption of cell division or enlargement is directly related to the decrease in the rate of photosynthesis due to water insufficiency (Anjum *et al.,* 2011).
In plants, nitric oxide (NO) is a messenger molecule in another of the metabolic changes that take place under the effect of drought stress. NO is a colorless inorganic molecule, consisting of a nitrogen and an oxygen atom, which is lipophilic, gaseous, easily diffusible without a receptor-dependent, very short half-life, containing an unpaired electron, also called free radical (Olson, 2011).
NO is synthesized and released in small amounts in plant cells under normal conditions. In plants, NO is synthesized by two different enzymatic and non-enzymatic metabolic pathways. The NO synthesis varies depending on the plant species, the tissue, and the growing conditions. The NO production site in plant cells is the cytosol, nucleus, peroxisome matrix

and chloroplasts (Barroso *et al.,* 1999 and Pedroso *et al.,* 2000). At the same time, non-enzymatic processes also play a role in NO formation in plants.
In acidic or light media, NO2 can be converted to NO (Cooney *et al.,* 1994). Nitric oxide is an important signaling molecule with a variety of physiological functions in plants. It is thought that the plants play an important role in the growth and development of the fruits from the seed to the flowering stage. In addition, NO can be produced in different plant species and organs in case of environmental stress caused by abiotic and biotic factors. Nitric oxide is a very active molecule that has been proven to protect plants against a variety of biological pathways to the damage caused by oxidative stress conditions (Carlos and Lorenzo 2001).

The main objective of this work was to identify possible complementary roles in plant development of NO with the messenger molecule property in some metabolic changes that occur under the influence of drought stress in plants.

Material and Methods

Material

Plant material

Demre's pepper varieties with strong root structure and resistant to diseases are used in the study.

Method

Pepper (*Capsicum annuum*) Seedlings Growing:
The study was carried out in the Physiology Laboratory, Faculty of Agriculture, Van Yuzuncu Yıl University, in a climate room where normal atmosphere was provided. Pepper seeds were germinated in pumice-filled plastic germination containers in a climate-controlled chamber (split conditioning system, 25 ± 1° C, and 70% humidity). The seedlings that began to show their first true leaves began to be made with Hoagland nutrient solution (Hoagland and Arnon, 1938). In the ponza environment, the seedlings pretreatment process, which consists of the second true leaves, was carried out. This was done with sodium nitroprusside (SNP) and nitric oxide (NO) capture 1 µM cPTIO in Nitric oxide (NO) buffer at concentrations of 0.01, 1, 100 µM in ½ Hoagland solution for 2 days in brown bottles. Later, pre-treated and untreated seedlings were placed in aquaculture environment. Sprouted seedlings were transferred at the second true leaf stage to a water culture system consisting of 25 × 25 × 18 cm plastic baths containing Hoagland nutrient solution. The pepper seedlings were wrapped with small foam pieces and placed on specially made plastic trays, fitted with holes to accommodate each seedling. The trays were placed in the baths, with the plant roots immersed in the nutrient solution. The nutrient solution was aerated by thin plastic hoses attached to an aquarium pump. Drought stress was applied by adding 10% Poly Ethylene Glycol (PEG 6000). The implemented applications are shown in Table 1.

Table 1. Experimental practices

1-Application: ½ Hoagland (Control group)
2-Application: ½ Hoagland + 10% Poly Ethylene Glycol (PEG 6000)
3-Application: ½ Hoagland + 0.01 µM SNP + 10% Poly Ethylene Glycol (PEG 6000)
4-Application: ½ Hoagland + 1 µM SNP + 10% Poly Ethylene Glycol (PEG 6000)
5-Application: ½ Hoagland +100 µM SNP + 10% Poly Ethylene Glycol (PEG 6000)
6-Application: ½ Hoagland + 1 µM C-PTIO + 0.01 µM SNP +10% Poly Ethylene Glycol (PEG 6000)
7-Application: ½ Hoagland + 1 µM C-PTIO + 1 µM SNP + 10% Poly Ethylene Glycol (PEG 6000)
8-Application: ½ Hoagland + 1 µM C-PTIO + 100 µM SNP + 10% Poly Ethylene Glycol (PEG 6000)

Samples were taken from the plants harvested on the tenth day after the application of the drought. Root, stem and leaf weights, leaf counts and inter-node distances were looked at as growth parameters of the plants.

The experiment was designed as a completely ran-domized plot with three replicates. Data were analyzed statistically, and the means of each treatment were analyzed by Duncan's multiple range test using SAS software (Sas-Instıtue,1985).

Results and Discussion

Responses to drought stress in pest plants subjected to drought stress with PEG 6000, and in plants pre-applied with SNP and c PTIO were also investigated (Table 2).

Table 2. Root weight (g), stem weight (g), leaf weight (g), number of leaves (number), plant height (cm), distance between plant nodes (cm).

Application	Rot. W.	Stem.W.	Leaf.W.	Leaf.Num.	P. Leng.	D.B.P.N.
CONTROL	4,43 B	4,34 BC	15,11 A	14,66 B	22,00 A	2,16 BC
PEG	4,29BC	3,09 DE	9,60 C	10,66 C	18,33BC	2,67 AB
SNP 0,01+ PEG	4,44 B	4,84 AB	14,51 A	16,33 A	19,83 B	2,83 A
SNP 1+ PEG	5,54 A	5,07 A	12,48 B	13,67 B	18,67BC	2,16 BC
SNP 100+ PEG	3,34 D	2,66 E	9,98 C	10,33 C	15,67 E	2,16 BC
C.PTIO+SNP 0,01+ PEG	3,81CD	3,75 CD	11,35 B	11,00 C	18,00CD	2,33 BC
C.PTIO+SNP 1+ PEG	3,33 D	2,51 E	9,64 C	10,66 C	16,67DE	2,00 C
C.PTIO+SNP 100+ PEG	2,65 E	1,60 F	5,52 D	8,33 D	15,67 E	1,83 C

The difference between the averages with the same capital letter in the same column is insignificant compared to $P \leq 0.05$.

When we examined root weights of plants as a result of application of PEG 6000 to pepper plants, it was seen that there were differences between applications. In the case of SNP 1 application, root weight increased compared to control, while C. PTIO + SNP100, C. PTIO + SNP1 and SNP 100 decreased compared to control. PEG and SNP 0,01 were found in the same statistical group interval as the control. In terms of body weights, it is seen that there were differences between applications. In the case of SNP 1 and SNP 0,01 application, body weight was increased compared to the control, while C.PTIO + SNP100, C.PTIO + SNP1 and SNP 100 decreased compared to the control. If SNP is 0,01, the same statistic was found in control group. When we examined leaf weights of plants, it was observed that there were differences between applications and there was no application which shows an increase compared to leaf weight control. C. PTIO + SNP100, C. PTIO + SNP1 and PEG decreased with respect to the control. If the SNP is 0.01, the same statistic is found in the group interval (Table 2).

When we examined leaf counts of plants as a result of applying PEG 6000 to pepper plants, it was seen that there were differences between applications. In the application of SNP 0.01, leaf numbers increased with respect to the control, while C. PTIO + SNP100, SNP 100, C. PTIO + SNP1 and PEG decreased with respect to the control. SNP 1 was found in the same statistical group interval as the control. When we examined the size of the plants, it was seen that there were differences between the applications. There has not been any application in terms of plant height, which is higher than the control. SNP100, C. PTIO + SNP100 and C. PTIO + SNP1 were decreased compared to the control. SNP 0.01, SNP1 and PEG were found in the same statistical group interval. It is seen that there are differences between applications at the intersection points of plants. SNP 0.01 and PEG, SNP100 and C.PTIO + SNP1 were decreased compared to controls. SNP1, SNP 100 and C.PTIO + SNP0.01 were found in the same statistical group interval as the control (Table 2).

Doses of 0.01 and 1 μM of SNP and c.PTIO + SNP pre-treatments of root, stem and leaf weight of the growth and development parameters of the pepper plants pretreated with SNP and c-PTIO at different doses were in the same range as the control plants without drought It has become. Much better than PEG treatment without pretreatment with SNP and c.PTIO +

SNP. As the SNP and cPT + SNP did not have a positive effect of 100 μM, it was seen that the plants got more stressed compared to the PEG without pretreatment. The same cases were also observed in terms of number of leaves, plant height and inter-node spacing. Sekmen *et al.,* (2005) found that plants subjected to pretreatment by salt stress on tomato plant showed increased root and stem weights and lengths on day 28 compared to plants treated with salt stress without pretreatment. On the 43rd day of stress, however, pretreatment lost its effect and plants gave the same response as plants without pretreatment. Likewise, Tuna and Eroglu (2017) applied NO pretreatment to pepper plants under salt stress and looked at stem root and leaf weights of plants under stress. While the root, stem and leaf growth of the plants were decreased compared to the control, they were found to be better than the salt treatment without pretreatment. Many researchers who have done similar work in our study have achieved similar results. Erkılıç, (2005) also found that exogenous salicylic acid applied to salt stressed pepper plants had a positive effect on some growth parameters such as wet and dry weight. Kausar *et al.,* (2013) reported that nitric oxide pretreatment of wheat (Triticum aestivum) plants subjected to salt stress affects the growth and yield of plants in a positive way.

In a different study by Tian and Lei (2006) the effects of SNP, a NO donor, on drought stress induced by 15% PEG in wheatgrass were investigated. Whereas 0.2 mM SNP administration increased the growth of shoots and provided high water content. In addition, investigators have reported that oxidative damage was reduced by the addition of 0.2 mM SNP.

Conclusion

In this study aimed to determine the possible role of NO (nitric oxide) as a precursor molecule in some metabolic changes occuring under the effect of drought stress in plants and to try to determine its effects on plant growth; it was concluded, that of 0,2 mM SNP application increases the plant growth.

OLIVE PRODUCTION AND TRAITS OF MAIN CULTIVARS GROWN SOUTHEAST ANATOLIAN PART OF TURKEY

Bekir Erol AK*, Ebru SAKAR, Sehnaz KORKMAZ

University of Harran, Faculty of Agriculture, Department of Horticulture, 63200 Sanliurfa , Turkey
*Corresponding author: beak@harran.edu.tr

Abstract

Olive (*Olea europea* L.) is grown in Mediterranean countries in the world. Turkey is the fourth largest producing country. It is grown for table consuming or oil production. The main olive producing country in the world is Spain. Generally the oil needs of the world population equates to 186 billion tons per year. World olive oil production is 3 billion tons approximately. Olive oil consuming is important for cardiovascular system for human health. The highest olive oil consumption in the world is 12.8 kg/person in Greece.

Olive production in Turkey is 1,300,000 tons, with 190,000 tons for olive oil. Table olive is also divided into two types; one of them black, another is green olive which pickled. The yield is not enough due to lack of some technical applications such as irrigation, fertilization etc. The intensive producing provinces are Eagean, Mediterranean, Marmara, Southeast part of Turkey. General common growing cultivars are 'Gemlik', 'Halhali', 'Kilis Yaglik', 'Kan Celebi', 'Kalembezi', 'Nizip Yaglik' etc. Main black olive is 'Gemlik'. It is used as table consumption. However, each cultivar has different traits.

Keywords: *Olive cultivar, Southeast Anatolian Region, Turkey.*

Introduction

The total average olive production in the world, between 2010 and 2017, was 20,007,854 tons. Turkey between the years 2010-2017 the average olive production is 1,744,875 tons. Olive production in the world ranking, Spain is first country, second is Italy, the others are Greece and Turkey.

The European olive (*Olea europaea* L.) is a major source of edible oil and processed edible olives. Today, the olive is cultivated over a total world surface area of almost 10 million hectares, on 60% of which it represents the main crop. The traditional area of olive cultivation is the Mediterranean basin, which includes 95% of the olive orchards of the world, and where more than the 95% of the olive oil and the 75% of the table olives are produced. A rough estimate of the global number of olive trees is over 800 million. The annual yield of olives is estimated at 10 million tonnes, most of which is used for oil production and less than 10% consumed as table olives (Fabbri et al., 2004).

The presence of olive trees in the world of table olives and grain producing countries significantly parallel to the olive production in Spain, Turkey, Italy, Greece, USA, Morocco, Syria and Egypt. Turkey ranks second after Spain in the production of table olives. Turkey ranks first in the world production of black table olives for table olive production. Spain ranks first in the production of green table olives. Turkey produced 85% of fruits black and green color, 70% of the table olives produced in Spain are green, 26% are color-oriented and 4% are black; 73% of table olives produced in Italy are black, 22% are green and 5% are color-oriented; 65% of table olives produced in Greece are processed and evaluated in black, 27% in green, and 8% in color (Tunalioglu, 1995).

In Turkey, 20% of the Marmara region of olive production is almost all kinds of Gemlik table production, 65% of the Aegean Region, Mediterranean and Southeast Anatolia Regions have a production of 15%. Overall Turkey produced 85% of black and 15% are covered in green

and color-oriented. According to these data in Turkey the Gemlik variety of black table olives is the most produced (Tunalioglu, 2003).
Olive oil yield, along with fruit production, is the main factor determining productivity in olive oil cultivars, thus explaining why it is one of the main breeding selecting criteria for the species (Rallo, 1994). Varieties to be planted for fruit production in a region has great importance. Soil structure is of great importance as well as the conditions that should be taken into consideration in terms of climatic conditions for the region where the variety will be grown. It is very important that climatic conditions are resistant to winter cold, they meet the cooling requirements required for flowering and fruit set. Tthe amount of rainfall in winter and the sum of summer temperatures necessary for the ripening of fruits. Soil structure in terms of pH, salinity rate, organic matter amount, water holding capacity and so on. The suitability of the properties should also be considered (Ak and Parlakci, 2007).

Classification of Olive Cultivars in Turkey

When it is desired to grow olives economically in a region, the answer to this question should be sought. The product to be obtained will be used for table consumption or for oil production. In other words, according to consumption or evaluation methods, olive is divided into two groups as table and oil. Varieties to be evaluated as table; Grain Weight (g) is defined as 9-12 g good, 5-6 g Medium and 1-2 g Small (Bad). In the varieties considered as oily; Fat Ratio (%) 25-30 good, 20-25 Medium and 15 and below (bad) is called. Another way of determining the variety of characteristics is the number of fruits per kilogram. If there are 175 fruits per/kg, it is classified as Jumbo size, 176-250: very big size, 251-335: Moderate, 336-421: Small,> 421: Very Small (Canozer, 1991).
All kinds of olives can be processed for table consumption. However, because of differences in quality, black, green and color-oriented table olives are prepared for consumption using different processing techniques. Generally, the proportion of flesh is small, the kernel is small, can be separated from the flesh, thin and flexible peel, high sugar content and preferably low fat varieties are processed as table. Table olives are presented to consumption after various processing techniques in the form of kernel, crushed, peppered, carrot, almond filled and sliced olives (Tunalioglu, 2003).
As it is known, our country has produced 1,022,500 tons of olives according to the averages of the last 10 years. It ranks 4th among the olive countries in the world and 5th with the production of 105.9 thousand tons of olive oil.

Cultivars in Turkey

It is known that there are around 600 varieties of olives in the world (Tsouchtidi, 2007). A significant amount of olive cultivation occurs in these countries (Spain, Italy, Greece, Tunisia, Turkey, Syria, Morocco, etc.) and prominent varieties are available. In this respect, countries that are advanced in production work have done so by concentrating on one or more varieties. In this respect, Arbequina, Blanqueta varieties in Spain, Koroneiki in Greece, Kalamata varieties became widespread.
In Turkey, different varieties have come to the fore depending on different usage purposes. These are; Celebi, Gemlik, Edincik Su, Karamursel Su, Samanli cultivars in Marmara Region, Ayvalik, Cakir, Cekiste, Cilli, Domat, Erkence, Izmir sofralık, Kiraz, Memecik, Memeli, Uslu cultivars in Eagean Region, Büyük topak ulak, Sari hasebi, Sari ulak, Saurani, Tavsan yuregi in Mediterranean Region, Egriburun, Halhali, Kalembezi, Kan Celebi, Kilis Yaglik, Nizip Yaglik, Yag Celebi, in Southeastern Anatolia Region, Marantelli, Otur, Patos etc. in Black Sea region well as different types in Turkey.
For the development and continuity of the export of olive oil in our country, it is the most important factor to increase the quality of the cultivation of oil varieties and the quality of the fruit. For this, both on the basis of production, taking into consideration the periodicity

situation, and on the basis of processing should go to the modernization and protection of both the manufacturer and the exporter (Kaska et al, 2005).

Some Characteristics of Main Varieties are Grown in Southeastern Anatolia

In a research on the pomological characteristics of olive varieties in the Southeastern Anatolia Region, four of the economically produced olive varieties (Kilis oil, Nizip Yaglik, Tatayin and Yag Celebi) were evaluated as oily and the other four (Halhali, Kalembezi, Egriburun and Kan Celebi) were used and will be suitable for processing table (Table, 1). On the other hand, 40% of the olives in the region are Kilis oil, 30% Nizip Yaglik, 10% Halhal, 5% Yag Celebi and 10% Tatayin varieties (Karaca and Ulusarac, 1996). In the study of Karadag et al. (2003), some of the findings obtained from an adaptation study conducted in Kilis. According to these findings, it has been determined that Gemlik variety, which has become widespread in the region, has 247 fruits per 1 kg, weight of 100 fruits is 407 g, flesh ratio is 62.82%, and pit ratio is 37.18%. According to these findings, when compared with the standard features of Gemlik variety, it was seen that fruits were bigger but flesh ratio was low. It was determined that the fat content was 19.76% and it was 29.98% in comparison with the source prepared according to the standards. There are also differences between varieties in terms of showing periodicity. The characteristics of the Gemlik variety, which is widely grown in the Southeastern Anatolia Region and has been cultivated in the region with new facilities in recent years, are also presented below. (Canozer, 1991; Ozkaya, and Kaynas, 2003; Bulbul, 2007).

Nizip Yaglik

Its origin is Nizip district of Gaziantep. It is common in Nizip, Gaziantep and Cizre districts of Şirnak and Kahramanmaras. The tree is of medium vigor and has a large crown formation. It has the characteristic of collective development in youth. It gains a flat and drooping structure when it yields. Branching is good, the branches are well-dressed. Thick branches are beige-green, young branches are green-beige. Old branches are usually narrow, some are right angles, young branches are wide-angle and drooping. Medium strength and beige color of the body, young trees in a smooth structure, the tree gets rough appearance as the bark cracks. The medium long, broad elliptical leaf has a linty, slightly hazy surface with a lighter hue than the typical green color of the olive leaf, usually 000761 (Lavender green), and some with a light colored needle at the tip 000858 (Leek green). Lower surface glabrous, green-grey. Stalk color is yellowish green. The average length 58.48 mm, average width 14.06 mm, length / width ratio is 4.15. Cluster lengths are 14-31 mm, average Cluster length is 24.40 mm, the number of flowers in the Cluster 10-30, the average number of flowers is 17. Cylindrical, close to round, symmetrical in length and transverse, the fruit is large and small mixed, usually very small size. There is no spine formation, the tip is usually flat, some inward collapsed. The handle pocket is large, round, medium depth. Green fruit, typical olive green, ripe fruit dark cherry-black color, medium hardness. The flesh under the skin is cherry in color, but the main flesh is light green-white. The flesh is easily separated from the pit.

The weight of 100 fruits is 217.60 g and the volume is 200.00 cm^3. The number of fruits per kilogram is 460. Fruit length is 20.82 mm, fruit width is 17.17 mm and length / width ratio is 1.21. Flesh ratio of fruit; 81.31%, the oil content is 27.36% and the moisture content is 40.49%. Like fruits, the pits are large and small and can be considered as large according to the size of the fruit. The longitudinal and transverse symmetrical, cylindrical, widest point is in the middle, with a spine protrusion on both sides and a needle at the end. Thin, scattered grooves on the surface of the pit acquire a slightly rough structure and are beige-brown. Pit length 11.76 mm, width 7.07 mm, length / width ratio is 1.66. 18.69% of the fruit is pit.

Kilis Yaglik

Its origin is Kilis district of Gaziantep Province. It is widespread in Gaziantep, Kilis, Oguzeli, Sanliurfa, Turkoglu in Kahramanmaras and Cizre in Sirnak. The tree is of medium vigor and forms a fast-growing, medium-sized, flat and drooping crown. Branching is good, the branches are well-dressed. Two-year-old and older branches are milky brown and young branches are green-beige. Old branches are narrow-angle, young branches are wide-angle and drooping. The medium strength and dark beige body is generally smooth. Medium long, large elliptical leaf, the upper surface of the hairless, slightly hazy 000761 (Lavender green), some 000858 (Leek green) color, with a small needle at the tip. The lower surface is slightly pile grey-green. Stalk color is yellowish green. The average length of 57.46 mm, average width 13.18 mm, length / width ratio is 4.35. Cluster lengths 20-40 mm, average Cluster length 29.7 mm, the number of flowers in the 14-30, the average number of flowers is 20. Round, transverse and longitudinal symmetrical fruit, mixed large and small, usually very small size. The spine is not round, the end is round. The handle pocket is small, of medium depth, usually round, sometimes shuttle-shaped. Green fruit, typical olive green, ripe fruit is bright dark black color, medium hardness. The Flesh is easily separated from the pit.
The weight of 100 fruits is 176.80 g and its volume is 14.91 cm^3. The number of fruits per kilogram is 566. Fruit length is 17.58 mm, fruit width is 14.91 mm and length / width ratio is 1.17. Flesh ratio of fruit; 82.25%, the oil content is 31.82% and the moisture content is 40.79%. The fruit pit is oval, large and has a small needle at the end. The surface is covered with smooth and streaked veins and has a yellowish-beige color with a length of 11.93 mm, a width of 7.81 mm, and a length / width ratio of 1.52. 17.75% of the fruit is pit.

Halhali

Origin is the district of Derik in Mardin Province. It is widespread in Hatay, Gaziantep, Kahramanmaras and Mardin provinces. The tree is of medium vigor and forms a rounded crown. Branching is good, the branches are well-dressed. Old branches are milky brown and right angled, young branches beige and wide angle. The medium-strength and grey-beige body is generally smooth. The long, narrow, elliptical leaf has a lint-free top surface of 000761 (Lavender green), some of which has a color of 000858 (Leek green) and a small needle at the tip. The lower surface color is grey-green. Stalk color is yellowish green. The average length is 63.18 mm, average width 11.82 m, length / width ratio is 5.34. Cluster lengths are 21-35 mm, average Cluster length is 26.6 mm, the number of flowers in the Cluster 9-25, the average number of flowers is 12. The fruit, which is close to the round, symmetrical to the transverse and longitudinal, is of medium size. The spine is not round, the end is round. The handle pocket is small, smooth and round. Green fruit, hazy-light green, ripe fruit dark cherry-black color, medium hardness. The flesh is easily separated from the pit.
The weight of 100 fruits is 383.01 g and the volume is 370.50 cm^3. The number of fruits per kilogram is 261. Fruit length is 19.54 mm, fruit width is 16.09 mm and length / width ratio is 1.21. Flesh ratio of fruit; 82.79%, the oil content 21.11% and moisture content 49.03%. The fruit pit is oval, large and has a needle at the end. The surface is veined, rough and pinkish-beige color, 12.37 mm in length, 6.28 mm in width, length / width ratio is 1.96. 17.21% of the fruit is pit.

Egriburun

Its origin is Nizip district of Gaziantep. It is possible to come across it in Hatay, Iskenderun, Nizip, Gaziantep and Halfeti districts of Şanliurfa. The type of euphorbia has taken its name from the shape of the fruit. Other varieties with the same name can be found. The tree is of medium vigor and forms a medium-sized, rounded crown with a central part. Branching is frequent and well-dressed. Thick branches are beige-green and narrow angled, young branches are green and skirt branches are wide-angle. The medium strength and dark beige-brown body has a rough structure. The upper surface of the leaf is medium-long and wide elliptical and has a color of 000761 (Lavender green), some of which is 000858 (Leek green). The bottom surface is grey-green in color and has a small needle at the tip. Stalk color is yellowish green. The average length is 55.81 mm, the average width is 12.88 m, length / width ratio is 4.33. Cluster lengths 26-33 mm, average Cluster length 20.20 mm, the number of flowers in the wedge is 10-28, the average number of flowers is 20. The fruit, which is oval, transverse and longitudinal symmetrical, is small. There is no spine death and the tip is curved. The handle pocket is medium-sized, deep and slightly grooved on both sides. Green fruit, dark green, ripe fruit is dark purple, the color of the flesh under the skin is purple in color, and the color of the kernel gets pinkish white color. Fruit flesh is hard and easily separated from the flesh pit.

The weight of 100 fruits is 258.00 g and the volume is 250 cm^3. The number of fruits per kilogram is 388. Fruit length is 21.21 mm, fruit width is 15.01 mm and length / width ratio is 1.41. Flesh ratio of fruit; 86.09%, 20.84% and 50.23% of the moisture content. Fruit pit is oval, small, twisted and needle. The surface is slightly rough and dark beige-brown in color with a length of 14.77 mm, a width of 7.80 mm, and a length / width ratio of 1.89. 13.91% of the fruit is pit.

Kalembezi

Its origin is Nizip district of Gaziantep. It is a variety found in some olive groves in Nizip, Kilis districts of Gaziantep Province. The tree is of medium vigor and has a medium-sized, scattered, drooping crown structure. Branching is not very frequent. Old branches are beige and connected with different angles, young branches are beige-green color and skirt branches are wide angle. The body is of medium strength and dark grey and has a corrugated and rough structure. The leaf is medium-long and medium-wide elliptical and its top surface is hazy, lint-free 000858 (Leek green) and in some, 000761 (Levander green). The bottom surface color is grey-green, sometimes with a light yellow-green needle at the tip. Stalk color is light green. The average length is 58.50 mm, the average width 12.86 m, length / width ratio 4.54 species. Cluster lengths 18-27 mm, average Cluster length 24.00 mm, the number of flowers in the 11-23, the average number of flowers is 15. It is oval, round and symmetrical in length and transversely. There is no spine formation and the tip is round. The handle pocket is round and shallow. Green fruit, typical olive green, ripe fruit is dark cherry with hazy, black color. The ripe fruit flesh is greenish yellow and medium hard and easily separated from the pit.

The weight of 100 fruits is 222.00 g and its volume is 225.00 cm^3. The number of fruits per kilogram is 450. Fruit length is 18.28 mm, fruit width is 15.07 mm and length / width ratio is 1.21. Flesh ratio of fruit; 84.29%, the oil content is 31.50% and the moisture content is 46.16%. The fruit pit is oval and medium in size and has two sides of vertebrate which is flattened from the top. The tip of the pit is needle. The surface is veined, slightly rough and brown in color with a length of 13.48 mm, a width of 8.70 mm and a length / width ratio of 1.54. 15.71% of the fruit is pit.

Kan Celebi

Its origin is Nizip district of Gaziantep. It grows in and around Gaziantep and develops well in well-maintained environments. It has a large flat and rounded crown. Branching is normal and branches are common. Old branches are usually narrow-angle, young branches are wide-angle. Two and older branches are light brown, young branches are milky brown. The surface of the body is dark grey and very strong, corrugated, lumpy but smooth. The top surface of the leaf is very long and narrow elliptical, lint-free, 000858 (Leek green) color and the bottom surface is grey-green color with a needle at the end. The average length is 67.62 mm, the average width is 10.96 m, the length / width ratio is 6.16. Cluster lengths 24-45 mm, average Cluster length 38.00 mm, the number of flowers in the Cluster 11-28, the average number of flowers is 19. Round, transverse and longitudinal symmetrical fruit, very large. The spine is not round, the tip is usually round. The handle pocket is smooth, round-shaped, medium depth. Green fruit, typical olive green, ripe fruit is dark cherry-black, the fruit flesh under the skin is cherry color, the color of the kernel turns pinkish cream color. Fruit flesh is medium hard, easy to separate from the pit.

The weight of 100 fruits is 615.10 g and its volume is 620 cm^3. The number of fruits per kilogram is 163. Fruit length is 25.73 mm, fruit width is 21.37 mm and length / width ratio is 1.20. Flesh ratio of fruit; 88.90%, the oil content is 16.90% and the moisture content is 50.03%. The fruit pit is oval, small, with a bent downward tip and marked needles, flattened from the top and vertebrate on both sides. Veins are white lines on the surface and are of beige color. Pit length 16.52 mm, width 9.15 mm, length / width ratio is 1.80. 11.10% of the fruit is pit.

Yag Celebi

Its origin is Gaziantep. It is a variety grown in Kilis and Nizip districts of Gaziantep Province. The tree is of medium vigor and forms a medium-sized drooping crown. Branching is good and the leaf density of the branches is good. Main branches are grey-beige, young branches are green-grey. Old branches are steep or close to the narrow angle of the dike, young branches are wide-angle. Medium strength, dark grey color, corrugated and lumpy body, smooth surface. The upper surface of the leaf is medium long and wide elliptical in grey-green color. Stalk color is greenish yellow. The average length is 52.84 mm, the average width is 12.10 mm, the length / width ratio is 4.36. Cluster lengths 24-36 mm, average Cluster length 31.50 mm, the number of flowers in the 6-6, the average number of flowers is 18. Long oval, downward slightly bent tip, asymmetrical fruit is large. There is no spine formation, the tip is bent down and there is a nipple formation at the tip. The handle pocket is deep, with protrusions at the edges and grooved in 2 or 4 separate directions. Green fruit, typical olive green, ripe fruit is bright dark cherry-black color, medium hardness. The flesh is easily separated from the pit.

The weight of 100 fruits is 442.15 g and the volume is 430.00 cm^3. The number of fruits per kilogram is 226. Fruit length is 26.32 mm, fruit width is 17.44 mm and length / width ratio is 1.50. Flesh ratio of fruit; 84.57%, the oil content is 21.10% and the moisture content is 53.40%. Fruit pit is long cylindrical, slightly asymmetrical, medium-sized, with a small needle at the tip. Due to the deep grooves, the surface is rough and dark beige-brown with a length of 19.46 mm, a width of 8.91 mm, and a length / width ratio of 2.18. 15.43% of the fruit is pit.

Gemlik

This variety is not actually of Southeast Anatolian Region. However, intensive planting has been done in the region in recent years. Its origin is Gemlik district of Bursa province. It is grown in Bursa, Tekirdag, Kocaeli, Bilecik, Kastamonu, Zonguldak, Sinop, Samsun, Trabzon, Balikesir, Izmir, Manisa, Aydin, Icel, Adana, Antalya and Adiyaman. Medium-vigor tree, large, smooth, round forms an angle. Branching is good, the branches are well-dressed. Branches turn green-grey color and the knuckle is short. The average length is 50.68 mm, average width 11.84 m, length / width ratio 4.28. Cluster lengths 15-26 mm, average Cluster length 20.30 mm, the number of flowers in the wedge is 10-23, the average number of flowers is 14. Close to the round, cylindrical, symmetrical transverse and longitudinal fruit, medium-sized. It does not have a spine formation and has a rounded v-tip. The handle pocket is small, smooth, round-shaped and medium-sized. Green fruit, hazy typical olive green color, ripe fruit bright, dark black color, medium hardness. The fruit flesh is easily separated from the pit.

The weight of 100 fruits is 372.80 g and the volume is 370.00 cm^3. The number of fruits per kilogram is 268. Fruit length is 22.33 mm, fruit width is 17.91 mm and length / width ratio is 1.24. Flesh ratio of fruit; 85.86%, the oil content is 29.98% and the moisture content is

45.05%. Fruit pit is oval, medium-sized and has a needle at the end. The surface is deep, frequently corrugated, rough and brown-beige in color with a length of 13.81 mm, a width of 7.98 mm, and a length / width ratio of 1.73. 14.14% of the fruit is pit.

The yield of this variety which develops to medium strength in a good maintenance environment is good. It gives fruit regularly every year. May 12-June 9 flowering varieties, between May 16-June 13 between the fruit vineyards. The fruit reaches the green ripening period between August 20 and September 10 and reaches black ripenin on 1-15 November. Its production is produced with thick or green branch cuttings. This variety, which is partially resistant to cold, is the most important variety considered for black table according to the Gemlik method. Since the fruits are rich in oil, non-table quality products can be processed as oil. This cultivar has 80% of the wood being in Marmara, Turkey. The presence of Gemlik trees in general constitutes 11%..

Conclusions

Over the last 30 years, the production and the consumption of olive oil have increased together. It is unlikely that this trend will change in the near future, considering the recent introduction or increase of olive cultivation and olive-oil consumption in countries such as Japan, Australia, China and South Africa. Remarkable increases (up to 10-fold) have been observed in several countries, including Australia, where olive-oil consumption has passed the level of 1 kg/person/year. Hence, the volume of olive oil consumed worldwide during the next 10 years is expected to exceed three million tonnes annually (Fabbri et al., 2004)

Olive cultivation is carried out economically especially in Gaziantep, Kilis, Mardin, Adiyaman and Şanliurfa provinces in Southeast Anatolia Region. However, certain varieties have gained weight in the region. Lack of irrigation, high alkaline soils, nutritional problems with low yield per tree, small fruit, all contribute to the production of mainly oil varieties. Olive is called an immortal plant because of its continuous regeneration feature. Therefore, the life of an olive tree can be up to 500 years depending on the climate and maintenance conditions. In fact, such a monument tree occurs in Sanliurfa (Ak and Korkmaz, 2018).

In recent years, with the support of the Ministry of Agriculture, olive plantation areas have increased rapidly in Şanliurfa and Adiyaman. It is known that especially Gemlik variety has become widespread in the region. This variety is grown as a black table variety under irrigated conditions in the western regions of our country. It is not possible to predict how it will work in both irrigated and non-irrigated conditions in the Southeastern Anatolia Region. The reason why this variety is widespread is that they can be easily produced by cuttings. On the other hand, under irrigated conditions, it was observed that this variety yielded in a short time and yielded fruit regularly without showing periodicity. It is also a kind of table and oil olive, and is partially resistant to cold. When the physiological water requirements of the trees are not met, grains are crumpled and spilled. It was observed that the fruits of the Gemlik variety produced in the region, with low air humidity and high temperatures, lower the table quality and the outer skin is thicker.

THE TRAITS OF PISTACHIO ROOTSTOCKS AND THEIR IMPORTANCE

Bekir Erol AK

University of Harran, Faculty of Agriculture, Department of Horticulture, 63200 Sanliurfa , Turkey
Corresponding author: beak@harran.edu.tr

Abstract

Rootstock is very important for fruit production. They effect some traits such as vigour, quality of fruits, yield, diseases, resistance for different soil types etc. Rootstocks are very important for pistachio nut production as well. Rootstocks may give resistance to biotic and abiotic stresses such as insect pests and diseases, low and high temperatures, drought, low soil moisture, salinity and its effects on the size of the tree size, alternate bearing, yield, quality, shell splitting and blank nut production, etc. There are 11 Pistacia species and hybrids in general. But for P. lentiscus, almost all of the Pistacia species can be used as rootstock for P. vera. Most common Pistacia spp. are P. vera, P. khinjuk, P. atlantica, P. terebinthus, P. palestina etc. in Turkey. In Greece and Italy (Sicily) the use of P. terebinthus is also common. In North Africa P. atlantica is used. In California, although both P. atlantica and P. terebinthus were used in the early days of the pistachio industry, now P. atlantica is the preferred rootstock because of its greater success in budding and faster growth than P. terebinthus. However, since both species are very susceptible to Verticillium wilt, a new rootstock, P. integerrima, or UCB=1 (hybrid) are now recommended to growers because of its vigour and resistance to the disease.

Keywords: *Pistacia, Rootstock, pistachio, fruit*

Introduction

Almost all commercially available fruit trees have been budded or grafted; that is, the top portion, or scion, of the desired fruit variety is attached to the root system, or rootstock, of a different variety. Trees are grown this way because some popular varieties grow and crop better on rootstocks other than their own. In some cases, the rootstock is more resistant to certain troublesome diseases. The choice of rootstock is very important for some fruits, such as apples, but not of much consequence for others. Apple trees are grown on a wide variety of rootstocks. These are called size-controlling rootstocks because they control the size of the tree; however fruit size is not reduced. In general, the smaller the tree, the sooner it will bear fruit after planting (Choudhary and Mehta, 2010).

Rootstocks are propagated by seed or vegatatively i.e. cuttings, layering. *Pistacia* spp. Are generally propagated by seed. Rootstock is very important for pistachio nut production. Choice of rootstock depends on resistance to insect pests and diseases, low and high temperatures, drought, low soil moisture, salinity and its effects on the size of the crown, alternate bearing, yield, quality, shell splitting, blank nut production, etc. (Ferguson et al., 2005; Ak, 2002)

The pistachio nut belongs to the genus *Pistacia* of the family *Anacardiacea.* The *Pistacia* genus has 11 species. The edible pistachio of commerce is the species *Pistacia vera* L. In addition to many named cultivars, significant populations of wild germplasm exist, primarily in central Asia from Turkey to Afghanistan. The species has been long propagated for nuts throughout the Mediterranean and Middle East. Several reports (Hormaza et al., 1994) suggest that the Romans were responsible for the spread of *Pistacia vera* within the Mediterranean basin. According to Zohary (1952), the distribution range of *Pistacia* species comprises five different centres and our literature survey supports this idea: (1) Northwestern America region), (2) Mediterranean region, (3) Irano-Turanian region, (4) Sino-Japanese region and (5)

Northeastern African region. Zohary (1952) also indicated several isolated areas such as Saudi Arabian desert (*P. palaestina*), Egypt (*P. khinjuk*) and southern Crimea (*P. atlantica*).
Apart from P. lentiscus almost all of the Pistacia species can be used as rootstock for P. vera. (Ak and Parlakcı, 2009). Although in Iran and Turkey P. vera seedlings have been used as common rootstock for centuries, seedlings of P. terebinthus in Turkey and P. mutica in Iran have also been used during the last few decades. In Greece and Italy (Sicily) the use of P. terebinthus is also common (Table 1). In North Africa P. atlantica is being used such as in Morocco. In California although both P. atlantica and P. terebinthus were used at the beginning of the pistachio industry, now P. atlantica is the preferred rootstock because of its greater success in budding and faster growth than P. terebinthus. However, since both species are very susceptible to Verticillium wilt, a new rootstock, P. integerrima is recommended to the growers because of its vigour and resistance to the disease (Needs and Alexander, 1982; Crane and Maranto,1988; Kaska, 1990).

Table 1. The Countries and common *Pistacia* species (Ak, 2013)

Afghanistan	*P. vera (from seed), P. khinjuk, P. atlantica, P. mutica*
Algerie,Morocco	*P. lentiscus, P. terebinthus, P. atlantica, P. vera*
Armenia, Georgia	*P. mutica*
Azerbaijan	*P. mutica, P. atlantica*
Greece	*P. lentiscus, P. terebinthus, P. palaestine*
Iran	*P. vera, P. atlantica, P. khinjuk*
Israel	*P. lentiscus, P. atlantica, P. palaestina, Hybrid P. saportae*
Italy	*P. lentiscus, P. terebinthus, P. vera*
Lebanon	*P. palaestina, P. lentiscus, Hybrids*
Mexico	*P. mexicana, P. texana*
Syria	*P. atlantica, P. palaestina, P. khinjuk, P. vera*
Spain	*P. atlantica, P. lentiscus, P. terebinthus*
Tunisia	*P. atlantica, P. lentiscus, P. terebinthus*
Turkey	*P. terebinthus, P. atlantica, P. khinjuk, P. palaestina, P. vera*
USA	*P. integerrima, P. atlantica, P. terebinthus, PG II and UCB=1 (Hybrid)*

Pistacia vera and *Pistacia mutica* species are cultivated in Iran. Generally Ghazvin and Badami pistachio cultivars seeds are used as rootstocks because of their resistance for salinity and *Phytophthora* (Hokmabadi et al., 2008). In Syria *P. atlantica* and *P. vera* cultivar Ashoury seeds are used as rootstock.
In Turkey, there are four common *Pistacia* species (*P. vera, P. atlantica, P. khinjuk, P. terebinthus*) used as rootstocks. Except for *P. vera*, the others are not commonly used as seedlings because of their low percentage of seed germination. According to observation, Siirt cultivar seeds have better growth and development than the other cultivars.
In U.S.A, *P. atlantica, P. terebinthus* and *P. integerrima* were used in last decade. Very recently the hybrid of *P. integerrima* and *P. atlantica* have been used for Kerman pistachio cultivar. The main hybrid rootstocks used is UCB=1 (*P. atlantica x P. integerrima*) and PG-II (*P. integerrima x P. atlantica*) for their different features (Ferguson et al., 2005). In Spain commonly *P. atlantica* is used as rootstock besides *P. terebinthus*.
Some important characteristics of the main rootstocks are summarized below (Kaska and Bilgen, 1988; Kaska, 1990; Ak, 2015; Ak, 2019).

Pistacia vera, L.

The trees of P. vera are big in size and around 10 meters tall. They have wider crowns than the other pistachios. The compound leaves consist of 1-3 pairs of leaflets and one terminal leaflet which is of the same size as the lateral leaflets. The petioles are short. The upper surfaces of the leaves are quite dark and shiny green but the lower surfaces are dull-green (Bilgen, 1968). The male flower clusters are bigger and more compact than those of the other pistachios.

P. vera seedlings are stronger and more homogeneous than the other rootstocks. Budded trees on this rootstock grow slowly during the first year but growth becomes faster in the following years. There is no incompatibility problems in budding with the varieties of pistachio (Ozbek, 1978, Ozbek and Ayfer, 1959). In the budded trees the juvenility period lasts long. Therefore, the trees bear fruit quite late. In arid zones the trees reach the bearing stage 15 to 20 years after planting. They can withstand drought, high lime content and salinity in the soil but are sensitive to high soil moisture, therefore, drainage is necessary. P. vera seedlings are sensitive to Melodogyne nematodes and some soil borne diseases (Kaska, 1990). In Turkey it is used because of rapid growing traits. But in the last years it is affected by excessive irrigation water or rainy weather conditions. In such conditions P. khinjuk will be better as rootsotock for pistachio cultivars.

Pistacia khinjuk, Stocks.

The trees of P. khinjuk look like P. vera. Hovever, they are taller in height and compact in shape. The compound leaf consists of five pairs of leaflets and one terminal leaflet which is quite large. The petioles of leaflets are short. In comparison to P. vera the ovaries are small but the styles are more pronounced and the stigmas are yellow-green (Özbek, 1978). During the ripening process the exocarp first becomes red and then turns olive-green. The endocarp is rather hard. The female flowers are similar to most of P. vera whereas the anthers in the male flower clusters are smaller and redder. The fruit is small (7 to 9 mm in length and 8 to 10 mm in width) but rich in oil. The exocarp is green-blue and the kernel is darkish pistachio green. Because of this attractive colour the nuts of P. khinjuk are used in the pastry and ice cream industry (Kaska 1990).

The fruit which is grown in Turkey did indicate differences in terms of size. There are generally two types of P. khinjuk called Buttum. These are divided into A and B type. Buttum A type fruits are bigger than B type and it is called Cultured Buttum in Siirt region. The fruit in this Buttum (A type); is 10.42 mm long and 7.31 mm wide on average. 100 fruit weighs are 38.69 g, as well as the number of fruits per 100 g was determined to be 258.6. The thickness of the hard shell is 1.00 mm. On the other hand, the outer green shell of the Buttum A is more firmly attached to the darker green and harder shell (endocarp) than type B. Buttum B; is about half the size of type A and in Siirt province called "Wild Buttum". This type is 8.3 mm long and 5.4 mm wide. The weight of 100 fruit is 19.98 g. This classification and its characteristics were determined by Bekir Erol Ak (Ak, et al. 2012).

This rootstock is hardier and more resistant to drought than P. terebinthus. Therefore it is grown at much higher altitudes (2,500 to 3,000 m) and in arid areas. In the eastern part of South East Anatolia the trees of P. khinjuk are grown as woods and form big trees. P. khinjuk occurs naturally in South East Anatolia, Sinai Desert, Syrian Desert, North of Iraq, Iran, Baluchistan and Kashmir (Yaltirik, 1967; Ayfer, 1959). The value of this rootstock is not known well. Hovever, when the giant trees of P. khinjuk are top-budded, they bear fruit within 5 to 6 years. Detailed studies are needed on the value of this rootstock vhen it is grown from seed. Moreover, the behaviour of different pistachio varieties budded on this rootstock needs to be investigated. In the last decades P. khinjuk has showed better performance according to rootstock x scion trials.

There is little swelling on the rootstock and scion of the cultivated pistachio grafted on the *P. khinjuk* rootstock. *P. khinjuk* was found to be the best utulizing from nitrogen in soil among *Pistacia* species used as rootstock ((Ak, et al. 2012).

Pistacia atlantica, Desf.

P. atlantica is one of the important rootstocks for P. vera. The nuts are small in size; therefore, their germination creates problems. Since they are open pollinated and compatible with other pistachios, the seedlings may not be homogeneous. However, by discarding the non-homogeneous materials this problem can be overcome. The seedlings grow slowly and come to the budding stage within two to three years on dry sites. Tap roots of P. atlantica are not as strong as P. vera, therefore they are not as difficult to transplant as P. vera. This rootstock can be recommended for irrigated plantations. They are also successful in somewhat heavier soils. Thus in such soils they give better results than P. vera seedling roots which are sensitive to high moisture in soils (Özbek, 1978, Ayfer, 1959, Spiegel-Roy et al. 1972; Needs and Alexander, 1982; Crane and Maranto, 1988). P. atlantica is sensitive to temperatures below -10°C (Maranto and Crane, 1982). This is the reason why it is widespread along the Mediterranean coastline but is not grown in continental areas. One of the most important facts about P. atlantica is its resistance to Melodogyne nematodes and some soil borne diseases such as Phytophtora parasitica. Hovever, the seedllngs are sensitive to Verticillium wilt. Therefore they are not recommended for planting in Verticillium infested soils where cotton was previously grown.

Pistacia atlantica Desf.'s trees grow up to 20 meters, forming trees with a width of 10-15 meters. P. atlantica is a strong rootstock and well-compatible with pistachio cultivars. There is no swelling or in-compatibility signs at the grafting point. The tree which is grafted on P. atlantica has big size and is a high yielding tree. It is a decidious tree and the seedling grows slowly for the first years.

P. atlantica can be used as rootstock for growing pistachios under irrigated conditions. They grow well in non-heavy base soils. P. atlantica is sensitive to temperatures below –9.4 oC. therefore, it is spread all over the Mediterranean coastline. On the other hand, this rootstock is resistant to nemetodes and some soil-borne diseases such as Phytophthora parasitica. Although it reaches the thickness for budding but sometimes the bark is not easily sparated from wood part. This means it may create problems in terms of removing the bark.

Fruits (P.atlantica)are oval-shaped, 5-7 mm long, 4-5 mm wide, dark green or bluish if filled, and one side reddish light yellow if non-filled. The number of fruits is 1033 per 100 g and it is determined that 100 fruits are 9.70 g. (Ak, et al. 2012). The trees of P. atlantica are rather tall. Mature trees may reach up to 7 to 20 m. The compound leaves consist of one terminal and 2 to 5 pairs of pointed leaflets. This species and some of its subspecies are distributed in Turkey, Greece, Aegean Islands, Cyprus, North Africa, Syrian Desert, Crimea (Russia), Caucasia, Iran, Afganistan, and Baluchistan (Davis, 1967).

Pistacia terebinthus, L.

The trees of this species are grown generally as bushes. The plant has a strong and deep root system (Ayfer, 1964). Therefore it can be grown in poor, rocky and stony soils. It is a kind of dwarfing rootstock for P. vera so the trees budded on this rootstock can be easily recognized. The male flower clusters of this species are distinguished by their red colour in comparison to pale or yellow colour of the other species. The leaflets are pointed. In each leaf there are generally 4 to 6 pairs of leaflets. The nuts are very small (5 to 6 mm in length, 3 to 5 mm in width) (Ozbek, 1978).

P. terebinthus is as hardy as P. vera but hardier then P. atlantica. Therefore, it is preferred to P. atlantica in cold areas. In Turkey, it can be grown successfully at elevations up to 1200 m

(Ak, 1992). It is also resistant to Melodogyne nematodes but very susceptible to Verticillium wilt. P. terebinthus is suitable for planting in calcareous soils along the Mediterranean coast. It grows very well in places where the annual precipitation is about 400 to 600 mm. As in the case of P. atlantica it can also grow in somewhat heavy soils. According to Joley (Woodroof, 1982) pistachio varieties budded on P. terebinthus and P. atlantica grow faster than the ones on P. vera.

P. terebinthus, grows more slowly than pistachio seedlings, but they are more resistant to nematodes than are also resistant to Phytopthora. They can be sized 3-5 m depending on maintenance and soil conditions,. They are usually found in the mountains in the form of bushes in forests. Each bushes have an average of 20 plantlets.

Fruit; It is 3-5 mm wide and 5-6.5 mm long and similar to lentil grains. When the outer shell is mollusc and ripe, it is bluish, olive-green and fleshy. Fruits are eaten freshly or roasted with this outer crust or squeezed out of the oil. On the other hand, fruits are crushed and roasted and ground like coffee. Bekir Erol Ak determined that the number of fruits per 100 g is 1455 and the amount of 100 fruits is 6.88 g. (Ak, et al. 2012).

P. terebinthus has a very strong root system and the roots have a very good growth ability in rocky soils. It is a good rootstock for rocky barren and especially non-fertile soils. They also grow naturally in both chalky and clay and deep soils and can withstand long summer droughts. Among all *Pistacia* species, the most powerful root system is considered for *P. terebinthus*. Some researchers have reported that pistachio grafted on *P. terebinthus* have been alive for 200 years.

Pistacia integerrima

P. integerrima is considered to be a variety of P. chinensis (Joley, 1979) but Monastra et al. (1988) stated that it is a synonym of P. khinjuk. In recent years it has been used in California as rootstock for pistachio as it grows vigourously and is resistant to Verticillium wilt (Needs and Alexander, 1982). It is recommended for replanting and new plantations in the cotton areas where the soils are infested with the wilt-causing fungus. According to Maranto and Crane (1982) P. integerrima is less tolerant of cold temperatures than either P. atlantica or P. terebinthus (Kaska 1990; Ferguson et al., 2005)

Hybrid Rootstocks

There are two common and main hybrid rootstock developed in Californa. They are respectively Pioneer Gold II (PG II) and UCB I. PG II is the result of open pollination in an isolated situation with multiple *P. atlantica* trees as the female parent and multiple *P. integerrima* trees as the pollen parents. UCB I is the result of a closed pollination with a single tree of the same parents. (*P. integerrima* pollen is introduced into a closed greenhouse in which the *P. atlantica* tree is grown.) Thus, both are the same interspecific hybrid but are produced from different seedling parents and therefore both exhibit seedling variability. Both of the hybrid rootstocks have increased vigor compared to *P. atlantica*, and generally equal or greater vigor compared to *P. integerrima*. (Ferguson et al., 2005).

After *P. integerrima* was discovered to be tolerant of Verticillium wilt, it became the most widely planted rootstock in California. It is vigorous, buds easily and results in a uniform tree stand. It is the least cold tolerant of the commonly used rootstocks and can be damaged by winter freezes and early frosts, particularly if they occur when the tree is young. The researches indicated that its growth rates and early production is superior to *P. atlantica* and 19.1% less than UCB-I, equal to or slightly less than the two interspecific hybrids. Nutrient studies have shown *P. integerrima* to be less efficient than *P. atlantica* for boron, zinc and copper uptake (Ferguson et al., 2005).

Conclusions

Rootstock is very important for pistachio as it is other fruit trees. The relationship between rootstocks and cultivars are very important. It can be affected by soil structure, salinity, mineral nutritions, resistance to soil borne diseases etc. Some researches are determined that Pistacia khinjuk is seems to be prefferable rootstock for pistachio. Rootstocks also effects the scion if there is facilities of irrigation or not. Excessive irrrigation occurs diseases problems.

Abstract

Pistachio is mainly grown at Southeast Anatolian part of Turkey. It is grown in a very bad soil conditions and non-irrigated areas. It is often called "rich plants for poor soils". In this research the plants were grown on three different soil types. Soil samples were taken from 3 different regions of these three different types of soil (A Parcel: Deep Red Soil (Kepir), B Parcel: Konglomera type (Pur), C Parcel: Boz soil (Lime content high) in fall. According to obtained results, pH was determined between 7.68 to 7.86 and lime content was 18.46 % to 35.10 %. Organic matter was very low because of high temperature. The highest shell splitting was obtained from the trees grown in A type soil conditions. Shell splitting rate varied between 38.65% to 50.39%. The empty fruit rate also varied according to soil types. Fully filled fruit rate was affected by soil type as well.

Keywords: *Pistachio, soil types, splitting, empty fruits.*

Introduction

Pistachio can be grown in only several parts of the world due to special climatic requirements. The most important pistachio producer countries in the world are Iran, U.S.A., Turkey and Syria, respectively. Growing and processing techniques after harvest in Iran and U.S.A differ from those in other countries. Modern growing and processing techniques are performed in USA only (Ak, 1992).

Pistacia vera is grown at 30-40 m altitude and suited in microclimate areas in the world. The biggest (420,000 ha) production areas belong to Iran. Second country is Turkey. But its yield is very low when the production areas are compared (Arpaci et al., 2005). This situation makes the scientist to think about the problems and solutions. Pistachio is growing in unfertile, rocky and high lime soil and rainfed conditions. It has grown in non-irrigated areas so far. But now, there is a dam named Ataturk, it provides facility of irrigation in Southeast Anatolian region where pistachio have been growing for hundreds of years (Kaska, 1995).

There are major cultivars in each main producing country. According to Sheibani (1995) there are 60 named cultivars in Iran. But main production cultivars are Ohady and Kaleh Ghochi. In Turkey, Kirmizi, Uzun and Siirt are the major cultivars. Keten Gomlegi is a domestic regional cultivar. Turkish cultivars are preferred in many European and U.S.A. markets due to their good taste and uniformly green kernels. In U.S.A. the main cultivar is Kerman. In Syria, different cultivars are common such as Ashoury, Oleimy, White Batoury etc. But the main cultivar is Ashoury (Ak, 2014).

The aim of the this research is to determine the effects of different soil types on splitting, blank, and shelling percentage of pistachio cultivar " Keten Gomlegi".

Material and Methods

Material

This research was carried out during period 2016-2017, in Bozova town in Sanliurfa in Turkey. The orchards were established in three different parcels with three different soil types such as: A Parcel: Deep Red Soil (Kepir), B Parcel: Konglomera type (Pur), C Parcel: Boz soil (Lime content is high). Some climatic conditions are given in Table 1.

Pistachio trees were "Keten Gomlegi" cultivar of pistachio (Figure 1). The trees are 30-40 years old and grown in rainfed conditions. In the orchard, five trees were selected which are similar to each other for yield and appearances. Each tree was accepted as one replication. **Keten Gomlegi cultivar description:** This cultivar is mainly grown as domestic cultivar in Sanliurfa and Gaziantep province in Turkey. Tree grows weak. Habit is semi-erect. Flowering time mid-late. Density of branches are very high and length of branch is small. The colour of florescence is yellowish-green. Leaf pedicel is short and color is deep green and thick. Oil content is approximately 59 % and protein content is 26 % around. (Gokce and Akcay, 1993; Ak, 2014).

Methods

The fruit samples were taken from five marked trees during the harvesting time. Samples are taken from four sides of trees, each side two clusters, totally four clusters for each tree and after drying some physical analysis were done such as splitting, blanking, unsplitted rate or totally filled nut rates.

The soil samples were taken in Fall after the first rain. Soil samples were taken from three soil depths (0-20 cm, 20-40 and 40-60 cm) and three different places. These samples were analyzed in the laboratory and results are given Table 2 and Table 3. Statistical analysis, (LSD: Least Significant Differences) were done on either soils or fruits.

Results and Discussion

In this research, the effect of different soil types on Keten Gomlegi pistachio cultivar was investigated. During the harvesting time analyses were done on each of five trees. The results were given in tables.

Soil Analysis

Soil samples were taken from different soil types and parcels. The soil analysis results were given Table 2 and Table 3.

Table 2. The contents of pH, salt, lime, structure and organic matter of different soil types

SOIL TYPES	Soil Depth	Some Physical Traits of Soil				
		pH (SC)	**Salt (%)**	**Lime (%)**	**Structure (%)**	**Organic Matter (%)**
A TYPE	0-20	7.92*	0.032	18.16	54.63	0.69
	20-40	7.82	0.037	19.83	57.56	0.53
	40-60	7.83	0,037	17.39	60.13	0.60
	AVERAGE	**7.86**	**0.035**	**18.46**	**57.44**	**0.60**
B TYPE	**0-20**	7.76*	0.027	35.40	47.30	0.87
	20-40	7.68	0.030	35.47	48.03	0,78
	40-60	7.62	0.023	30.60	47.30	0.69
	AVERAGE	**7.69**	**0.026**	**33.82**	**47.54**	**0.78**
C TYPE	**0-20**	7.66*	0.017	35.30	41.80	0.61
	20-40	7.68	0.018	34.48	42.90	0.56
	40-60	7.72	0.017	35.54	44	0.67
	AVERAGE	**7.68**	**0.017**	**35.10**	**42.90**	**0.61**

*: This is average of different three samples.

Different soil types contain different traits. But the deepness is also differing by means of pH, salt, lime etc. The contents of pH is higher (7.86) in soil Type A. Besides pH, salt content is also higher while lime content was lower than others. Of course, it can be seen as contrast to soil types. This is may be due to different part of orchards and different soil types. Organic matter found was very low in the all soil types (Table 3). This value is normal because summer temperature is very high (Table 1). Organic matter is getting lower because of temperature. Tekin et al. (1985) conducted trials in Sanliurfa, Gaziantep, Ceylanpinar where pistachio is densely grown and similar results were determined. Bozova city area where this research has been performed is located in the same part of Turkey.

Table 3. Comparison of traits of different soil types.

SOIL TYPES	Some Physical Traits of Soil				
	pH (SC)	**Salt (%)**	**Lime (%)**	**Structure (%)**	**Organic Matter (%)**
A TYPE	7.86* a	0.035 a	18.46 b	57.44 a	0.60 b
B TYPE	7.69 b	0.026 b	33.82 a	47.54 b	0.78 a
C TYPE	7.68 b	0.017 c	35.10 a	42.90 c	0.61 b
AVERAGE	**7.74**	**0.026**	**29.12**	**49.29**	**0.66**
LSD (%5)	**0.109**	**0.005**	**3.587**	**3.455**	**0.153**

*: This is average of different three samples.

Statistical analysis also shows that all soil types are different to each other. pH is high, salt is normal and lime content is high while organic matter is very low. (Table 3). Generally, soil Type A is the better than others. It is named "Kepir" deep red, fertile soil conditions.

Splitting Rate (%)

The effect of different soil types on pistachio nut splitting rates is shown in Table 4 and Table 5. As seen in Table 4, there are some differences between the trees. According to Table 5, the highest splitting rate (50.39 %) was obtained in Type A soils while the lower is determined as 36.64 % in Soil type C.

Totally Filled Nut Rate (%)

Filled nut rates varied depending on soil types. According to obtained results, total nut rate (100 %) is obtained from the trees grown in Soil Types C. The lowest (87.85 %) totally filled nut rate was obtained from Soil Type A.

Blank Nut Rate (%)

Blank nut rate can be changed due to irrigation, fertilization, pollination etc. In these orchards the mentioned factors were eliminated and all conditions were similar. According to obtained results the blank nut rate was higher in Soil Type A then in other soil types. The reason can be due to mineral nutrition of soils. Fruits are remaining on the branches after June dropping time. The other soil types' fruits are dropping because of the fruit load or other reason.

Table 4. Effects of different soil types on some physical traits of pistachio nut.

C TYPE	38.65	61.35	61.35	0	100 a
AVERAGE	**43.70**	**56.30**	**52.10**	**4.18**	**95.81**

Generally speaking, unsplit nut rate is higher (56.30 %) than split nuts rate. This is mainly due to lack of water. This situation is caused by non-effective fertilization or feedings as some elements are effective when soil is irrigated.

Shelling Percentage (%)

The obtained results regarding shelling percentages of Kernel are given in Table 6, which is related to growth on different soil types. According to results, the highest value at 52.40 % in Full and split fruits were in Soil Type A. The lowest (50.51 %) value is determined in Soil Type C. The results between the unsplit fruits were similar to splitted fruits. This means that Soil Type A had better conditions for shelling percentage.

Table 6. Comparison of shelling percentages of Pistacio cultivar “Keten Gomlegi” grown on different soil types.

SOIL TYPES	Splitted nut (%)	Non-Splitted nut (%)	Shelling Average (%)
A TYPE	52.40 a	50.63	51.51 a
B TYPE	52.26 a	49.32	50.77 ab
C TYPE	50.51 b	48.55	49.53 b
AVERAGE	**51.72**	**49.50**	**50.60**
LSD (%5)	**1.608**	**N.S.**	**1.425**

Shelling percentages among the unsplitted fruits is not statistically significant. The best one was in Soil type A and split fruits (Table 6).

Conclusions

Pistachio grows well in different soil conditions. But it is more fruitful if it is grown under fertile and physically good soil conditions, otherwise, it can be grown as a plant in all kinds of soil types. Soil type A is very well conditioned which provides positive factors for the kernel or fruits.

Although blank nut formation is a varietal character, it is extensively affected by climate, efficiency of pollination, fertilization, irrigation and rootstocks. Blank nuts found in the Turkish cultivars are due to inefficient pollination and lack of irrigation. Insufficient pollination conditions of the orchards are mainly responsible for high blank nut percentages (Ak et al., 1998). Besides this, vegetative or stimulative parthenocarpy and embryo abortion have another impact on blank nut formation. The tendency to parthenocarpy and percentage of abortive embryos can be different from one cultivar to another (Caglar et al., 1997). Splitting of pistachio nut depends on cultural practices such as irrigation, fertilization and soil cultivation (Ak and Parlakci, 2006). But it is a genetic character. Generally it depends on kernel development. In this experiment we showed that when pistachio is grown in fertile soil the quality will be higher.

Abstract

The sorbent, or water-retaining agent, we produced is based on the introduction of biodegradable units into the macrochain at the stage of synthesis of polymers. The sorbent granules, containing biodegradable fragments in the mesh structure, were obtained by radical polymerization in the redox environment. Bacillus sp/ microorganisms were introduced into the sorbent matrix. It also seems highly effective to use a whole complex of products for processing vegetable and animal raw materials containing starch, pectin, chitosan and other polymeric materials. They are both available and can be decomposed as the result of microbial activity into water, carbon dioxide and nitrogen derivatives. The purpose of this work was to study the effect of moisture-retaining materials on the yield of potato. The sorbent demonstrated the ability to absorb and retain moisture in the plant root area, which allowed an increase in the potato crop production. The data showed that due to the moisture retained inside the sorbent and the moisture released to the plants, it was possible to form an additional potato crop. If the sorbent is enriched with microbes Bacillus sp. and the dose of the sorbent is 20 kg / ha, it increases the yield production by 1.7. The difference of yield output in the pilot plots caused the extra water retention in the soil. The biological activity of the soil varied considerably at the experimental plots, and the figures for the catalase activity were by 1.1-1.5 higher than the control option. Thus, we could observe a tendency of the increase in its activity by the end of the vegetation season.

Keywords: *sorbent/water-retaining agent, humidity sorption, Bacillus sp, microbiological activity of the soil, barley production capacity.*

Introduction

The issue of water retention in the soil has always been extremely important for the regions lacking in rains, as it inevitably affects the yield production capacity (Rode, 2008). The black-earth region in Russia is no exception. Farming in the risky climate faces a lot of problems, for example, when the lack of rains coincides with a particular vegetation phase of the plants (Kadyrov et al., 2005).

Thus, solutions to such problems should aim at developing efficient water-saving technology and thus effectively provide plants with moisture. The research shows that using microorganisms as elements in the water-retaining agents can contribute a lot to the eco-safety of the latter. Providing plants with necessary moisture during a particular vegetation period as well as increasing the microbiological activity in the root area will definitely decrease the stress effect from bad weather conditions and enhance the yield production capacity.

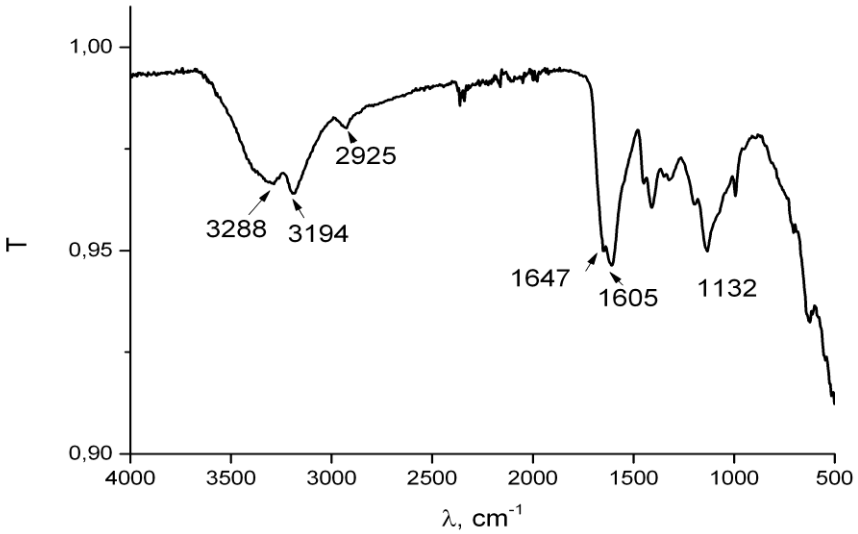
Materials and Methods

The polymer we used in our research, or the agent with qualities of super absorbing agent (SA), was synthesized in accord with traditonal methods (Bellamy et al., 1963). We added non-organic and organic matter to the reaction mass (concentration ratio 4:1) during the last stage of polymerization and as a result developed the modified polymers. IR spectra of the SA

samples were developed on the basis of Fourier transformer *Bruker Vertex 70*. In order to study the effect of the SA on potato production capacity, we launched a field experiment in 2017-2018 (Vernekhavsky District of the Voronezh Region, Russia, the site location data is 51.800372, 40.216045). The methods used were developed by B. Dospekhov (Dospekhov, 1985).
The research was based on the Dutch potato sort Picasso. It is a medium-late variety species (cooking type), with a high yield capacity. It was developed in the Netherlands by "Agrico" company, and later, in 1995, included into the Russian State Plant Registry.
The experiment had three variants: 1. Control – potato; 2. Control + SA 10 кg/ha; 3. Control + SA 20 кg/ha; 4. Control + SA 20 кg/ha + microorganisms;
The microbial agents used in the research are produced in Russia. The concentration used was 10 g/кg, which was added to the SA at the last stage of its development.
We used traditional methods (Khaziev., 1990) for estimation of the amount of ammonifying bactreia and microbiota participating in the decomposition of the non-nitrogenous compounds in the soil, and also the ferment activity of the soil. The soil in the experimental plots is qualified as typical black-earth with the average amount of organic matter of % - 6.16, $pH_{кс1}$ 5.9, the amount of labile soil nutrients (мg/кg) P_20_5 108, K_2O 163. The amount of nitrate nitrogen and nitrogen exchange ammonium in absolutely dry soil was 17.7 мg/кg and 4.59 мg/кg, respectively.

Results and discussions

The SA (i.e. the water-retaining agent used in the research) is based on the principle that at the stage of polymer synthesis the macro chain is joined by biodegradable links. It also seems highly effective to use a whole complex of products for processing vegetable and animal raw materials containing starch, pectin, chitosan and other polymeric materials. Such materials are widely available and biodegradable as they decompose into water, carbon dioxide and nitrogen derivatives.
FTIR spectra data were used to confirm the structure and composition of the obtained sorbents (picture 1).



Picture 1. FTIR spectrum of the original polymer

The FTIR spectrum of the polymer without added microelements and humic acids contain absorptions bands for values of 1647 и 1605 cm^1, corresponding to stretching modes of the

C=O-group (amide I) and NH_2-group (amide II) of amide parts (Bellamy et al., 1963). Broad absorption bands with the value of 3180-3300 cm^{-1} signal that there are OH и NH_2-groups of a biodegradable component (Kuznetsov et al., 2016, Kuznetsov et al., 2017). The FTIR spectra of the SA samples containing additives show the shift of typical absorption bands. It means there is an interaction and formation of associates by functional macromolecule groups of the polymer with its additives that are embedded in the polymerization mass. In this regard, the obtained SA can be used not only as «water reservoirs» but also as fertilizers, which are able to carry functional additives. In regard to the above-mentioned, bacteria *B. Subtilis sp* seem to be of interest with a view to developing a water-retaining agent with efficient functions:

1. They can function as antagonists for pathogenic and opportunistic pathogenic microorganisms due to their production of antibiotics and their ability to acidify soil;
2. They can produce ferments, which remove the rotten matter in fibre;
3. They synthesize a number of aminoacids, vitamins and biologically immune-activating factors;
4. The activity of *B. subtilis* in rhizosphere contributes to the plant resistance to the toxic effect of heavy metals.

At present, farmers are using an innovative microbiological agent called «Phytosporin M», which contains *B. Subtilis* 26 D. It is highly effective for fighting fungi- and bacteria-based diseases found in any crops (Selyavkin et al., 2015). *B. Subtilis, being aerobiotic sporogenic bacteria, are quite common in our environment. They have a unique ability to survive in plants in the highly competitive environment and act as antagonists to phyto pathogenic organisms. Due to this quality, such bacteria can be effectively used in biological plant protection.* It is especially important that they are able to carry endophytic mircoorganisms to the plant root area and thus not only to protect the plant from pathogenic factors but also to improve its physiology. During the experiment, we tested and compared the original soil samples and those enriched with the bacteria-based polymer (Popov, 2004).Phytotoxity of soils is the result of pollutants and toxic substances getting into soil and inhibiting the growth and development of higher plants. It is always necessary to identify the degree of phytotoxity when monitoring chemically contaminated soils or when assessing the possibility to use some wastes as fertilizers. It could be, for example, the sewage sediment, composte or hydrolyzed lignin.

The degree of soil toxity can be assessed through analyzing some plants development. It is a well-known fact that plant resistance to environmental stresses depends on its age, or rather a particular phase of development. In this regard, the highest degree of vulnerability is found in seeds during the germination phase. In this period plants are most susceptible to the environmental impact. Hence, plants at this stage are most convenient objects of ecological analysis and testing. It is necessary to analyze and assess different parametres during their germination and make conclusions.

The main parametres studied during biotesting plants for phyto toxity is germinating capacity and seed vigor. Testing is usually based on wild plants, which have a good germinating capacity and are locally growing. For example, to test soils in central Russia (sod-podzol type), they usually use peas and oats, for steppe and forest-steppe areas – wheat, beans and medick (lucerne). According to the National State Standard system, we can also use seeds of oil radish and oats. Soil contamination with heavy metals can be detected by using seeds of garden-cress pepperweed, which are quite sensitive to ions of heavy metals. Therefore, if the soil is contaminated, the seeds sprouting and germinating capacity become low. In addition, in this case the plant shoots and roots demonstrate vivid morphological changes, such as delayed growth and shoot distortion as well as the decrease in the length and weight of the roots.

In the next 3-4 days after the incubation of seeds, we counted the number of the shoots in the control group and experimental one, and then estimated the seeds germinating power (i.e. the percentage of sprouts within a given period) according to the following formula (1):

$$B = а/в \times 100\ (\%) \qquad (1)$$

where ***a*** is the number of the sprouts; ***в*** is the total number of the seeds under the experiment. The experiment can be extended for another several days to verify the obtained results. For this, it is necessary to provide lighting, estimate the germinating capacity of the seeds, measure the average length of the plant herb and roots, and the total weight of the plants in the control and experimental groups. To obtain the comparable results, testing data are used to estimate the toxity index of a particular evaluated factor: germinating power, germinating capacity, the length of the shoots and roots, the weight of the sprouts in each group. It is done according to the following formula (2):

TIF (toxity index of the factor) = TFo / TFk (2)

Where TFo – average value of a particular characteristic/factor in the experiment;
TFк – average value of the same characteristic in the control group. To estimate the toxity index of the soil, usually the following scale is used (Table 1).

Table 1. The scale of the soil toxity

Value of TIF	Toxity class
>1.10	VI (stimulation)
0.91 – 1.10	V - norm
0.71 – 0.90	IV – low toxity
0.50 – 0.70	III – average toxity
< 0.50	II – high toxity
Unsuitable habitat for the object	I – superhigh toxity causing death of the tested object

As a rule, the result can be considered to be true if an average length of the plant shoots and roots differs from that of the control group, and the difference is over 20%. If the difference is lower, it means the decrease in the plant growth and hence the possible high toxity degree of the plant. The lower the figures are, the more degraded the soil is and the less fertile it is. It eventually leads to the soil's inability for self-purification.
Table 2, as given below, shows the results of biotesting of the radish seeds. The data include values for the control soil and experimental sample enriched with the polymer.

Table 2. Biotesting of seeds

Results of biotesting							
Variant	Germinating power 3 days (%)	Weight of 100 sprouted seeds, grams	Toxity index of the factor (TIF)	Length of the shoot, cm	Toxity index of the factor (TIF)	Length of the root, cm	Toxity index of the factor (TIF)
1	100	10.6	-	3.6	-	5.7	-
2	100	3.9	-	0.4	-	0.6	-
4	100	4.3	1.1/0.4	0.7	1.75/0.19	1.4	2.3/0.25
5	100	11.9	3.05/1.1	4.4	11/1.2	5.3	8.8/0.92

1. control – water;
2. control – soil; 3. Initial/ original polymer . 4. The plymer enriched with microorganisms.

In Table 2 the values given with a slash (/) indicate the toxity index in relation to soil and distilled water.

The data in Table 2 show that all the TIF values for the soil control samples demonstrate a stimulating effect, and for the distilled water control sample the polymer affected the length of the shoots. Biological activity of soil has a number of indicators (Emtsev et al., 2006, Zvyagintsev, 1987). One of the signs of the soil fertility, for example, is the amount of microorganisms and, as a result, their effect on the mineralization of the organic matter in the soil. Also, one of the experiment objectives was the assessment of catalase activity, which shows the degree of soil biological capacity. The results demonstrate that the amount of catalase slightly varied across the board and reached its maximum by the end of harvesting, which was confirmed by some earlier data (Selyavkin et al., 2015). The variants enriched with the bacteria-based polymer showed the increase in ammonifying bacteria and those which use mineral forms of nitrogen. The data given below demonstrate some of biological characteristics of soil and figures for potato production in 2017- 2018.

Table 2. Characteristics of biological activity of soil and potato production in 2017-2018.

Variants	Phase pf potato growth												Yield tones/ha
	Sprouts				Blossoming				Top necrosis				
	beef peptone agar (BPA)	starch-and-ammonia agar (SAA)	BPA / SAA	Catalase	BPA	SAA	BPA / SAA	Catalase	BPA	SAA	BPA / SAA	Catalase	
1	9.1	10.9	1.2	1.5	7.3	5.1	0.7	3.3	7.0	8.4	1.2	3.3	7.2
2	11.0	14.3	1.3	1.7	11.4	21.6	1.9	3.6	14.0	16.8	1.2	3.6	11.8
3	22.0	30.8	1.4	1.8	26.0	49.4	1.9	3.6	15.0	19.5	1.3	3.8	12.2
													LSD 0.05= 0.64 tonnes/ha

Catalase - ml 0.1M $KMnO_4$ per1gr of soil within 20 minutes

During the phase of potato vine necrosis, the biggest amount of both groups of microorganisms was found in Variant 3. The soil there was enriched with the SA and Bacillus sp. It enhanced the biological soil activity and contributed to rehabilitation of the root area and plant protection capacity against phyto pathogens. As a result, the potato production was significantly improved (Popov, 2004).

The decrease in soil moisture capacity below 60-70 % from the minimal value can cause a negative impact on plant development. The maximum production of particular potato sorts in the Black-earth region of Russia largely depends of water: for example, 1 tonne of potatos needs up to 10 tonnes of water, which normally comes from underground water or rainfall. During the research period, the amount of moisture at the stage of planting the potato seeds and during the vegetation period reached about 2900 m^3 /ha. In our opinion, it was a limiting factor for potato production capacity. Despite favourable agrophysical conditions of black earth and the opportunity to control the moisture level in the soil, the process of water retention and its influence on the production capacity varied.

The field experiments in 2017 - 2018 were based on standard agrotechnology and involved the introduction of a fertilizer complex containing $N_{20}P_{11}K_{11}$ at the planting stage (250 кg/ha). The total amount of the rainfall during the vegetation period was about 70% of the long-term annual average, which allowed providing the effective moisture capacity and, as a result, obtain only 7.2 tonnes/ha of the potato in the control field. Apparently, it was because of limited moisture due to its high evaporation. After adding the bacteria-based SA in the near-seed area, the biological soil activity in the root area increased and gave boost to production capacity of the potato. The potato production figures for soil with the SA and the bacteria-based SA were 11.8 и 12.2 tonnes/ha, respectively.

Conclusions

The obtained results clearly demonstrate a positive effect of the ammonifying bacteria-based absorbent. At all stages of the potato development the amount of this type of bacteria (Variant 8) was 4 times as high as their amount in the control variant.

The structure of the polymers enriched with bacteria enables them to retain moisture effectively and therefore makes them functionally efficient. The experiment also showed that both the original, or innitial, polymer and the bacteria-based one do not have a toxic effect on plants and enhance its biometric characteristcs. The stimulating effect reaches values of 3 to 8.8 according to the toxity scale and positively affects the size of the formed roots and the total weight of sprouts. Biological soil activity varied across the board: for example, the catalase activity became 1.2 times as high in comparison with the control.

According to the results of the research, the SA dose of 20 кg/ha contributed to the potato production capacity increasing it 1.6 as high. The potato yield was over 1.7 times as high compared to the control variant, which is due to the difference in providing soil with moisture and its retaining as well as involving bacteria.

Abstract

Anethum graveolens L., commonly called dill, is frequently grown in herb, vegetable and flower gardens not only for harvest of its aromatic leaves and seeds, but also for ornamental display of its attractive foliage and flowers. It prefers well-drained sandy and medium loamy soils with pH in the range from 5.3 to 7.8 and highly acidic conditions could stunt its growth. Thus, a necessary lime should be applied. The aim of this study was to investigate the influence of an appliance of Ca - containing metallurgical slag from Steel factory from Smederevo, Republic of Serbia, on chemical composition of an aerial biomass of dill, through vegetative experiments performed in semi-controlled greenhouse conditions. The effects of metallurgical slag were compared to those of commercial lime material ($CaCO_3$) in combination without and with standard mineral and organic (NPK nutrient of animal origin) fertilizers. Lime material, along with metallurgical slag, particularly in combination with organic fertilizer, showed positive effects on elemental composition of dill and its yield. The contents of toxic heavy metals in herb comparing to non-fertilized treatment were not significantly increased and were within the permissible levels in plants in all the treatments in spite of their higher content in metallurgical slag. Based on the results obtained in present study, the studied metallurgical slag of the standardized chemical composition can be recommended for the wider practice toward improving the productivity of highly acid soils such as Stagnosol.

Keywords: *Metallurgical slag, Commercial lime material, Organic and mineral fertilizers, Stagnosol, Dill.*

Introduction

High soil acidity is a property of the majority of Serbian soils and application of only organic and mineral fertilizers is not enough to sustain their productivity. On these soils, along with regular fertilization, it is necessary to apply calcium containing fertilizers - calcifiers, for improving their biological and physico-chemical properties and obtaining higher yields (Pivić *et al.*, 2011).

The use of traditional commercial alkaline liming materials such as limestone, dolomite and burnt lime to acid soils for the amelioration of acidity consequently improving crop production is a common practice (Huang *et al.*, 2012). Along with these materials present in Serbia and regarding its alkaline nature, metallurgical slag from the steel factory, located in Smederevo, Serbia, can be of great importance.

Crops vary greatly in their soil affinity and ability to tolerate low pH. Dill (*Anethum graveolens L.)* is a commonly cultivated herb which grows mainly for its edible leaves and seeds, though it is also used medicinally. It requires moderately rich loose, well-drained, sandy and medium loamy soils. In general, it is an easily grown plant, although it belongs to those herbs that tolerate a soil pH in the range 5.3 to 7.8 and extremely acidic conditions could stunt its growth (Dressendorfer, 2010). Thus, a necessary lime should be applied.

Although the significant quantities of metallurgical slag are generated as waste material every day from steel industries, its physicochemical property offers a high potential for its utilization in agriculture. As metallurgical slag contains fertilizer components such as CaO, SiO_2 and MgO, its alkaline property remedies soil acidity. The liming materials in metallurgical slag comprise water-soluble and less water-soluble Ca and Mg compounds. Free Ca in slag reacts rapidly with water to form $Ca(OH)_2$. The $Ca(OH)_2$ will react rapidly with soil acidity (NSA, 2011). In addition to these three components, it also contains components such as FeO, MnO and P_2O_5, so it has been used for a broad range of agricultural purposes. Certain authors reported on field trials in Pennsylvania that crop yields of corn, wheat, oats, buckwheat and soybeans with metallurgical slag application were as good or better than an equivalent amount of limestone (White *et al.*, 1937). In developed countries such as Germany, USA, France and Japan, converter slag is used to produce siliceous and phosphorus fertilizer, as well as micronutrient fertilizer (Huang *et al.*, 2012).

Some slags may contain elevated concentrations of trace metals such as Fe, Cd, Cr, Cu, Pb, Mo, Ni and Zn. They occur naturally in soil and some of them are essential plant nutrients. If concentrations in the slag are similar to soil concentrations, they present no problem. If they are present at substantially higher concentrations in the slag than in the soil, repeated application of the slag could significantly increase soil metal concentrations, leading to plant toxicity. Nevertheless, the bioavailability of these metals in slags is very low (NSA, 2001).

The aim of this research was to investigate the effect of Ca-containing metallurgical slag, a by-product from steel factory, on yield and chemical composition of the aerial parts of dill (*Anethum graveolens L.)*. The effects of metallurgical slag were compared to those of other lime material (calcite, $CaCO_3$) in combination with and without standard mineral and organic (NPK nutrient of animal origin) fertilizers.

Material and Methods

The study was carried out under semi-controlled condition in the greenhouse of the Institute of Soil Science, Belgrade (Serbia), in experimental cassettes of diameter 1.0x1.0x0.5 m, from the fourth decade of March to the fourth decade of June, during 2017. The trial was undertaken with Stagnosol (WRB, 2014), a type of soil from Western Serbia region, generally characterized by very acid reaction and poor physical and biological properties (Pivić *et al.*, 2011). Each cassette was filled with 650 kg of the studied soil, brought from an experimental field of Institute of Soil Science - Varna, near Šabac town. In the experiments the comparison of the effect of metallurgical slag (MS) with other lime materials (calcite, $CaCO_3$, containing 60% of carbonate) in combination with and without mineral NPK [composite NPK (15:15:15)] and commercial organic (solid NPK 4:3:4 nutrient of animal origin - Nervosol Complex, NC) fertilizers were studied.

The following seven designed treatments were carried out in three replications: control (untreated soil) - T1; $CaCO_3$ - T2; NPK mineral fertilizer + $CaCO_3$ - T3; NC + $CaCO_3$ - T4; MS - T5; NPK mineral fertilizer + MS - T6; NC fertilizer + MS - T7.

Before sewing the dill, the amount of fertilizers, lime and slag was measured according to the experimental design and mixed with soil (calculated as for 1 ha): NPK fertilizer (15:15:15) = 500 kg ha^{-1}; NC fertilizer = 170 kg ha^{-1}; $CaCO_3$ = 4 t ha^{-1}; $Ca(OH)_2$ = 2,8 t ha^{-1}; MS = 4 t ha^{-1} (same as the amount of $CaCO_3$, in spite of lower amount of slag). Both MS and calcite with granulation of 0.2 mm were used in the experiment.

Chemical composition of MS applied (Table 1) was determined in our previous study (Pivić *et al.*, 2011). Accordingly, this material has very alkaline reaction, with the content of calcium in oxide forms (CaO) from 33-45%, of which about 50% is easily soluble in 1 M ammonium acetate; content of the total magnesium was mainly in forms of MgO, while nearly all the amount of phosphorus(P) is in available forms for plants; contents of the total iron (Fe) and manganese (Mn) are high, but with lower amounts of their soluble forms; zinc (Zn) is contained in lower amounts, while the content of copper (Cu) is a little higher.

Table 1. Chemical composition of MS (Pivić *et al.*, 2011).

Parameter	Average value	Parameter	Average value
pH in H_2O	12.48	Total P_2O_5 (%)	0.61
Total Ca (%)	26.20	Total Fe (%)	15.34
Total CaO (%)	36.60	Available Fe (mg kg^{-1})	3.38
Total $CaCO_3$ (%)	65.80	Total Mn (%)	1.80
Available Ca (%)	17.18	Available Mn (mg kg^{-1})	3.12
Total Mg (%)	0.41	Total Zn (%)	14.60
Available Mg (%)	0.70	Total Cu (%)	228.8

Organic fertilizer used is a solid NPK 4:3:4 nutrient of animal origin, commercially called Nervosol Complex. According to its main chemical composition, it consists of 4% of total nitrogen (N), 4% of organic N, 3% of phosphorus in the form of P_2O_5, 4% of potassium in the form of K_2O, and 30% of organic carbon (C) (Đurić et al., 2015).

The soil samples for analysis were air-dried, crushed, passed through a sieve (≤ 2 mm) and crushed into dust by hand. The preliminary observation of the soil studied included the analysis of the following chemical parameters: soil acidity (pH in 1M KCl) was analyzed potentiometrically with glass electrode (SRPS ISO 10390:2007, 2007); total nitrogen (N) was analyzed on elemental CNS analyzer Vario EL III (SRPS ISO 13878:2005, 2005); available phosphorus (P_2O_5) and potassium (K_2O) were analyzed by Al-method (Đurđević, 2014); the total contents of investigated trace biogenic elements - iron (Fe), zinc (Zn) and copper (Cu), as well as cadmium (Cd) as the toxic heavy metal, in soil samples were determined by inductively coupled plasma-atomic emission spectrometry (ICP-AES) after the digestion of the samples with aqua regia (ISO 11466:1995, 1995; ISO 22036:2008, 2008).

The aerial parts of dill plants were taken and after drying at 105^{o}C the plant biomass was weighed. For all the plant samples from all the treatments the chemical composition of the aerial parts was analyzed. The content of N was determined on elemental CNS analyzer Vario EL III (Nelson and Sommers, 1996). Phosphorus (P) was determined by spectrophotometer with molybdate (Đurđević, 2014a), and potassium (K) - by flame emission photometry (Đurđević, 2014b). In the determination of investigated trace biogenic elements - Fe, Zn and Cu, as well as cadmium (Cd) as the toxic heavy metal, atomic absorption spectrometry - AAS was used (Wright and Stuczynski, 1996).

The obtained data on soil properties represent the arithmetic means of three replicates and standard deviation values. The effects of T1-T7 treatments on the studied chemical parameters and yield of the plants were evaluated using the analysis of variance (SPSS 20.0, Chicago, USA), followed by Duncan's Multiple Range Test (DMRT). Significant differences between means were tested by the LSD test at P = 0.05.

Results and Discussion

In Table 2 the data on main chemical characteristics of plowed layer of the studied Stagnosol are displayed. The soil is characterized by very acid soil reaction, low content of available P, then, it is well supplied with available K, medium provided with total N, Cu and Zn, and very highly provided with Fe (Table 2). Content of toxic metal Cd was low and far from the maximum limiting value of 0.8 mg kg^{-1} (OGRS, 2018).

Table 2. Chemical properties of the studied soil (mean ± standard deviation value*)

Property	Value*	Property	Value*
pH in 1M KCl	4.12±0.14	Total Fe (mg kg^{-1})	133.5±1.05
Total N (%)	0.12±0.02	Total Zn (mg kg^{-1})	0.61±0.03
Available P_2O_5 (mg 100g $^{-1}$)	9.42±1.39	Total Cu (mg kg^{-1})	1.68±0.04
Available K_2O (mg $100g^{-1}$)	17.00±2.58	Total Cd (mg kg^{-1})	0.08±0.00

Certain types of soil, including stagnosols, require the periodic application of soil conditioners such as commercial liming materials to provide aeration, increase moisture retention, and promote root permeation and growth. In several experiments in European countries it was determined the ability of metallurgical slag to raise the pH of acid soils (Rodriguez *et al.*, 1994; NSA, 2011).

The optimum pH range in soil for growth of most crops in soil is between 5.5 and 7.0, within which most plant nutritives are available (Prasad and Power, 1997). Data on the content of macroelements in dill aerial parts (Table 3) show the statistically significant differences (*P* *) between the treatments at P<0.05 for P and K, and no significant difference (NSD) for N. Nevertheless, there is a noticeably tendency of an increase in the content of N, P and K in tested plant material in the treatments that included NC fertilizer and NPK mineral fertilizer, respectively, in combination with MS (T6 and T7), in relation to other treatments. Improved organic and mineral nutrition in combination with MS would explain the promotion of dill biomass growth which led to the promotion of its yield. The data on yield of dill were in accordance with chemical ones, meaning that the yield was highly significantly higher (*P* ***) at P<0.05 in treatments T6 and T7 (Table 3).

Table 3. Macroelements content in dill and its yield depending on the treatment used

Treatments	Macroelements (mg kg^{-1} of dry biomass*)			Biomass yield (kg per cassette*)
	N	P	K	
T1 - control (untreated soil)	2.84±0.08[ab]	0.29±0.02[cd]	2.90±0.51[c]	3.08±0.10[b]

P value	NSD	*	*	***
LSD (0.05)	0.446	0.108	0.547	0.227

*means ± standard deviation; LSD - least significant difference; NSD - no significant difference at P=0.05; *, **, *** - statistical significant differences at P<0.05, P<0.01 and P<0.001, respectively; values followed by the same letter in a column are not significantly different at P<0.05.

The nature of applied treatments and their combinations have an impact on trace elements accumulation, their mobility and storing capacity in plant tissues (Riesen and Feller, 2005). Some of them may pose a toxicity threat if present at elevated levels as their availability and mobility increases under acidic conditions (Pawlowski, 1997). The concentration of trace elements in dill aerial parts shows that there are statistically highly significant differences (*P* ***) between different treatments at P<0.05 for Zn and Cu, and no significant differences (NSD) for Fe and Cd (Table 5). It should be noted that there was not found higher accumulation of Fe in tested plants in the treatments where metallurgical slag was applied in spite of its significant content in this raw material. According to the reference values of Kloke *et al.* (1984), the content of Cd was within the safety limits and permissible levels in all the treatments, which is a highly desirable outcome (Table 4).

Table 4. Effect of applied treatments on the content of trace elements in dill biomass

Treatments	Trace elements (% of dry biomass)			
	Fe	Zn	Cu	Cd

Conclusions

The results of the paper indicate that the treatments with combination of metallurgical slag and organic and mineral fertilizer, respectively, showed positive effects on the content of main and beneficial biogenic macroelements in aerial biomass of dill, particularly in relation to control. Improved organic and mineral nutrition in combination with metallurgical slag would explain the promotion of dill biomass growth which led to the promotion of its yield, as the data on yield of dill were in accordance with chemical ones. The contents of trace elements in herb, including toxic Cd, comparing to non-fertilized treatment were not significantly increased and were within the permissible levels in plants in all the treatments in spite of their higher content in metallurgical slag. Generally, the studied metallurgical slag of the standardized chemical composition can be recommended for the wider practice toward improving the productivity of highly acid soils such as Stagnosol.

Abstract

The aim of the present study is to assess the possibilities for an alternative weed control in soybeans by using cover crops with proven allelopathic potential as oats and rye. The study was conducted in the period 2015-2017 on the Experimental Field of the Soybean Experimental Station in Pavlikeni (Bulgaria). Weed communities in the studied soybean agrophytocenosis ranged between 5 to 8 species and practically does not change under the influence of meteorological factors. Weeding was of a mixed type with a prevalence of one-year late spring weeds (58% - 92%), which were also identified as dominant weed species. The values of the diversity indices and distribution uniformity of the weed species are negligibly influenced by the dynamics of the weather conditions. It was found that under the specific conditions of the experiment, the survival capacity of the soybean plants to the technical maturation phase was in the range of 0.76 to 0.96. The ability to self-restore of soybean was relatively good (from 1.16 to 5.09) and a slight increase in the soybean population (from 0.15 to 1.63) was observed. The use of oats as an allelopathic active cover crop in soybean reduces the weed infestation rate from 33.6% to 67%, as well as the amount of fresh and dry biomass accumulated in the late spring weed group by 12% to 68%. The capping ability is the result of limiting the density of some annual weeds (*Amaranthus* spp., *Abutilion theophrasti* Medik., *Chenopodium album* L.), although compensatory processes in the population density of other weed species. The use of rye as an allelopathic active cover crop in soybean reduces the weed infestation from 49% to 63% with the increasing of the rye sowing rate when compared to the control ($p<0.05$).

Keywords: *soybean, oats, rye, allelopathy, weeds*

Introduction

Weed management takes an important place in soybean cultivation, where herbicides represent the biggest part of the applied pesticides. In last decades, the chemical method for weed control is a main element into the management strategies for weed density regulation due to its rapid action and easy application (Georgiev *et al.*, 2008; Koger *et al*., 2002). Significant problems are a rich variety of weed species, high biological and ecological plasticity, resistance to herbicides, leading to their fast expansion (Nakova, 2003; Heap, 2007). Some significant changes in the weed associations under the influence of many factors revealed to the search for new alternative methods and resources for weed control which are non-destructive to the environment (Hwu *et al*., 1999; Duke *et al*., 2000; Fujinaria and Yoshida, 2000). Many scientific publications recommend the development of non-chemical approaches for weed management, including allelopathic active cover crops or intercropping. Main findings are related to the significant weed-suppressing ability of *Hordeum spp., Avena spp., Secale spp*. and their use as an effective method for biocontrol against weeds in many important forage crops, and also to the economic benefits of such usage (Stancheva, 2000; Bhowmik and Inderjit, 2003; Dimitrova, 2008). Insufficient and extremely limited are studies on the effect of allelopathic and / or cover crops on the growth and reproductive forms of various grain legumes, including soybean (Camal-Maldonado *et al*., 2001; Vasilev and Kertikov, 2003; Adler and Chase, 2007). Aim of the present study is to assess the possibilities for alternative weed control in soybean (*Glycine max* (L.) Merill) by using cover crops with proven allelopathic potential as oats (*Avena sativa* L.) and rye (*Secale cereale* L.).

Material and Methods

The study was conducted in the period 2015-2017 on the Experimental Field of the Soybean Experimental Station in Pavlikeni (Bulgaria). Each experimental variant was set in four replications with an area of the harvested plot of 5 m^2, respectively. Object of research was soybean (*Glycine max* (L.) Merill), Srebrina variety) and the sowing was mechanized at a seed density of 280 000-300 000 germinating seeds/hectare and a distance of 70 cm between rows (Georgiev *et al*., 2008). Evaluation of natural background of weed infestation was based on the dynamics of weed density in the soybean agrophytocenosis. The level of weeding and the species composition of weeds have been quantified at the end of the vegetation of the crop and were presented in number individuals on m^2. The values of the diversity indices (H) and distribution uniformity (J) of the weed species were calculated on the basis of the experimental data following the method of Begon *et al*. (1986). Aggregation and intra-population distribution of weed species ($S\sqrt{x}$) was assessed according to Odum (1975). The degree of aggregation of weeds was determined by comparing the groups of different sizes with the theoretical distribution of Poisson, which shows the frequency of groups of different sizes for each unit of investigation (Sendecor, 1961).

Assessment of the survival capacity of the soybean plants under the natural background of weed infestation have been made at the end of each vegetation period. Structural elements of yield (number of beans per plant; number of seeds per plant; mass of seed per one plant) were determined according to the methodology of Stoimenova (1990). The ability to self-restore of soybean agrophytocenosis under the natural background of weed infestation was evaluated using the methodology of Begon *et al*. (1986). Assessment of the possibilities for alternative weed control in soybean using oats (*Avena sativa* L.) and rye (*Secale cereale* L.) as an allelopathic active cover crop was made in mixed soybean-oats and soybean-rye agrophytocenosis, respectively. Sowing of the cover crop was made in parallel with sowing of the soybean, but in perpendicular direction and a distance of 10 cm between rows. Three experimental sowing rates of oats/rye were applied – 12.5%, 25% and 50% of the standard sowing rate (180 kg/ha). Weed composition, weed density and other indices in mixed agrophytocenosis were determined as described above. For the determination of the relative index of competition (RCI) between weed and soybean plants, the formula of Goldberg *et al*. (1999) was used. Raw experimental data of the study were processed (descriptive statistics, t-test, $p<0,05$) by the statistical package Statistica 7.0 (StatSoft Inc., 2004).

Results and Discussion

Evaluation of natural background of weed infestation

Identification of the main patterns in weed associations dynamics in soybean was a key element of the theoretical basis for the development of integrated weed control systems defined by the specific conditions. The level of total weed infestation varied considerably over the years - from 62 to 486 individuals per m^2, depending on the quantity and distribution of rainfall during the growing season. In years with relatively unfavourable conditions, total weed infestation was in the diapason 62 to 363 individuals per m^2, and in years with higher precipitation the weed density ranges from 249 to 486 individuals per m^2 (Table 1). The increase in total weed infestation of soybean plots was mainly due to the increased density of *Sorghum halepense* (L.) Pers. (number of stems per unit area) and was not so expressed to the annual and dicotyledonous weed species (*Amaranthus retroflexus* L., *Chenopodium album* L., *Setaria* spp.). The species composition of weed communities (S) varies in relatively narrow ranges of 5 to 8 weed species and practically does not change under the influence of meteorological factors. The weed diversity index (H) in the studied agrophytocenosis also varied in relatively narrow ranges and was independent of the amount and distribution of rainfall during the study period with an average value of 0.920, assuming values in the range of 0.835 to 1.035. Weeding was of a mixed type with a prevalence of one-year late spring weeds (58% - 92%), which were also identified as dominant weed species. The values of distribution uniformity (J) of the weed species was negligibly influenced by the dynamics of the weather conditions with an average of 0.508, ranging in the diapason from 0.428 to 0.578. Dominant weed species (over 15%) in the studied soybean agrophytocenosis were *Solanum nigrum*, *A. retroflexus* and *S. halepense*, while subdominant weed species (from 5% to 15%) was *Setharia* spp. We found that was the degree of weed aggregation ($S\sqrt{x}$) was in accordance with the quantitative ratio (P_i) of weed species. Dominant (over 15%) and subdominant (5-15%) weed species, forming the main infestation in the studied agrophytocenosis, have group distribution ($S\sqrt{x}$<1), while the secondary (0.1% to 5%) and the tertiary (0.1%) weed species were evenly distributed (($S\sqrt{x}$>1) during the whole period of our study ($p<0.05$). Analysis of the results obtained showed that species composition (S), diversity index (H) and distribution uniformity (J) in weed communities changed negligible during the three-year study period, despite the dynamics of meteorological factors. This fact could be very useful in practice as allow the weeds to be experimentally determined in a shorter period of time and more efficient weed control systems to be developed and applied.

Assessment of the survival capacity of the soybean plants and the ability to self-restore of soybean agrophytocenosis under the natural background of weed infestation

Many authors have shown that the comparatively low competitiveness of soybean against weeds was predetermined by the slow growth in the first stages of its development (Lyubenov, 1988; Stoimenova, 1989). Studies by Stoimenova (1987), Alexieva and

Stoimenova, (2004) and Bensch *et al.* (2003) have shown that when the soybean stand was infested with *A. retroflexus* and other late-spring weed species by the end of crop growth, than the structural elements of the soybean yield were decreased by 29.3% to 73.2%.
It was found that under the specific conditions of the experiment, the survival capacity (l_x) of the soybean plants to the technical maturation phase was in the range of 0.86 to 0.96 in the years with favourable meteorological conditions, decreasing to 0.76 in the years with unfavorable ones. The intensity of soybean dying (K_x) ranged from 0.02 to 0.14, with dependence on both the degree of weed infestation and the agrometeorological conditions. In the years with rainfall, it took values from 0.02 to 0.14, and in the case of drought - 0.12. The higher intensity of soybean dying in the more favorable year (2015) may be explained by the higher degree of weed infestation of the crop combined with an increase in weed density in the studied agrophytocenosis. In the studied period, the degree of weed infestation in soybean stands from phenophase sprouting to phenophase technical maturity had a negative impact on the structural elements of soybean yield, with statistical reliability at $p <0.05$ for all tested parameters. The correlations between yield and precipitation ($r = 0.758$-0.998) and between yield and weed density ($r = 0.836$-0.999) were very high ($p<0.05$). The ability to self-restore of soybean was relatively good (from 1.16 to 5.09) and a slight increase in the soybean population (from 0.15 to 1.63) was observed. Regardless of the relatively high reproduction rates (R) of soybean plants grown under the natural background of weed infestation, a significant reduction of the structural elements of the yield was found as follows: number of beans per plant - 78.7%; number of seeds per plant - 83.3%; mass of seed per one plant - 67.3% ($p <0.05$). So, it could be concluded that weeding and agrometeorological conditions were the most significant limiting factors for the development of the soybean crop, as well as the most important factors for the quantity of the yield.

Assessment of the possibilities for alternative weed control in soybean using oats as an allelopathic active cover crop

The use of oats as a cover crop affected the dynamics and extent of weed infestation in the studied soybean agrophytocenosis. From the soybean germination to phenophase R2, the weed suppressing effect of oats was in the range of 33.6% to 38.4%, disproportionate to its increased sowing rate, at a relative competition index (RCI) of 0.62 to 0.66 (Table 2). By prolonging the vegetation period to phenophase R4, the weed suppressing effect of oats increased significantly and ranged from 64.7% to 67.0% while the RCI was in the range of 0.33 to 0.35 ($p<0.05$). An exception was found in the soybean phenophase R8 at the lower sowing ratios of oats (12.5% and 25%) where the differences reliably exceed the same compared to the control variant ($p = 0.05$). Reducing the degree of weed infestation was found to be a result of the elimination of *S. halepense* (L.) Pers., *Echinochloa crus-galli* (L.) Beauv., *Setaria spp*. and the inhibition of late-spring weeds density (*Amaranthus spp., Abutilon theophrasti* Medik*., Ch. album* L.), although some compensatory processes at the population's density of *Convolvulus arvensis* L. have been established. The species composition (S) of weed communities in the mixed soybean-oats agrophytocenosis varied from 4 to 8, while the weed diversity index (H) varied from 8.4 to -21.2 with a distribution uniformity (J) of -4.2 to -10.2. The experimental data obtained were consistent with the published results of Stancheva (2000) and Dimitrova and Serafimov (2007a, b), according to which the compaction of crops is an agro-technical approach to biological control of weeds. The weed suppressing capacity of the cover crops is due to their phytotoxic compounds that act inhibitory on the growth of weeds (Fujinaria *et al*., 2000; Dimitrova and Serafimov, 2009).

Assessment of the possibilities for alternative weed control in soybean using rye as an allelopathic active cover crop

The analysis of the experimental results from 2015 (high amount of rainfall) showed that in the period from sprouting to phenophase R2 the level of the weed infestation in mixed soybean-rye stand significantly decreased from 49% to 63% with the increasing of the rye sowing rate when compared to the control ($p<0.05$). By prolonging the vegetation period to the phenophase R4 and phenophase R8 of soybean, the weed suppression capacity of rye was maintained and the relative index of competition (RCI) was in the range of 0.21 to 0.78 ($p<0.05$). An exception was found in the soybean phenophase R8 at the lowest rye sowing rate where the weed density of experimental mixed stand statistically exceeds that of the control variant and the RCI has a negative value of -0.04 (Table 3).

Weed suppressing capacity of the rye in 2016 at the sum of the rainfall close to the mean annual value (I = 20.9) was strongest to the phenophase R2 ($p<0.05$). By prolonging the vegetation period to the phenophase R4, the allelopathic inhibitory effect of the rye has decreased and the differences were significant only at the higher sowing rates of rye (25% and 50%) at a relative index of competition (RCI) of 0.16 to 0.26 ($p<0.05$). In phenophase R8 of soybean the weed infestation level of mixed soybean-rye agrophytocenosis significantly exceeded that of the control variant ($p<0.05$) and the RCI had a negative value ranging from -0.34 to -0.48 with the exception of the highest rye sowing rate of 50%, where RCI = 0.29.

Reducing the degree of weed infestation during the early stages of the development and formation of mixed soybean-rye agrophytocenosis could be explained by the presence of some residual amounts of the glycoalkaloid 2,4-dihydroxy-1,4(H)-benzoazin-3-one (DIOBA) separated from the roots of the rye and/or the presence of 2,3(H) –benzoxazinilone, derived from DIOBA degradation. Many authors have shown that these glycoalkaloids act as strong inhibitors of the germination and initial development of some mono- and dicotyledonous weed species (Yenish *et al*., 1995, Creamer *et al*., 1996, Weston, 1996; Reddy, 2001).

Conclusions

Use of oats as an allelopathic active cover crop in soybean reduces the weed infestation rate from 33.6% to 67%, as well as the amount of fresh and dry biomass accumulated in the late spring weed group by 12% to 68%. Capping ability is the result of limiting the density of some annual weeds (*Amaranthus* spp., *Abutilion theophrasti*, *Chenopodium album*), although compensatory processes in the population density of other weed species. The use of rye as an allelopathic active cover crop in soybean reduces the weed infestation from 49% to 63% with the increasing of the rye sowing rate when compared to the control ($p<0.05$).

Abstract

Aim of this study was to evaluate the allelopathic effect of five invasive weeds (*Sorghum halepense* L. Pers., *Sonchus arvensis* L., *Cirsium arvense* L. Scop., *Xanthium strumarium* L.and *Aristolochia clematitis* L.) in forage crops on two *Sorghum* crops (*Sorghum sudanense* (Piper) Stapf and *Sorghum vulgare* var. *technicum* (Körn.)). An ex-situ experiment was carried out as follows: 10 seeds of each test variety were placed in Petri dishes between filter paper and the dried weed biomass extract was added at concentrations of 0.1, 0.2, 0.4, 0.8, 1.6 and 3.2% w/v. Petri dishes were placed in a thermostat-operated device at a temperature of 22 ± 2°C for a seven-days period. Distilled water was used as a control. Number of germinated seeds, % of seed germination against the control, and weed inhibition rate (IR) were measured. Our study revealed that the alellopathic effect of the tested five invasive weeds on seed germination of *S. sudanense* and *S. vulgare* var. *technicum* varied according to the plant species (both weed and cultural) and the concentration applied. Most pronounced negative effect on the germination process of *S. sudanense* seeds have expressed the cold aqueous extracts from *Sonchus arvensis* L. and *Cirsium arvense* (L.) Scop. – IR varied from 4.67-5.0% up to 70.3% at the highest test concentrations ($p<0.05$). Maximal inhibition of seed germination of *S. vulgare* var. *technicum* in comparison with the control was found at 3.2% w/v extract of *Sorghum halepense* (L.) Pers. (IR=58.4%), followed by the two highest concentrations of *Xanthium strumarium* L. extract (IR=41.6-45.9%).

Keywords: *interaction, allelopathy, seed germination, inhibition rate*

Introduction

Sorghum, originated in East Africa, is one of the first crops, which was taken into cultivation (House, 1985). At present, *Sorghum sudanense* hybrids are preferred as a fodder due to higher yields and tillering ratios and also their thin stems and higher leaf ratios (Uzun *et al.*, 2009). *Sorghum vulgare* var. *technicum* is mainly utilized for producing brooms, washing brushes, knittings, paper, wallboard, fences, biodegradable materials for packaging due to their peculiar resistance (Popescu and Condei, 2014). Sorghum cultivar plants are more tolerance to drought and high temperatures, diseases, pests, various soil types and show higher water use efficiency and, higher production capacity per unit area (Undersander and Lane, 2003; Uzun and Cigdem, 2005). Main disadvantage of Sorghum crops is their high sensitivity against weed infestation in the first 30-40 days after sowing (Marinov-Serafimov and Golubinova, 2015). Drastic effects of weeds on germination and growth on *Sorghum* and other crops are due to their competiveness with cultivated crops for resources and allelopathic potentials. Through allelopathy, weeds may cause significant effects on the growth and germination capacity of other crops. Weeds may possess diverse allelochemicals, which can interfere with other plants in a number of ways by either retarding or enhancing the germination and growth of receiving plants (Oerke, 2006; Marinov-Serafimov and Golubinova, 2015).

The summarized results of the experimental work of Cheema *et al*. (2002; 2008), Alsaadawi and Dayan (2009), Jesudas e*t al*. (2014), Głąb *et al*. (2017), Jabran (2017) show that the skrining to determine the allelopathic effect of species of the genus Sorghum on germination and initial development of a number of weed species has been well performed. Allelopathic interference in the system "weed - Sorghum crop" has been poorly studied (Shahrokhi *et al*., 2011; Asghar *et al*., 2013; Dafaallah and El-Twom, 2017), necessitating the establishment of allelopathic tolerance of Sorghum crops towards invasive weed species.
Aim of this study was to evaluate the allelopathic effect of five invasive annual and perennial dicotyledonous weed on germination and initial development at *Sorghum sudanense* (Piper) Stapf and *Sorghum vulgare* var. *technicum* (Körn.) in order to determine species sensitivity which could serve as a means of increasing efficiency in the early stages of the selection process.

Material and Methods

Collection of weed material and preparation of cold aqueous extracts

Aboveground biomass from five invasive weed species (*Sorghum halepense* (L.) Pers., *Sonchus arvensis* L., *Cirsium arvense* (L.) Scop., *Xanthium strumarium* L., *Aristolochia clematitis* L.) in forage crops was collected in a natural environment of weed infestation in the Institute of Forage Crops, Pleven at BBCH 51-55 (Hess *et al*., 1997). No separated aboveground biomass of available weed species was chopped together to the length of 0.5-3.0 cm, drying to a constant dry weight at 50 ± 5°C and was grind in a grinder Retsch SM – 1 at a sieve size of 1.0 mm. Cold aqueous extracts of dry weed aboveground biomass were prepared as follows: 100 g of dry weed biomass were soaked in 1 l distilled water and leaved at a temperature of 24 ± 20C for 24 h in a shuttle apparatus at 240/60 c^{-1}. After that they were decanted, filtered through filter paper and centrifuged in K24 centrifuge at 5000/60 s^{-1}. From these stock solutions were prepared test extracts of each weed plant with concentrations of 0.1%, 0.2%, 0.4%, 0.8%, 1.6% and 3.2% w/v, respectively. The experimental data were evaluated using analysis of variance with means separation based on Fisher's least significant difference test at $p<0.05$ with the software Statgraphics Plus for Windows Ver. 2.1 and Statistica Ver. 10.

Experimental design
