Ex-situ experiment was carried out as follows: 10 seeds of *S. sudanense* (300/43 mutant form) or *S. vulgare* var. *technicum* (local population), respectively, were placed into Petri dishes between paper and 10 ml weed test extract and one of the above mentioned concentrations were added. Seeds of the tested *Sorghum* genotypes were provided from the Selection Collection of the Institute of Forage Crops in Pleven, Bulgaria. Distilled water was used as a control. Each treatment consisted of three replicates including the control treatment. Samples were placed in a thermostat-operated device at 22 ± 2°C for 7 days and the number of germinated seeds, % of seed germination against the control, and weed inhibition rate, were measured. Percentage of seed germination was calculated after preliminary arcsin-transformation following the formula $Y=\arcsin\sqrt{(x\%/100)}$, forwarded by Hinkelman and Kempthorne (1994), and to induce half-maximal inhibition of growth (LC50) and P=0.05 confidence intervals were calculated according to Hamilton *et al.* (1977). Inhibition rate (IR) of tested weeds was calculated by the formula of Ahn and Chung (2000): $IR= 100 \times (n_{control} – n_{experiment})/n_{control}$, where n is the number of the germinated seeds. All collected data were analyzed using the software Statgraphics Plus for Windows Ver. 2.1 and Statistica Ver. 10.

Results and Discussion

Seed germination and seedling development are increasingly used in various bioassays as they allow the biological activity of various substances (herbicides, metabolites, allelochemicals

and even radionuclides) to be established with high reliability and low cost (Piotrowicz-Cieślak *et al.*, 2010). Our study revealed that the alellopathic effect of the tested five invasive weeds on seed germination of *S. sudanense* and *S. vulgare* var. *technicum* varied according to the plant species (both weed and cultural) and the concentration applied (Table 1).
When regarding the experiments with seeds of *S. sudanense*, it was obvious that the most pronounced negative effect on the germination process expressed the cold aqueous extracts from *Sonchus arvensis* L. and *Cirsium arvense* (L.) Scop. – IR varied from 4.67-5.0% up to 70.3% at the highest test concentrations ($p<0.05$). Lowest inhibition was found under the extract from *Xanthium strumarium* L., where the % germination against the control was in the range between 63.0% - 92.56% and the IR had values from 7.4% to 37.0%. The extracts of the other two weed species - *Sorghum halepense* (L.) Pers. and *Aristolochia clematitis* L., also have medium expressed negative effect on the seed germination of *S. sudanense*, with the maximal values of IR=44.4% at 1.6% w/v concentration (Table 1).

Table 1. Allelopathic effect of five studied weed species on the seed germination of *S. sudanense* and *S. vulgare* var. *technicum*

Weed species	Concentration (w/v)	*Sorghum sudanense* (Piper) Stapf		*Sorghum vulgare* var. *technicum* Körn.

Means followed by the same letter within column are not significantly different at ($p<0.05$)					

Considering the results with seeds of *S. vulgare* var. *technicum,* it was obvious that the negative effect on the germination process as a whole was not so strong in comparison with the *S. sudanense* seeds ($p<0.05$). Maximal inhibition of seed germination in comparison with the control was found at 3.2% extract of *Sorghum halepense* (L.) Pers., followed by the two highest concentrations of *Xanthium strumarium* L. extract. Least pronounced was the negative effect of the extract from *Aristolochia clematitis* L., where in all studied concentrations the germination was close to 80% and above. The extract of *Cirsium arvense* (L.) Scop. had the IR values in the range from 12.5% up to 41.6% and was quite similar to the extract of *Xanthium strumarium* L. with IR values in the range 12.5% - 45.9%. only in the experiment with *Sonchus arvensis* L. extract we could not observe some significant dynamics of the inhibitory effect related to the concentration variations. Germination % against the control varied from 62.50% to 87.50% and the IR was close to 37.5% in almost all cases (Table 1).

Seed germination is a critical phase of plant development (Ernst, 1998). This process begins with the uptake of water from the dry seed and its swelling and ends with the germination of the germ root through all the seed coatings (Bewley, 1997). Germination inhibition is one of the most studied effects of toxic exposure to heavy metals (Ernst, 1998; Sfaxi-Bousbih *et al.*, 2010), herbicides and biologically active substances, including allelochemicals (Kalinova *et al.*, 2012; Marinov-Serafimov *et al.,* 2017).

On the basis of their inhibition rate on the *S. sudanense* seed germination the five tested weed species could be ranked as follows:

1 group – IR<29.99%: *Xanthium strumarium* L. (IR average=21.59%), *Sorghum halepense* (L.) Pers. (IR average=22.24%) and *Aristolochia clematitis* L. (IR average=22.24%)

2 group – 30%<IR<49.99%: *Sonchus arvensis* L. (IR average=40.72%) and *Cirsium arvense* (L.) Scop. (IR average=40.72%)

On the basis of their inhibition rate on the *S. vulgare* var. *technicum* seed germination the five tested weed species could be ranked as follows:

1 group – IR<29.99%: *Aristolochia clematitis* L. (IR average=19.46%), *Cirsium arvense* (L.) Scop. (IR average=27.77%) and *Xanthium strumarium* L. (IR average=28.48%)

2 group – 30%<IR<49.99%: *Sorghum halepense* (L.) Pers. (IR average=31.25%) and *Sonchus arvensis* L. (IR average=31.25%).

This could be explained by the presence of glycoalkaloids, various phenolic acids (vanilla, syringe, ferulic, N-coumaric, etc.), condensed tannins, cyanoglycosides and hydrophobic p-benzoquinone, which are concentrated in the aboveground biomass of the studied weed species. Glycoalkaloids are known to have a highly toxic effect, with higher concentrations causing a lethal effect on germination of wheat seeds, while lower ones inhibit germination to varying degrees (Agarwal *et al.*, 2002). The differences found between reaction of two studied cultural Sorghum genotypes may also be due to differences in their allelopathic tolerance, since comparisons between them are made under the same conditions (Marinov-Serafimov *et al.*, 2017).

Conclusions

The results of this study are in good agreement with the previous findings that the alellopathic effect of weeds on seed germination varied according to the plant species (both weed and cultural) and the concentration applied. Both studied genotypes showed significantly high allelopathic tolerance to the invasive weed species – 68.1% for *Sorghum sudanense* (Piper) Stapf and 78.3% for *Sorghum vulgare* var. *technicum* Körn. This fact demonstrated that they are suitable for incorporation into various breeding programs as allelopathic tolerance donors. Reading of the allelopathic reaction is proved as fast and effective method for determining plant tolerance at different stages of the selection process.

Abstract

The forager bees perform the foraging tasks outside the hive in order to enhance the honeybee coloney survival. There is a lack of knowledge about how the neurobiological activities via protein phosphorylation in the brains of forager honeybee workers align with their tasks performances. The phosphoproteome in the brains of forager honeybee workers was characterized using Ti^{4+}-IMAC phosphopeptide enrichment, shotgun proteome, label-free quantitation, and bioinformatics. The identified 916 phosphoproteins in the nurse bee brain were involved in a wide spectrum of biological functions, metabolic pathways and kinase activities, indicating their pivotal roles to drive the brain maintenance, the neurobiological activities, learning, memory, and the cognition of the forager bee brain during navigation autside the hive. The more strongly represented phosphoproteins in the forager brains were strongly involved in the biological pathways of phosphatidylinositol signaling system, inositol phosphate metabolism, phototransduction, glycerophospholipid metabolism, and Wnt signaling. The most enriched kinases in the nurse bee brain were CDK2_CDK3, p38, JNK, ACTR2_ACTR2B_TGFbR2, CK2, CLK, PKC, and PKA, suggesting their vital roles in brain maintenance, signal transduction, and the olfactory learning processes to enhance the foraging activities performance. This study is the first in-depth and comprehensive phosphoproteome report on forager honeybee worker brains and provides novel insights into the molecular details of phosphoproteins that employ protein function to the needs of forager honeybee workers. These data provide basis information for future research to better understand the neurobiological roles of targeted proteins in the forager bee brain.

Key words: *Brain, Forager bees, Honeybee, Phosphoproteome.*

Introduction

The honeybee workers participate in all scenarios of routine activities that the colony needs. The worker's numerous tasks are very precisely organized depend on the division of labor which is largely dependent on age (Page and Peng 2001). Once the transition to foraging is made, bees no longer engage in within-hive tasks (Seeley 2009). Instead, they focus on foraging for the four resources colonies need: propolis, water, pollen, and nectar (Johnson 2010). Of the four, pollen and nectar make up most of the foraging activity, except in periods of heat stress in which water collection can be as labor intensive (Seeley 2009). The interaction within the brain three distinct regions; the mushroom bodies, the optic lobes and the antennal lobes (Menzel and Giurfa 2001) in the response of the environmental signals, generates and drives the forager bees' neurobiological activities during the foraging performance such as cognition, learning and memory. Therefore, to perform the navigation, cognition, learning, memory, and decisions during the foraging activities (Kappeler 2010) , honeybee brain involves varieties of activities in terms of changing the brain chemistry, brain structure, endocrine activity, and temporal patterns of gene and protein expressions (Robinson and Ben- Shahar 2002). Recently, Proteomics studies have become an important to gain in-depth insights and information about the neurobiological mechanisms in the neuro-cell level. To this end, however there is a gap of knowledge about phosphoproteins roles in the neuro-activities in forager bees' brains, the honeybee forager brain phosphoproteome will rather enhance our understanding about the phosphoprotein's roles in the forager brain neurobiological activities during foraging tasks performance.

Materials and methods

Chemical Regents

Unless otherwise specified, all chemicals were purchased from Sigma Aldrich (St. Louis, MO, USA). All reagents were analytical grade or better. Modified sequencing grade trypsin was bought from Promega Corporation (Madison, USA). Ti4+-IMAC material was kindly offered by Prof. Zhou H. F. (Dalian Institute of Chemical Physics, Chinese Academy of Sciences). ZipTip C18 column was from Millipore (MA O1821 USA). Protease Inhibitor Cocktail Tablets were from Roche (Mannheim, Germany). Other chemicals not mentioned here are sourced in the text.

Sampling Forager Honeybee Brains and Protein Preparation

We sampled the brains from five colonies of honeybee (*Apis mellifera ligustica*) maintained at the Institute of Apicultural Research, Chinese Academy of Agricultural Science, Beijing, China. 150 foragers were sampled at the entrance of the hives. The worker bees for foragers collecting didn't mark as the neurobiological activities are in link with the task performance. Only those bees returning with a pollen load were sampled to ensure they were really participating in foraging activity. Three biological replicates were produced. The collected bees were immediately anesthetized on ice, and the dissected brains were placed into tubes containing a cocktail solution of protease inhibitors and then stored at -80°C until analyzed.

Protein extraction of honeybee brains was carried out according to our previously described method (Zhang *et al.*, 2012) with minor modifications. Briefly, the sample was mixed with a lysis buffer containing 8M urea, 2M thiourea, 4% CHAPS, 20 mM tris-base, 30 mM DTT (1mg of brain/10μl of buffer). The mixture was homogenized for 30min on ice and then sonicated for 3min and centrifuged at 13,000g at 4°C for 15min. Ice-cold acetone was added to the recovered supernatant at a final concentration of 80% (V/V) and the mixture was kept on ice for 30min for protein precipitation. Subsequently, the mixture was then centrifuged at 13,000g at 4°C for 15min. The supernatant was discarded, and the pellets were used as protein samples for the following analysis. The final protein concentration was determined using Bradford assay.

Trypsin Digestion and Phosphopeptides Enrichment using Ti4+-IMAC

The protein sample was dissolved in 40 mM of (NH4)HCO3 followed by reduced with 100 mM of DTT [protein solution/DTT (V/V, 10:1)] for 1h to prevent reformation of disulfide bonds (Zhang et al., 2012). Then the mixture was alkalized with 100 mM of iodoacetamide (IAA) [DTT/iodoacetamide (V/V, 1:5)] for 1h in the dark. The protein mixture was digested by trypsin (20 ng/μl) in the ratio of 1:62.5 [enzyme/protein (W/W)] at 37°C for 14 h. The digested proteins were centrifuged at 13,500g at 4°C for 10min. The supernatant was recovered for phosphopeptide enrichment.

Phosphopeptide enrichment was performed using Ti4+-IMAC material according to the previously described method with minor modifications (Yu et al., 2009). Specifically, 10 μl of the prepared Ti4+-IMAC were dissolved in 500 μl of binding solution (80% ACN/6% TFA). Then, a 500 μl sample of digested peptide was added to the above mixture and incubated at room temperature for 60min. The mixture was centrifuged at 13,500 g at 4°C for 5 min. The supernatant was discarded and the precipitate was washed with 1ml of washing buffer I (50% ACN/ 6% TFA, NaCl 200 Mm) and washing buffer II (50% ACN /0.1% TFA). Finally, the

phosphopeptides were eluted twice with 200 µl of elution solution (0.5M K2HPO4) and the two fractions were combined.
The enriched phosphopeptides were manually loaded onto Reversed-Phase ZipTip C18 columns (desalting column) for concentrating and desalting prior to MS analysis. The desalted peptides were extracted in a Speed-vac system (RVC 2–18, Marin Christ, Germany) and dissolved in 0.1%formic acid (FA) thereafter.
NanoLC-MS analysis
An 8 µl sample of phosphopeptides was loaded onto a Q Exactive mass spectrometer (Thermo Fisher Scientific, Germany) coupled to EASY-nLC 1000 system using a nanoelectrospray ion source (Thermo Fisher Scientific, Germany) according to our previously established protocol with minor modification (Han et al., 2013). Specifically, reverse phase chromatography was performed using the Thermo EASY-nLC 1000 with a binary buffer system consisting of 0.5% acetic acid (buffer A) and 80% ACN in 0.5% acetic acid (buffer B). The peptides were separated by a linear gradient of buffer B up to 90% in 180min with a flow rate of 350 nL/min in the EASY-nLC 1000 system. The following gradient program was used: from 5 to 8% B in 5min, from 8 to 20% B in 115min, from 20 to 30% B in 40min, from 30 to 90% B in 10min and 90% B for 10min. The LC was coupled to a Q Exactive mass spectrometer via the nanoelectrospray source (Thermo Fisher Scientific, Germany). The Q Exactive was operated in the data dependent mode with survey scans acquired at a resolution of 70 000 atm/z300. Up to the top 10 most abundant isotope patterns with charge ⩾2 from the survey scan were selected with an isolation window of 1.6 Th and fragmented by HCD with normalized collision energies of 25. The maximum ion injection times for the survey scan and the MS/MS scans were 20 and 60 ms, respectively, and the ion target value for both scan modes was set to 1 ×106. Repeat sequencing of peptides was kept to aminimum by dynamic exclusion of the sequenced peptides for 30s.
Database Searching and Mapping Phosphorylation Sites
The raw files were searched against the in-house database generated from protein sequences of Apis mellifera (downloaded April, 2012) and augmented with sequences from Saccharomyces cerevisiae (downloaded April, 2012), totaling 61,380 entries using PEAKS studio software (version 6.0, Bioinformatics Solutions Inc.Canada). The search parameters were: Cysteine carbamidomethylation (C, +57.02) as a fixed modification; and methionine oxidation (M, +15.99), protein phosphorylation (+79.9663 Da) (STY) as variable modifications; enzyme, trypsin; missed cleavages, 2; peptide tolerance, ± 30 ppm; and MS/MS tolerance, ± 0.05 Da. A fusion-decoy strategy was employed to control FDR of protein and peptide identification used the cutoff score of >20 (−10logP) and FDR <1.0%. Scaffold PTM Version 2.0 (Proteome Software, Oregon, USA) was used to estimate the phosphosites localization probability by assigning Ascores (Beausoleil et al., 2006) to each PTM call. All MS/MS queries with an Ascore for every protein having a 95% or better probability were considered.
Label-free Quantitation of Protein Abundance
To evaluate the altered expression level of phosphorylated proteins between the brains of nurse and forager bees, a label-free quantitation was employed using Progenesis LC-MS software (Version 4.1; Nonlinear Dynamics, UK). The raw MS data was imported and processed with the software using a quantify-then-qualify strategy. The following MS feature alignment, editing MS1 spectra, peak modeling algorithm, quality control, peak detection, and statistical analysis of differentially expressed phosphoproteins between the nurse and forager bees' brains followed our recent published protocol (Fang et al., 2014). Then a file of a merged peak list containing differentially expressed phosphoproteins was generated by the software and it was searched against the above search engine, and a protein identification database using the same parameters thereafter. The search results of quantified proteins were

imported into software again to match each signal feature with the best peptide assignment. Similar proteins were grouped and only non-conflicting features were used for quantitation.

Bioinformatics Analysis

Functional annotation of the identified phosphoproteins having at least one site with a 95% localization confidence was performed using Blast2GO Pro v2.6.4 (http: //www.blast2go.com/ b2ghome, BioBam, Valencia, Spain).

Biological pathways were mapped using on-line iPath2.0 software (http://pathways.embl.de/) (Yamada et al., 2011) to navigate and explore the KEGG metabolic pathways of the forager bee brain phosphoproteins on a global and metabolic pathway-centric level.

Phosphorylation is catalyzed by protein kinases (Manning et al., 2002) and these enzymes can be recognized by specific sequence motifs in their substrates (Miller et al., 2008). The significantly enriched phosphorylation motif sets were extracted from all phosphopeptides with confident localized phosphosites (probability ⩾ 95%) using motif-X algorithm (http://motif-x.med.harvard.edu/motif-x.html) (Schwartz and Gygi 2005). The background was the uploaded Apis mellifera proteome (<10M of database size that randomly generated from A. mellifera proteome), the motif width was 13, occurrences were 20, significance was1x10-6, and motifs were extracted separately by pS, pT and pY sites at position 7. The motifs were categorized as basic, acidic, proline-directed, tyrosine, or "other" using a decision tree algorithm described previously (Huttlin et al., 2010). To assign the motifs to known kinases, two programs (http://www.hprd.org/PhosphoMotif_finder (Amanchy et al., 2007) and http://phosida.de/ (Gnad et al., 2007)) were used. All phosphorylation sites were subjected to kinase prediction using NetworKIN 3.0 algorithm (http://networkin.info/version_2_0/newPrediction.php) (Linding et al., 2008) to predict possible upstream kinases. A score threshold of NetworKIN score ⩾ 1.0 and String score ⩾ 0.6 were regarded as significant, and all kinases predictions were used. Since A. mellifera is not included in the NetworKIN database, Drosophila was selected as an alternative.

Results and discussion

Mapping the Phosphoproteome of Forager Brains of the Honeybee worker (*A. m. ligustica*)

In an effort to map the phosphoproteome in the brains of forager honeybee workers, IMAC phosphopeptide enrichment and shotgun proteome strategies were employed. A total of 13,253 phosphopeptides (3,091 nonredundant) from 916 phosphoproteins were detected in foragers with an FDR <1.0% both at the peptide and protein level.

The identified phosphoproteins in forager bees' brains were assigned to the GO categories and the phosphoproteins were classified to 21 functional categories including; regulation of biological processes (32.5%), metabolic processes (27.8%), transport (25.0%), response to stimulus & stresses (24.5%), development (23.9%), cellular component organization or biogenesis (23.3%), cell communication (22.6%), protein metabolic processes (22.6%), localization (22.2%), signaling (21.7%), nucleobase-containing compound metabolic processes (19.3%), cell differentiation (16.6%), signal transduction (16.5%), anatomical structure morphogenesis & development (15.6%), protein modification processes (11.0%), catabolic processes (9.7%), cytoskeleton organization (9.0%), biosynthetic processes (8.8%), cell-cell signaling (8.3%), behavior (7.2%), and unknown (6.9%) (fig. 1).

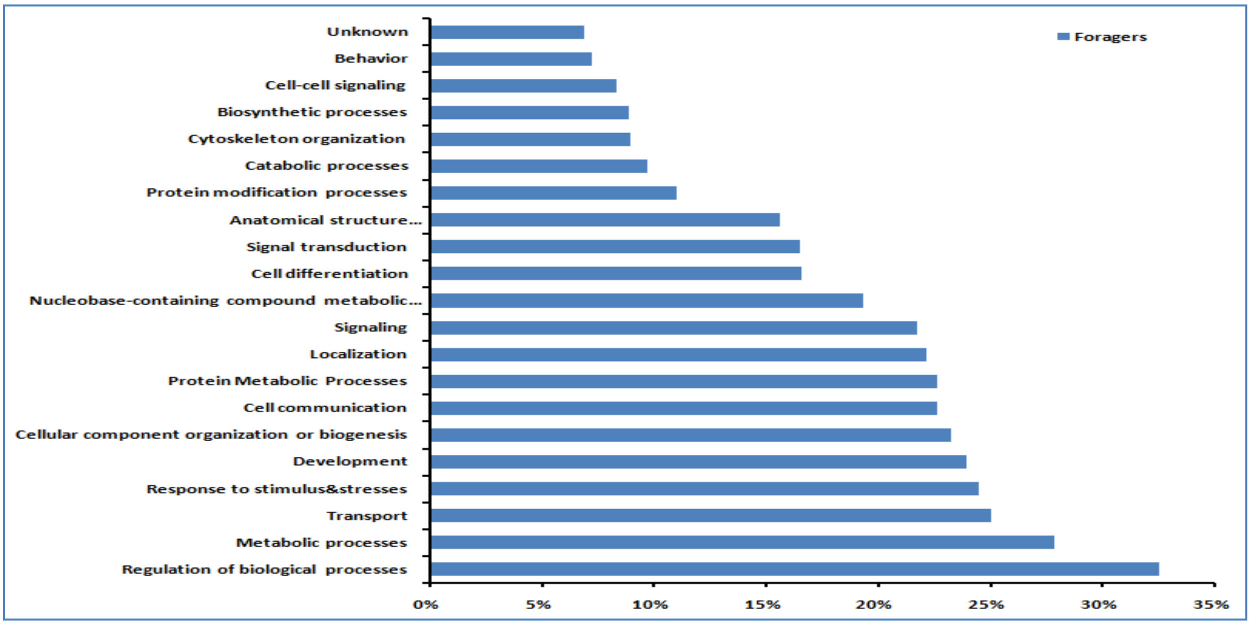

Fig. 1. The functional category of all the identified phosphoproteins in forager brains of the honeybee worker (*A. m. ligustica*). The percentage of each functional group is obtained on the basis of the number of phosphoproteins under each of the functional groups divided by the total number of the identified phosphoproteins in foragers individually.

Protein−Protein Interaction PPI Analysis

Of the 916 identified phosphoproteins in the forager’s brains, 208 phosphoproteins ($\geqslant$ 10 interactions of each protein) were identified as key node proteins in the PPI networks with a total of 11,621 interactions. These key node phosphoproteins in forager bees’ brains were implicated in the regulation of biological processes, protein metabolic processes, development, response to stimulus & stresses, cellular component organization or biogenesis, metabolic processes, cell communication, transport, signaling, localization, nucleobase-containing compound metabolic processes, anatomical structure morphogenesis & development, cell differentiation, signal transduction, protein modification processes, biosynthetic processes, catabolic processes, cytoskeleton organization, behavior, and cell-cell signaling funcional categories (fig. 2).

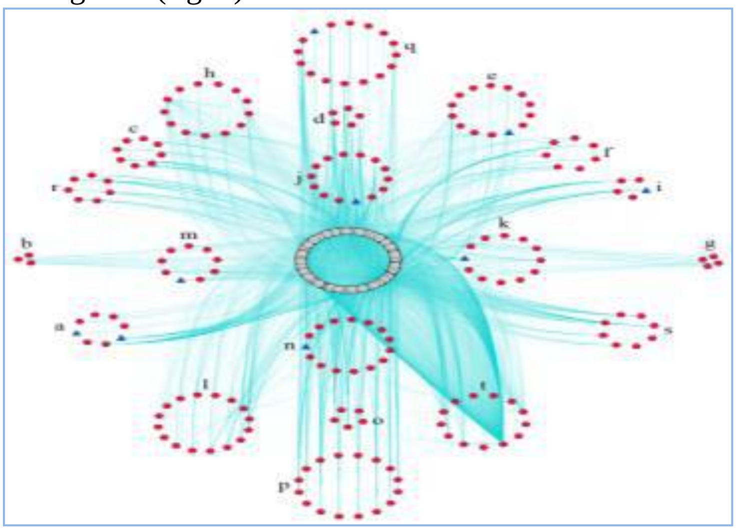

Fig. 2. Protein-protein interaction PPI network of identified phosphoproteins in forager brain of the honeybee worker (*A. m. ligustica*). PPI is predicted using the Interologous Interaction Database (I2D) and visualized by NAViGaTOR software (Brown and Jurisica 2005; Brown and Jurisica 2007b). The color symbols represent identified proteins connected in the PPI

network with at least 10 interaction degrees. The regular triangles stand for up-regulated phosphoproteins in forager brain of the honeybee worker. Letters from "a" to "t" represent the categories of anatomical structure morphogenesis & development, behavior, biosynthetic processes, catabolic processes, cell communication, cell differentiation, cell-cell signaling, cellular component organization or biogenesis, cytoskeleton organization, development, localization, metabolic processes, nucleobase-containing compound metabolic processes, protein metabolic processes, protein modification processes, regulation of biological processes, response to stimulus & stresses, signal transduction, signaling, and transport.

The top 10 key node proteins with high degrees of interaction in forager bees' brains were: polyubiquitin-A-like (610 interactions), actin related protein 1 (286 interactions), eukaryotic initiation factor 4A-like (256 interactions), fasciclin-2 isoform 1 (255 interactions), autophagy 1 (213 interactions), cyclin-dependent kinase 7 (213 interactions), histone deacetylase 4 (203 interactions), tubulin beta-1 chain (189 interactions), tubulin alpha-1 chain-like (169 interactions), and voltage-dependent anion-selective channel (166 interactions).

Pathway Mapping and Enrichment Analysis

To better explore and navigate the key functionality of the phosphoproteins in forager's brains, all identified 916 phosphoproteins in forager bees' brains were mapped to KEGG-derived metabolic pathways using iPath2.0. These phosphoproteins were matched to 81 metabolic map elements (redundant entries included). Pathways involved in carbohydrate metabolism such as fructose and mannose metabolism, amino acids metabolism, amino acids biosynthesis, and the chlorocyclohexane and chlorobenzene degradation were highly represented. Of which, pathways of the phosphatidylinositol signaling system, inositol phosphate metabolism, phototransduction, glycerophospholipid metabolism, and Wnt signaling were significantly enriched in the KEGG pathway database.

Motif Analysis and Kinase Prediction

Of all the confidently localized phosphosites in the forager bees' brains, 1,390 kinase-substrates were obtained from the phosphosites in foragers. These kinase-substrates mainly involved in 28 kinase families group in foragers brain phosphoproteins including; CDK2_CDK3, p38, JNK, ACTR2_ACTR2B_TGFbR2, CK2, CLK, PKC, PKA, GSK3, p70S6K, PKB, PAKA, PAKB, CK1, ATM_ATR, CaMKIIalpha_CaMKIIdelta, InsR, MAP2K6_MAP2K3_MAP2K4_MAP2K7, MAPK3_MAPK1_MAPK7_NLK, CDK1, MSN, AuroraA, CDK5, ROCK, DMPK, MST, NEK1_NEK5_NEK3_NEK4_NEK11_NEK2, and PKGcGK.

All the phosphosites harbored in the phosphoproteins identified in forager bees' brains were subjected for motif analysis by Motif-X algorithm. In total, [15] Ser motifs were extracted from the serine phosphorylation sites, i.e., [SP××××R], [SP××S], [SPS××S×××E], [KS×SPS], [S××××SP], [KS×SP], [SP], [SPS], [DS], [S×××S], [S××S], [S×E], [S××S×××SP], [S××××S] and [S××××P]. There were [12] Thr motifs were enriched from the threonine phosphorylation sites, i.e., [SVT××××E], [S××××T×E], [SPT], [SP××T], [SP××××T], [TP], [T×××SP], [S××T], [S×××T], [P××T], [T×××××P], and [S×T]. In addition, one motif [S×××Y] was identified from the tyrosine phosphorylation sites. In forager bees' brains, 4 acidic, 5 proline-directed, 1 tyrosine, and 18 "other" motifs were identified, of which 16 were novel, and the remaining 12 were matched to known kinases of ERK1, ERK2, CKII, CK1, and b-Adrenergic Receptor kinase (fig. 3).

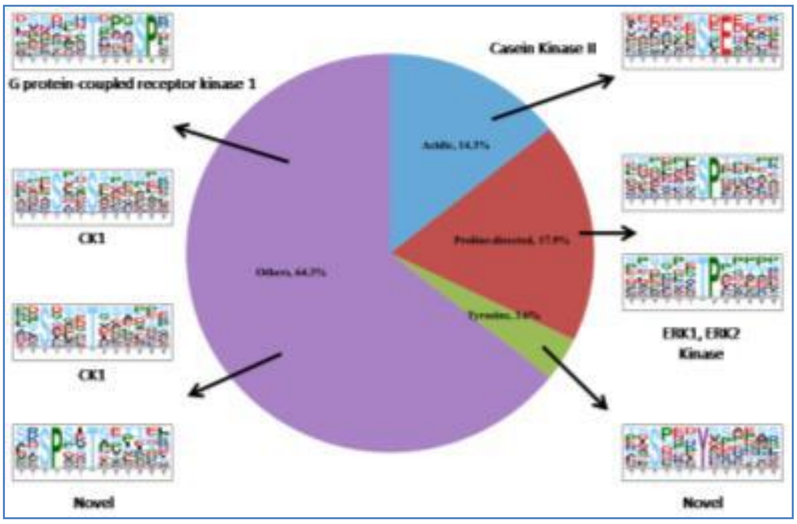

Fig. 3. Representative extracted motifs from the phosphorylated peptides identified in forager brain of the honeybee worker (A. m. ligustica). Motif extraction was done using the Motif-x algorithm (http://motifx.med.harvard.edu/motif-x.html). Phospho-motifs were classified according to ref (Lasonder et al., 2012). Known motifs were searched for the kinases using the resources at http://www.hprd.org/PhosphoMotif_finder (Amanchy et al., 2007) and http://phosida.de/.

As well known, honeybee (*Apis mellifera*) is the typical model for the molecular studies of social behavior. In addition, the division of labor behavior in the social insects brings to the light how much these social insects organized and advanced. Honey bee worker performs a sequence of tasks throughout her adult life as she shifts from a young nurse bee living inside the hive to a forager bee that navigates the outdoors. The foraging activities are the key factor of the honeybee colony survival, whereas outdoor worker bees collect the materials for the colony nutrition and maintenance such as; pollen, nectar, propolis, and water. To perform the different tasks, honeybees efficiently regulate highly advanced social behaviors and intelligent decisions (Tereshko and Loengarov 2005) by the functionality of brain cell chemistry, structure, endocrine activity, and changes in temporal patterns of gene and protein expression (Robinson and Ben - Shahar 2002; Robinson 2002). With age development, the brains of honeybee workers have already physiological matured and engaged in the neural activities associated with the field foraging tasks. To this end, the involovement of the identified 916 individual forager bee brain phosphoproteins in regulation of biological processes, metabolic processes, transport, response to stimulus & stresses, development, cellular component organization or biogenesis, cell communication, protein metabolic processes, localization, and signaling is supposed to help the forager to achieve their task performance by supplement of biological molecules for brain maintenance and energy depletion to support the intense cerebral activity during the foraging activities.

The top detected key node phosphoproteins in the PPI network of the forager bee brain phosphoproteome imply their importance in further supporting the regular maintenance and demands of the forager brain via synthesis of proteins and energy supplies during foraging. The actin related protein 1 is assumed to be involved in transportation of mitochondrion (Haghnia *et al.,* 2007) and vesicle-mediated transport, which is a vital process in signal transduction regulation. The polyubiquitin-A-like proteins involved in the cell phagocytosis (Stroschein-Stevenson *et al.,* 2005) and activating the autophagy-related protein 7-like which regulates the neurodegeneration and aging in *Drosophila* (Chen *et al.,* 2012). Eukaryotic initiation factor is important for resolving mRNA secondary structures (Fraser and Doudna 2006), which in turn, support forager brain maintenance during the forage activities, while Fasciclin-2 isoform 1 protein has been reported in relation to neuron recognition (Grenningloh

et al., 1991), synapse organization (Ashley *et al.,* 2005), olfactory learning, and short-term memory (Waddell and Quinn 2001) suggest that this protein is important for enhancement the honeybee workers cognition and decision. Moreover, tubulin proteins involved in centrosome duplication in drosophila (Müller *et al.,* 2010) suggests its pivotal role in cell cycle progression and forager brain maintenance. The histone deacetylase protein plays pivotal roles in neurogenesis and neuron generation within the nervous system (Neumüller *et al.*, 2011). As vision is a key factor for foraging and navigating, voltage-dependent anion-selective channel proteins participate in ion transport (Komarov *et al.*, 2004) and maintaining the photoreceptor response as a key factor in phototransduction (Lee *et al.,* 2007a). The key driver proteins for these networks highlight potential novel targets for further mechanistic studies of honeybee neurobiology.
The forager brain phosphoproteins molecular network covered the major central metabolism categories including carbohydrate metabolism such as fructose and mannose metabolism, amino acids metabolism, amino acids biosynthesis, and the chlorocyclohexane and chlorobenzene degradation were highly represented. These metabolic pathways imply the phosphoproteins importance in further supporting the regular maintenance and demands of the forager brain via synthesis of proteins and energy supplies during foraging. Foraging activity requires the development of a wide repertoire of navigational skills due to the spatial complexity and the acquisition of novel sensory information from the environment outside the nest (Tereshko and Loengarov 2005). As forager bees, information acquisition from the environment is the first step in the process of learning, memory, and navigation. The eyes of foragers are vital for the cognition of flower colors and patterns and to learn the new route to a food source (Pahl *et al.,* 2010). Toward this goal, the more strongly represented phosphoproteins which are significant in the phototransduction pathway reveal the paramount importance of visual perception (Srinivasan 2010) via the efficient information processing. In addition, the other significant enriched biological pathways in the forager brain coherent with the brain functions such as; the phosphatidylinositol signaling system and inositol phosphate metabolism pathways play central role in cellular responses (Dickman *et al.*, 2006), synaptic vesicle endocytosis and neurotransmitter secretion (Morrison *et al.*, 2000). The Wnt signaling pathway has a pivotal role in the signal transduction to support the brain interaction with the environment events (Nusse and Varmus 1992).
The enhanced enzymatic activities of kinase in forager brains such as CDK2_CDK3, p38, JNK, ACTR2_ACTR2B_TGFbR2, CK2, CLK, PKC, and PKA may play vital roles in the nerve cell differentiation (Morgan 2007), and cell proliferation regulation (Pearson *et al.*, 2001). This suggests their importance in the enhancement of the signal transduction function in the forager's brain. On the other hand, the enriched motifs from the phosphopeptides in the forager bee brain are matched with the extracellular-signal regulated kinases (ERK1/2), CKII, CK1, and b-Adrenergic Receptor kinase. of which, the ERKs are widely involved in the regulation of cellular proliferation, gene expression, differentiation, mitosis, cell survival, and apoptosis functions, and they are also important to many different stimuli such as heat shock via activating the ERK pathway (Pearson *et al.*, 2001). Therefore, ERKs are important both in response to environmental stimuli and brain maintenance in forager bees. Casein kinase 2 (CKII) has been reported to be activated Wnt signaling pathway (Gao and Wang 2006), while the casein kinase 1 (CK1) family are selective enzymes that function as regulators of signal transduction pathways in most eukaryotic cell types and involved in Wnt signaling, , DNA repair, and DNA transcription (Eide and Virshup 2001). Therefore, the forager brain phosphosites motifs provide specific binding sites for kinase recognition that is potentially useful for a mechanistic understanding of how kinases mediate phosphorylation events in the forager bee's nervous systems.

Conclusion

This study provides the first comprehensive and large scale in vivo dynamic phosphoproteome profile into the forager honeybee worker brain up to date. The identified 916 phosphoproteins in the nurse bee brain are mainly associated with regulation of biological processes, metabolic processes, transport, response to stimulus & stresses, development, cellular component organization or biogenesis, cell communication, protein metabolic processes, localization, and signaling. The forager brains' phosphoproteins expressions in the common biological pathways and kinase activities are vital to sustain central neural activity during the foraging activities. The more strongly represented phosphoproteins in the forager brains that are implicated in pathways phosphatidylinositol signaling system, inositol phosphate metabolism, phototransduction, glycerophospholipid metabolism, and Wnt signaling, and activated kinases such as CDK2_CDK3, p38, JNK, ACTR2_ACTR2B_TGFbR2, CK2, CLK, PKC, and PKA are required for brain maintenance, signal transduction, and the olfactory learning processes to enhance the foraging activities performance. Overall, the neural associated phosphoproteins networks identified in this study require further mechanistic studies of honeybee neurology. The knowledge gained from the further studies will lead to major advances in the honeybee brain neurobiology and other social insects.

Abstract

Flavored wines consist of a neutral wine/grape juice base, with the addition of alcohol and a mixture of dry ingredients, such as aromatic herbs. One of the most popular Greek flavored wines is Retsina, which results by addition of Aleppo Pine resin in grape juice during alcoholic fermentation. "Retsina" is a wine of traditional appellation produced only in Greece, while some Retsina wines produced in the Greek regions of Attiki, Viotia and Evia have additionally become entitled to bear a geographical indication of origin. Vermouths, also designated into the flavored wines category, originate from the addition of herbs and spices in a base wine. Both Retsina and vermouths are consumed by young people. Specifically, Retsina is also named "drink of students" because of its low cost and easy combination to a variety of foods of Mediterranean cuisine. Vermouths, on the other hand, is a very popular choice among young people, for an after-office drink or aperitif. The purpose of this survey was to assess the knowledge and preferences of young consumers regarding flavored wines, in particular Retsina and vermouth. The study was conducted from January to May 2019 in the region of Thessaly (central Greece). Four hundred questionnaires were filled in by randomly selected individuals, who were asked to answer key questions about flavored wines. The results of the survey showed that 79.5% of the respondents consumed flavored wines without being aware of the fact (45.5%). Respondents' consumption was limited to less than one bottle per month. They preferred Retsina over any other flavored wine (64.4%). They preferred domestically produced wines (53%), originating mainly from the Greek region of Thessaly (21.6%), because of their desire to support local businesses. The present study provides detailed statistical information on the behavior of young consumers regarding flavored wines in the Thessaly region.

Key words: *flavored wines, vermouth, retsina, young consumers.*

Introduction

The original purpose of aromatization, like fortification, was to preserve the wine from microbiological or oxidative spoilage. Nowadays, due to vastly improved winemaking techniques, materials and equipment, the original purpose of this practice has been lost, however the taste for aromatized wines remains strong in many parts of the world (Buglass, 2011).

Alcoholic beverage industry is one of the most dynamic sectors in Greece, with a high degree of competitiveness and big concentration of enterprises. Retsina is a traditional Greek white wine with the added spicy pine resin flavor. It has a history of thousands of years. It is one of best known Greek products in international markets, labeled "Traditional Wine" which means that only Greece can produce it (Kourakou – Dragona, 2015). It is a powerful "weapon" in the hands of capable wine-makers who have realized that a small country like Greece on the international markets can only stand if it invests in absolute quality. There are several producers currently working in this direction, making wonderful Retsinas and winning praise

from well-known wine-critics. The product's image inside the country is not so good, being labelled as a student /cheap wine and getting a negative vote by wine drinkers.
According Panesar et al. (2009), vermouth, which is officially classified as an "aromatized fortified wine", is produced by the fortification with alcohol of a white wine base and subsequent infusion with aromatic plants, seeds, fruits and other botanicals. Depending the recipe, its characteristic taste should be occur by the utilization of *Artemisia* species, according to Regulation (EU) No 251/2014 (Annex II). These types of wines are quite popular in European countries and in the USA (Amerine et al, 1980). Italy and France are famous producers of vermouths, however, a few Greek companies also have begun producing vermouths recently.
The aim of the project was to investigate the behavior of young people in terms of their knowledge and preferences in flavored wines and especially in Retsina and vermouth. Consumers are influenced by a variety of external factors (demographic, social, economic, technological, etc.) when making purchasing decisions, and age according to Garcia et al. (2013) is an important variable in differentiating consumer preferences. For this reason, the sample of respondents was selected on the basis of age, and especially younger consumers, who are the potential consumer audience of a society that can highlight a trend and reflect its needs. This study provides information to the wine industry in order to take steps to improve the knowledge of new consumers about these products and in particular about Retsina, which is a popular Greek wine.

Materials and Methods

The research was based on the collection of data on the behavior of young consumers towards flavored wines. The focus group selected based on legal drinking age in Greece (18 years old), the demographic cohort named Gen Z (18-23 years of age), along with Gen Y.1 (age range 24-29 years old), which represent the main age groups of university students in Greece (graduate or post-graduate levels) (Kamenidou et al. 2019). Millennials or Gen. Y cohort identify as wine drinkers, and correspond to a fast growing wine segment, according to Atkin & Thach (2012).
A total of 400 randomly selected young people, currently studying or owning a university diploma, with a level of income of € 13,000 to € 24,000, answered face to face questions about their knowledge and preferences regarding flavored wines. Participants answered 34 questions, grouped in 3 parts. The first part of questions negotiated consumer attitudes towards the beverage market and consumption of wine, the second part consisted of questions regarding wine selection (imported - domestic and organic), while the third part was composed by questions referring to Standardization - Packaging - Price - Label - Advertising. The survey was conducted from January to May 2019, in the region of Thessaly (central Greece). Data were processed using SPSS ver 17 statistical package. Limitations of the survey is the geographically restricted sample, which does not represent neither the general population, nor the whole country.

Results and Discussion

Considering that age is a variable that influences consumer preferences and is based on the principle that each generation has its own specific values, which in turn lead to different behaviors (Garcia et al, 2012), the research was conducted on young people 18 - 24 years (93.5%) to the majority of students (92.1%), since Retsina is also called 'student drink', as it is not lacking in any student hangout and is the first drink in their preferences.
Although largely young people are unaware of the particulars regarding aromatized/flavored wines (composition, alcohol, etc.), Retsina has got 64.4% of their preference among flavored

wines, vermouth 11%, while 25% of respondents prefer another flavored wine (e.g. aperitifs, sangria) (Figure 1).

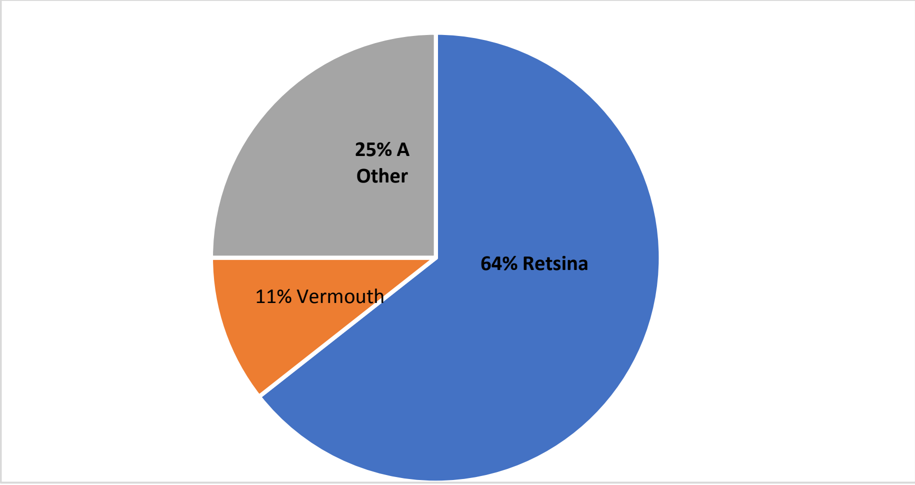

Figure 1. Consumption of flavored wines by young people

The largest percentage of respondents (44.9%) say that they spend less than 10 euro / month on the purchase of flavored wine (Figure 2), and they probably represent the consumers of Retsina, since the cost of a Retsina bottle (0.5L) range from 1.75€ to 10€. One out of four young consumers spends more than 20 euro per month for the purchase of aromatized wines (vermouth drinkers probably are included, since these products cost over 20 euro per bottle. Finally, 3.4% of the respondents spends 50-60 euro / month, thus enhancing the growth power of the alcoholic beverage industry and the entire wine production and marketing chain in general.

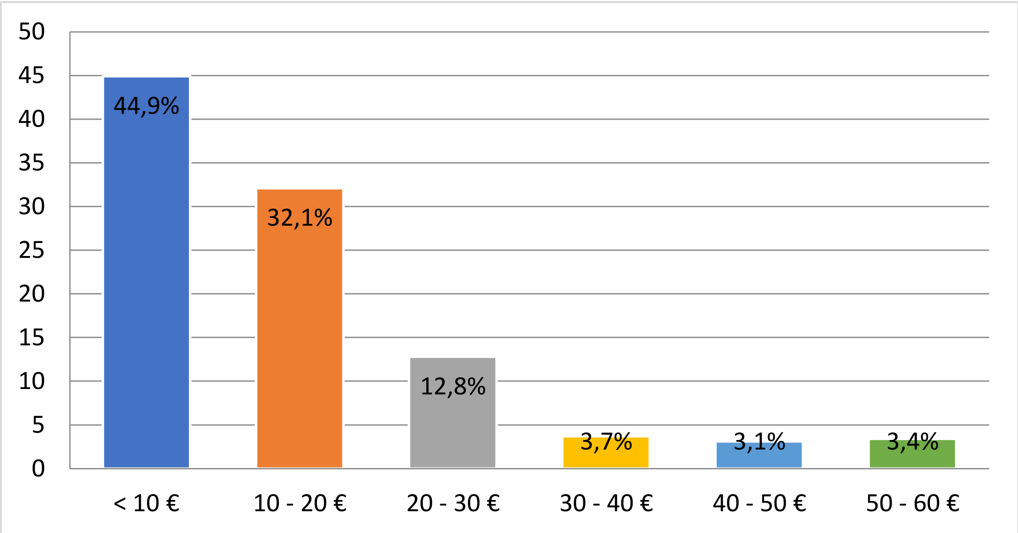

Figure 2. Money spent for the purchase of flavored wines in a monthly basis

It is important to note that over 50% of the research participants prefers to consume domestically produced aromatized wine over imported, due to quality, uniqueness, but also to support Greek companies. In addition, over one third of those preferring domestic aromatized wines express a strong preference for locally produced aromatized wine, originating from the region of Thessaly, which indicates that the criterion "local" plays a significant role in their buying behavior. Regarding the respondents' opinion on the criteria for the selection of flavored wines, the highest percentage of agreement is related to the parameters of taste (Table 1) and aroma, followed by the production company (agricultural cooperative), the price and quality (quality certification).

Table 1. Criteria to be considered for the selection of flavored wines

Parameters	Average value

Brand	2.8
Product /company certification	3.6

*1-not at all, 2-little, 3-moderate, 4-a lot, 5-too much

It is impressive, however, is that more than 66% of the respondents do not buy organic flavored wines, despite recognizing their superior quality (data not shown).
As far as prices are concerned, the majority of respondents think that they are good enough and in the event of a price increase consumers would not stop buying the products, just maybe reducing quantities.
Research participants usually prefer to consume flavored wines accompanied by food and especially at celebrations/gatherings. This is the case mainly for Retsina, which is served in restaurants by rarely in bars, while vermouths and other flavored wines are served almost exclusively in bars.
Finally, it is worth mentioning that the purchase of a flavored wine is highly influenced by the taste and personal experience (previous tasting), price and quality, while not letting the brand and advertising direct it. These research findings are also confirmed by the research of Garcia et al., (2013), with the exception of young people's preference for organic wines which in this study do not seem to have the same impact, which may be due to the lack of information about organic flavored wines.
The results indicate a conscious consumer audience regarding the consumption of flavored wines (Table 2)

Table 2. Criteria affecting the consumers for the selection of flavored wines

Criteria	Average value
Good taste	4.3
Reasonable price	3.7
Advertising	2.4
Brand	2.8
Packaging	2.6
Country of origin	3.2
Variety	3.3
Company of production and packaging	3.0
Quality characterization (eg. PGI)	3.2
Opinion of friends and family	3.3
Personal experience (previous tasting)	4.2

*1-not at all, 2-little, 3-moderate, 4-a lot, 5-too much

Conclusion

In this study it was revealed that young people consume flavored wines and prefer retsina over vermouth because it is a Greek product, is quite affordable and they believe that they contribute to the enhancement of local market. Characteristics that appear to affect young consumers of flavored wines in the region of Thessaly are the taste, personal experience (previous tasting) and price of the product. In addition, the characteristics that least influence the choices of the research participants appear to be advertisement, packaging and brand, indicating a conscious consumer audience interested in taste and good quality. This research could be used by wine companies as a reference to their marketing strategies targeting young consumers. Finally, conducting a more extensive country-wide research could confirm the interpretation of the existing findings.

Abstract

Commercial maize hybrids should incorporate high yield potential and stability across environments in order to be profitable for the farmers. A stable genotype must show almost no interactions with the environments where it is cultivated. The only effects acceptable in the field, are the favorable conditions in some environments that may increase yield above the level of expected performance. The purpose of the present research was to analyze yielding stability in maize, based on data from Randomized Complete Block designs conducted in two contrast environments: in Florina and Thessaloniki (Northern Greece). Ten commercial F1 maize hybrids were used: ZS-680, ZS-8720, ZS-650, ZS-600, ZS-500, ZS-700, Cresus, Jetta, Funo and ZP-704. Plots consisted of four rows 5m long, 0.75m apart, 20cm plant-to-plant spacing and four replications. Mean yield was estimated for each location and hybrid and stability index (a specific ratio of mean and standard deviation) was used to depict which commercial hybrids were more stable across the environments. Generally, there were differences in stability across environments and some hybrids showed stability in both Greek environments. ZS-700 generally showed the greatest values (83.43) followed by Cresus (54.29). In Florina, stability index values were generally greater than Thessaloniki, indicating a more stable performance in this specific environment. The more stable hybrids were ZS-700 and Cresus for Florina, and ZS-600 for Thessaloniki. Jetta showed satisfactory values in both environments, indicating a more balanced and stable performance across the two environments. These commercial hybrids could be recommended for cultivation in certain Greek regions. The stability index is a useful criterion for cultivar recommendation. From our dataset, Florina region contributed positively to stability performance.

Key words: *stability index, environment, performance*

Introduction

Commercial maize hybrids in order to be profitable for the farmers must incorporate high yield potential and stability across environments (Stratilakis and Goulas, 2003). Evans (1980) stated that breeding contributed to yielding performance by a) increased adaptability of genotypes, b) increased resistance to insect attacks and diseases, and c) increased responsiveness to inputs and new cultivation techniques. Fasoulas (1981; 1993) reported the main principles for efficient breeding, such as absence of competition during selection, special designs to reduce soil heterogeneity and exploitation of individual plant yielding capacity, in order to have high and stable yielding performance. Stability of genotypes across environments is considered of great importance for a commercial cultivar (Fasoulas, 1988) and a stable genotype must show almost no interactions with the environments where it is cultivated. The only effects acceptable in the field, are the favourable conditions in some environments that may increase yield above the level of expected performance. Stability estimations were previously conducted on the basis of stability index

$(\bar{x}/s)^2$, where $\bar{x}$ and s are the entry mean yield and standard deviation (Fasoula, 2013). Fasoulas (2004) stated that this index reveals genes that control stability and tolerance to various biotic and abiotic stresses. Initially, Fasoulas (1988) proposed the ratio VC or 1/CV (the coefficient of variation) between mean and standard deviation for stability estimations and later Fasoula (2013) used the squared form as a stability criterion considering this approach as the most appropriate to analyse stability. The concept of the use of coefficient of variation (CV) is not a new one. Edmeades and Daynard (1979) used it for stability estimations and Tollenaar and Wu (1999) as a means of efficacy in breeding. Edmeades and Deutch (1994) used many parameters for estimating stability and also they proposed evaluations in many different environments.
The purpose of the present research was to analyse yielding stability of ten maize commercial F1 hybrids, based on data from Randomized Complete Block designs conducted in two contrasted environments in the Greek regions of Florina and Thessaloniki.

Material and methods

Environment evaluation (Fasoulas, 1981; Ipsilandis, 1996; Greveniotis *et al.* 2019) was based on maize data from Randomized Complete Block designs conducted in Florina (Technological Educational Institute of Western Macedonia in Florina, Greece) and Thessaloniki. For this purpose, in the above mentioned locations, 10 maize hybrids were sown at the same date in 20 April: ZS-680, ZS-8720, ZS-650, ZS-600, ZS-500, ZS-700, Cresus, Jetta, Funo and ZP-704. Plots consisted of four rows 5 m long, 0.75 m apart, 20 cm plant-to-plant spacing and four replications. Only one of the four rows was harvested by a single-row harvester, the left of the two inner rows. Mean yield was estimated for each location for the 10 commercial F1 maize hybrids. Stability estimations were based on stability index $(\bar{x}/s)^2$, where $\bar{x}$ and s are the entry mean yield and standard deviation (Fasoula, 2013).

Results and discussion

In the quest of stability breeders mainly and then farmers, spent a lot of time testing genetic materials to prove their stable performance across environments and then in specific environments. Breeders especially choose their way to stability through different paths (Bernardo, 2002).
In our dataset the different genetic materials showed significant differences between their stability index. Differences were also found across environments. ZS-700 generally showed the greatest values (maximum 83.43) followed by Cresus (maximum 54.29). In Florina stability index values (mean= 25,64) were generally greater than Thessaloniki (mean= 6,88), indicating a more stable performance in this specific environment probably because of the local conditions that proved to be more favourable (Fasoulas, 1988). Thus, the more stable hybrids were ZS-700 and Cresus for Florina, and ZS-600 for Thessaloniki (16,19). Jetta showed satisfactory values in both environments (Florina and Thessaloniki), indicating a more balanced and stable performance across the two environments.
According to Fasoulas (1988) and Ipsilandis (1996) stability of performance is essential for the establishment of a commercial cultivar/hybrid. Thus, the stability index is a useful criterion for cultivar recommendation. Modern maize hybrids are considered to be more productive than older ones, because of their stability of performance even under difficult environmental conditions. They also correspond better to various inputs according to previous reports (Castleberry *et al.* 1984; Carlone and Russell, 1987; Duvick, 1992; 1997).
According to Fasoulas (1988), stability estimations may also lead to clarification of the type of a trait inheritance, meaning that stability index may also indicate if a specific trait exhibits

quantitative or qualitative behavior. Comparisons between traits may depict if a trait is controlled by a few, one or many genes.

Table 1. Stability index for all hybrids within and across environments

	Florina (Env A)		**Thessaloniki (Env B)**	
HYBRIDS	$(\bar{x}/s)^2$	$\bar{x}/s$	$(\bar{x}/s)^2$	$\bar{x}/s$
ZS-680	4.47	2.11	3.83	1.96
ZS-8720	13.18	3.63	3.00	1.73
ZS-650	10.14	3.18	2.92	1.71
ZS-600	22.90	4.79	16.19	4.02
ZS-500	5.43	2.33	6.51	2.55
ZS-700	83.43	9.13	6.86	2.62
CRESUS	54.29	7.37	6.63	2.57
JETTA	19.97	4.47	9.40	3.07
FUNO	4.70	2.17	9.47	3.08
ZP-704	37.85	6.15	3.97	1.99

Conclusions

Maize hybrids ZS-700 and Cresus for Florina, ZS-600 for Thessaloniki and Jetta in both regions, showed high stability according to stability index in the two Greek environments used. The differences between genotypes were also very significant, depicting the more stable ones. These hybrids could be recommended for cultivation in Greece, since the stability index proved to be a useful criterion for cultivar recommendation. Stability in extreme environments like Florina may prove to be very important for maximizing field yield. From our dataset Florina contributed positively to stability performance.

DEVELOPMENT OF CHANGES OF LACTIC ACID AND COLOR CONTENT IN HARVEST SEASON FROM ELDERBERRY (SAMBUCUS NIGRA L.)

Zsuzsanna PALÁGYI, Diána FURULYÁS, Mónika STÉGER-MÁTÉ*

Department of Food Preservation, Szent István University, Hungary
*Corresponding author: stegerne.mate.monika@etk.szie.hu

Abstract

Elderberry (*Sambucus nigra L.*) can be used in many ways in the food industry due to its nutritional characteristics its organoleptic properties and its rich color content. Currently this plant is used as a natural coloring or coloring food (concentrate, powder) in the food industry. In recent years, the rise in lactic acid content has been a problem for both Hungarian producers and the industry, which has a negative impact on the quality of products. Lactic acid bacteria often appear in plantations, due to weather conditions, especially temperature and precipitation. However, this also affects the anthocyanin content. Many items are rejected on receipt of raw material due to excess lactic acid limit, which makes it difficult to process of elderberry for both producers and acquiring companies. In our research, we monitored the development of lactic acid and color content in the elderberry samples from the plantations of BOTÉSZ (Bodzatermesztők értékesítő Szövetkezete – Hungarian elderberry association) under the elderberry harvest season. In our investigation, we used a variety of color content and lactic acid measurements to select a method that can be routinely applied in industrial environments. Based on our results, we would like to develop recommendations for good harvest practices that are planned to be presented at BOTÉSZ members' meetings and conferences.

Keywords: *Elderberry, lactic acid, color content, BOTÉSZ*

Introduction

Elderberry (*Sambucus nigra* L.) is variably usable fruit in food industry because of its taste, coloring properties and positive health benefits. It is a source of protein, fatty acids, vitamins and high biologycal activity compounds, like polyphenols. They have numerous positive medical effects, for example immune system stimulation, blood pressure stabilization, decreasing of uric acid levels and anti tumor activity. (Andrzej Sidor, October, 2015)
Due to these properties, elderberry is used in many different food products in Europe, such as pies, jellies, yogurts, syrups, jams, food colorants and alcoholic drinks. (Pedro Silva, January, 2017)

Measurements and methods

Samples: The harvesting season consists of mainly the next five days: 24 August – 30 August (on 25 and 26 August it was raining). The mass of the elderberry samples were each 700 – 800g in plastic bags, the next table shows the distribution of total 25 samples.

Table 1. Distribution of elderberry samples

2018. 08. 24.	2018. 08. 27.	2018. 08. 28.	2018. 08. 29.	2018. 08. 30.
8 samples	8 samples	3 samples	3 samples	3 samples

Preparation of samples: We took off the samples from the freezer, put them in a kitchen blender and made a homogene puree.
After this, we made an extraction with a solution consisting of 60% destilled water, 39% methanol and 1% formic acid. We added 30 ml of this solution to 1 g sample in a centrifuge

tube, put it in ultrasonic bath for 15 minutes and centrifugated for 10 minutes on 4000 rpm. This extraction is needed to perform some further measurements.

Table 2. Used measuring methods for each parameters

Measured parameter	**Method**
Anthocyanin content	pH differential method (J. Lee, 2005)
Lactic acid content	Food Lab Analysis Sytem (by Agrana Juice Ltd.)
Colour parameter (L*)	CIE Lab Color Measuring System with a Konica Minolta CR 410 manual digital color meter
Dry matter (refraction %)	Codex Alimentarius 558/93/EEC

Results and Discussion

As shown in the abstract, we examined the lactic acid and anthocyanin content during the harvest of 2018. As we see on Figure 1, the temperature decreased to 15°C from a light summer-end weather because of two rainy days, but after it started to rise again.

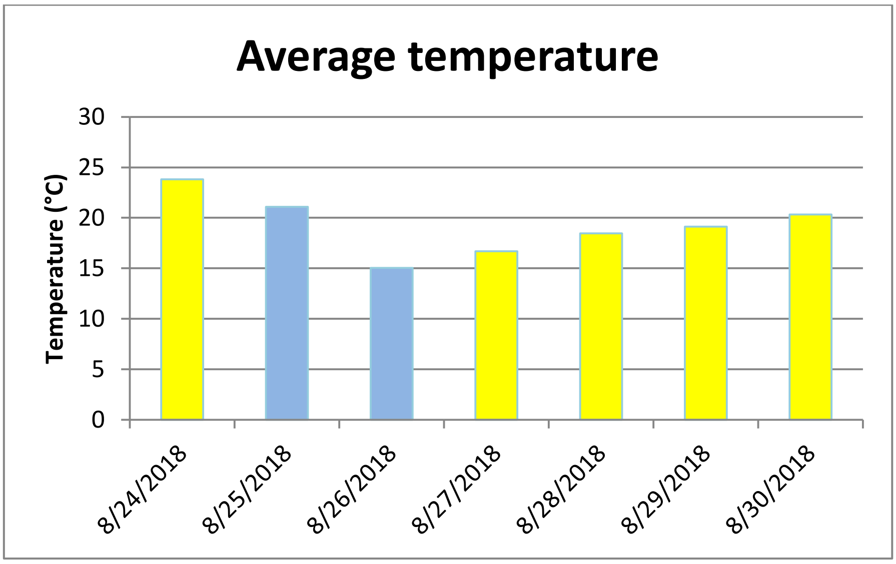

Figure 1. Average temperature changing during harvest

The problematic compound, the lactic acid had a level of about 40 mg/l in the samples of the first day. Three days later, after raining and temperature decreasing, this level dropped to the half, 20 mg/l. As the weather got warmer again, the lactic acid content grew back fastly, moreover to 80 mg/l, twice higher than the original level.

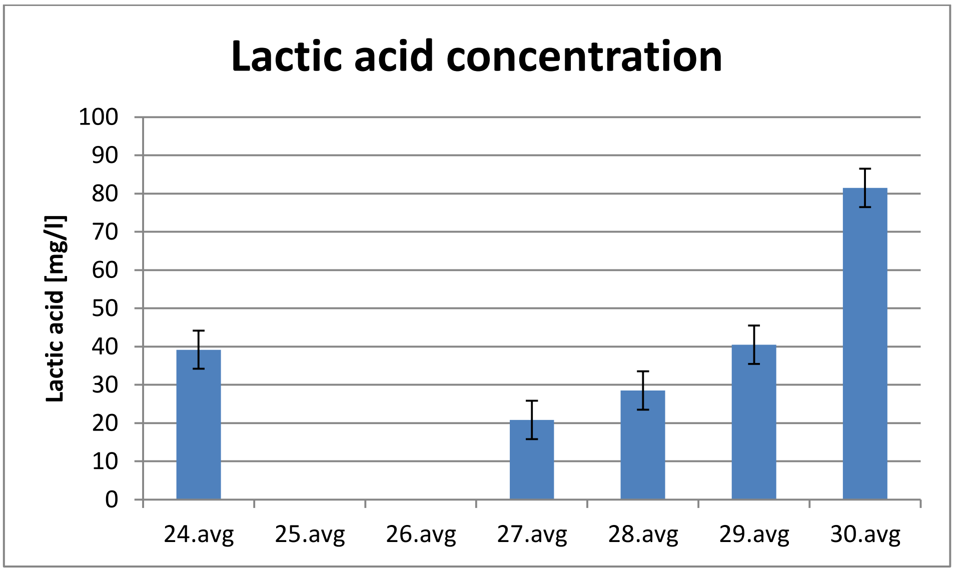

Figure 2. Lactic acid growing of elderberry samples

According to Figure 3., dry mass content was around 13% on the first day, which also decreased after raining to 11%, and started to grow as the effect of warming. Comparing to lactic acid content, this parameter rised only to the level before raining, not significantly higher.

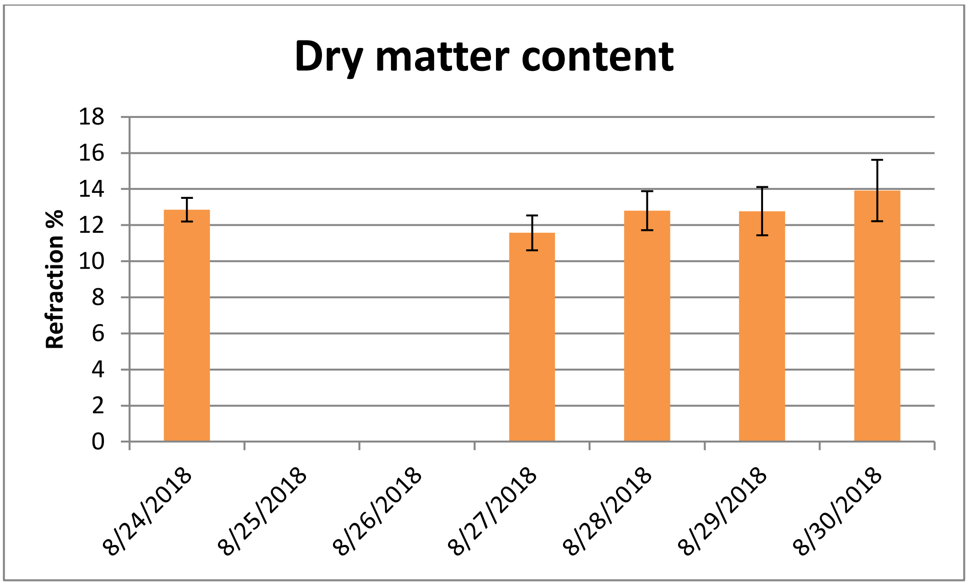

Figure 3. Refraction values during the mentioned days

The other main subject of our project is the coloring compound, the anthocyanin content. During maturation, many biochemical reactions occur in fruits, like aromatic compunds, sugars, ethylen and anthocyanins are synthesized. Some fruits and vegetables are bought according to the colouring content.
As shown on Figure 4., the anthocyanin concentration was the lowest on the first day of harvest: around 3900 mg/l. After raining, it got higher and higher (from 4000 mg/l to 4300 mg/l), but the levels do not follow each other in order.
Accordingly, there is an inverse proportion between anthocyanin concentration and lightness value: when the anthocyanin increased a lot on a harvesting day, the lightness value

decreased, as well. This tendency is the most visible on the pair of 2018. 08. 28. samples, where the anthocyanin concentration is the highest, 4450 mg/l, and the belonging L* is 18,5.

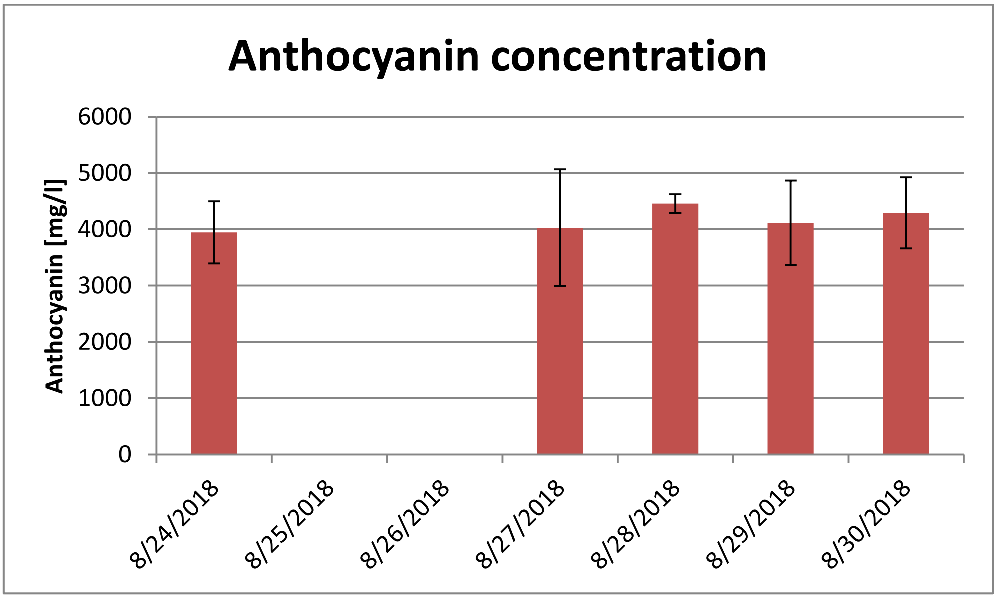

Figure 4. Changing of anthocyanin content in berries

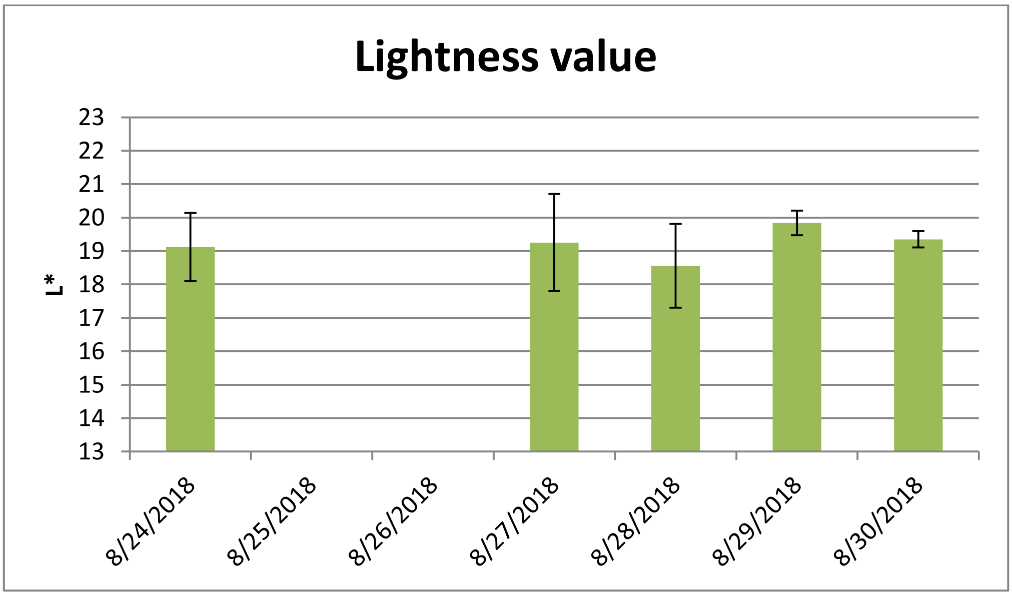

Figure 5. Colour index (L*) changing during the harvest

Conclusion

As the previous figures show, the temperature significantly influences the lactic acid concentration, and also has an effect on dry mass content of elderberry.

The proportion between temperature and lactic acid concentration is straight, which is in connection with the temperature optimum of lactic acid bacteria. They are mesophilic microorganisms, so the temperature lower than 20°C blocks their reproduction and lactic acid production. The refraction % dropping occured because the rain extracted some water soluble components from the berries. The temperature did not have an impact on anthocyanin content. This parameter also increased after raining, but there is not an order in datas, so the time of maturation is the factor that influences coloring content instead of temperature changing.

REVALUATION OF NATIVE CORN TO FACE ENVIRONMENTAL CHANGE

José Sergio BARRALES-DOMÍNGUEZ*; Edgar BARRALES-BRITO

Department of Phytotechnics. Chapingo Autonomous University. Chapingo, Mexico
[1]Postgraduate College, Montecillo, Mexico

Abstract

Each sowing with improved maize moves to the native maize (MN). Producers accept them for their good performance under favorable conditions, but this behavior in rainfall agriculture is not certain. It is known that the genetic diversity within the MN ensures a certain yield under droughts in Mexico, so the objective of this work is to analyze the flowering stage in blue MN (MNAz) under the rain variations and point out its advantages under that environmental tension. Three locations (Loc) were planted with MNAz of 14, 16 and 18 rows, in which the dynamics of flowering and yield were recorded. Within each corn, there were cobs of different rows, predominantly those of 16 in the three locations. In 2018, in the eastern region of Tlaxcala, Mexico, agriculture suffered losses due to droughts of 30 and 45 days, causing economic damage to the country. Under these conditions, in Loc1 the yield of MNAz1 was 4,431.4 kg/ha and in MNAz2 2,213.7 kg/ha; in Loc2 with MNR/N it was 3,911.8 kg/ha and in Loc3 with MNAz3 it was 1,076.5 kg/ha. The performance is explained by the dynamics of female flowering under drought, through characters of escape to drought. In Loc1 the prolificity index was 0.92 in MNAz1 and 0.64 in MNAz2; in Loc 2 of 1.2 and 0.54 in Loc3. The improved corn yields between 0.1 and 0.8 ton/ha locally, which stimulates the MN to improve.

Keywords: *Native blue corn, female flowering, rain, prolificity index*

Introduction

The massive planting of improved maize causes its genetic erosion, which endangers native corn. In Mexico, it is estimated that around 25% of the corn planting is improved, reaching up to 70% in regions with technology (Ortega *et al*., 2000). Although there are producers who keep native seeds, at present this is no longer so true, due to the difficulty of preserving them. Therefore, it is also studied how to conserve them in regions where this practice exists, finding that with metallic silos they are conserved with grain moisture below the recommended 13.5%, ensuring germination greater than 86.2% (Manuel *et al.,* 2007). The above is important because in MNAz of the high plateau a variant of the flour starch dominates that makes it specific for tlacoyos, tamales and blue tortillas (Muñoz *et al*., 2009), but very sensitive to the attack of pests in the warehouse.

Yield is determined by the production environment, so, yielding maize families, they were because they flourished in times with good rainfall (PP), while those of low yield female flowers ("jilotes") in times with low PP. With limitations of humidity, the rain that explains the yield is the one that accumulates from two weeks before to two weeks after the "jiloteo". In contrast, without humidity limitations, the temperature around female flowering (FF) is what explains the yield potential (Barrales *et al*., 1984). It is also known that in regions with prolonged drought the production of corn stubble becomes more important than of grain (Muñoz *et al*., 2009).

The nutraceutical importance of colored corn is important today, although it was already known that corn with anthocyanin pigment is what regulates the color of anthocyanins (Salinas *et al.,* 2012), whose safety for consumption human forces to take advantage of its antioxidant, antimutagenic and anticancer properties (López-Martínez, 2009), given the public health problems in Mexico. It was found that the antioxidant activity has a high correlation (r

= 0.72 **) with the anthocyanin content (Ruiz *et al*, 2008), but it is suggested to see its changes when making food.
The quality of native or native corn is not in doubt, and proof of this is the diversity of uses associated with each type of corn. Blue corn has a protein quality with lysine contents between 3.0 and 4.13% and tryptophan between 0.417 and 0.629% (Vidal *et al*., 2008). It is also mentioned that there are maize that contribute more than 50% of the needs of lysine and tryptophan, which makes it possible to suggest, quantify its contents in each pigmented corn and recommend its specific use in infant feeding.
Lately, the genetic improvement in corn is directed to variables of interest for the dough and tortilla industry, such as starch content, oil and protein quality (Vázquez-Carrillo *et al.*, 2018), however, what is needed it is to benefit consumers, which implies recovering the MN with its nutritional, nutraceutical and functional properties. In that sense, given the recurrent presence of droughts during flowering in corn that causes loss of yield, this work is proposed with the objective of analyzing the flowering stage in blue MN (MNAz) under the variations of rainfall at that stage.

Materials and methods

In 2018, during the seasonal agricultural cycle in Cuapiaxtla, Tlax., four batches of evaluation with MNAz with different rows (NH) were sown. In the first batch (Loc1), blue maize was planted with 18-rows (MNAz1) and 20-rows (MNAz2), registering the emergence date (FE) on April 29. In Loc2 16-row mixed red and black corn (MNR/N) was planted with FE on May 8 and Loc3 was planted 16-row corn (MNAz3) with FE on May 7. In each locality four evaluation sub-lots were delimited, five rows of five meters long and 85 cm wide, distributed in the four ends of each lot. Within each sublot 25 plants were marked to record male flowering (FM) or panicle emergence (EmPa) and female flowering (FF) or "jilot" emergency (EmJil) during flowering. Male Flowers and female flower were counted every eight days to have the dynamics of flowering. With simple linear regression (Ostle, 1974), the age of the plant and the number of flowering plants were related, to estimate the daily appearance of "jilotes".
During the biological cycle of the plants, rain was recorded with a Weekly Accumulation Rain Gauge (Barrales, 1980), to analyze the dynamics of FF and the yield in each environment, according to the variation of the rain. The rainfall received by the plants was estimated since two weeks before the FF (PPpreFF), until to two weeks after it (PPposFF). The yield was evaluated in the two central grooves of each sublot, where the number of harvested plants and cobs that were carried at constant weight was recorded and the yield components, grain yield per ha, cob weight and of grain per plant, pot weight, percentage of pot and prolificity index to see the number of ears per plant. Simple linear regression, analysis of variance and test of means were used with the Tukey procedure (Steel and Torrie, 1980), using the SAS package.

Results and Discussion

In all locations there was drought (S) in the flowering stage, a recurring phenomenon in temporary agriculture. In corn, the lack of water during flowering almost does not prevent EmPa, but it does affect EmJil, which in extreme cases does not occur, and with it, although there is little pollen, there are no stigmas that receive it, decreasing the fertility of the ovules and seed formation.
In each variety the typical floral asynchrony of the corn plant was observed, that is, the panicle first appears and then the jilote, as a mechanism to reduce self-fertilization. In heterogeneous populations of heterozygous maize such as MN, not all plants bloom at the same time, so that early plants start with EmPa and then they will be the first to emit jilotes, coinciding with other plants that start their EmPa and that will be the ones that pollinate it.

This mechanism puts the later ones at risk, which emit jilotes when there is no plant with pollen release, causing cobs with few grains. When relating plants with EmPa and EmJil over time, simple linear regression models (Table 1) were found with high coefficients of determination (R^2), greater than 0.9. In the models, according to the regression coefficient, it is observed that every day they appeared between 0.73 panicles in MNR/N and 0.88 in MNAz3. In the case of "jilotes", between 0.61 in MNR/N and 0.71 "jilotes" per day in MNAz1, MNAz2 and MNAz3 were recorded every day. In the latter, 100% of EmJil was never registered, due to the greater intensity of the drought.

Table 1. Linear regression models that quantify the relationship between the number of male or female flowering plants (X) with the age of blue corn plants (Y), planted in three locations under reinfall conditions in Cuapiaxtla, Tlax. 2018.

In Loc1 with MNAz1 and MNAz2 up to 63 days of age of the plants, 224.35 mm rainfall accumulated, and then have three weeks without rain defining an S of 34 days (between 64 and 98 days dde (days after the emergency)). The average EmPa was day 82 in MNAz1 and one day later in MNAz2, and in both, the average EmJil was at 96 dde. It has been found that the accumulated rainfall since two weeks before until two weeks after the FF (Barrales *et al.*, 1984) influences the yield more; in this case, on average both maize received in this period, 34.3 mm of rain. It was observed that 13.3% of the plants were early and received only 2 mm of rain in pre-flowering; at 90 dde, 48% were blooming and those received 28.1 mm of PPposFF and the rest of the plants received 34.9 mm in the same period. The 12.3% of the plant were the latest and received the greatest amount of rainfall distributed between pre and post-flowering female. In the locality where the MNR/N was evaluated, until day 54 where it rained 235.27 mm, and then there was an S from 55 to 90 dde. In this locality the average EmPa occurred at 83 dde and EmJil at 96 dde, which coincides with a maximum rainfall on day 90, accumulating rain of 148.47 mm until day 131, which allowed the corn to evade effects of drought. During the average flowering period, 34.3 mm of rain were received, especially after FF, although in this case the earliest plants were 5% and received 69.9 mm of rain after EmJil; 22.7% of plants received 73.2 mm of rain after EmJil, and the other 41.3%, 9.3% and 13.3% received 84.1, 111.3 and 91.7 mm of rain before and after EmJil, which allowed them to have good Humidity conditions, although it was not the highest performance. In the lot with MNAz3 the lowest amount of rain was recorded, because until day 70, was

155.02 mm of rain accumulated, then face four weeks without rain. It was until day 91 when it rained, accumulating until day 125, 93.34 mm. The average EmJil occurred at 95 dde, and around flowering 41.4 mm of rain was received, mainly in post FF, from day 96 to two weeks later. Until the 97th day, the plants received rain after EmJil, so that 4% of early plants received 27.1 mm, 36% of plants received 39.9 mm and 24% received 42 mm of rain. Later plants coincided with better rain conditions. Thus, 17.3% of plants received before and after EmJil, 60.6 mm of rain and 5.3% of late plants received 93.3 mm of rain around the FF. Grain yields were 4431.5, 2213.5, 3911.8 and 1076.5 kg/ha in MNAz1, MNAz2, MNR/N and MNAz3 respectively (Table 2). In the locality with MNAz1 and MNAz2 a total of 365.18 mm of rainfall was recorded in the biological cycle, which contrasts with the locality where MNAz3 was with the lowest yield, where it rained 348.80 mm, that is, only 16.38 mm of rain less. It happened that, before the S in both environments, in the first one 224.35 mm had already been received while in the other only 155.02 mm of rain, which caused an effect on the development registering a prolificity index of 0.5 (Table 2).

Table 2. Result of the test of means with the Tukey procedure in variables registered in blue maize evaluated in rainfall agriculture conditions in Cuapiaxtla, Tlax. 2018.

Variable	MAz1	MAz2	MR/R	MAz3
number of plants per hectare	57254.9 a	45882.4 b	33823.5 c	44411.8 b
Number of cob per hectare	52647.1 a	29117.6 c	40294.1 b	24411.8 c

seed weight (mg)	376	372	343	372

Need to explain what are the letters a, ab and what the different letters mean statistically
Another important element that influenced the performance in Loc1 was that after S, between 99 and 147 days, it rained 136.46 mm, followed by a week without rain and then between 155 and 168 dd, 4.37 mm were received. On the other hand, in the MNAz3 after the S it rained between 91 and 125 dde, 93.34 mm and then returned to present another four weeks without water that directly affected the grain filling. Here, in the end, between 154 and 181 dde were recorded 100.44 mm of rain, which in no way favored the filling of grain, but it affected the quality of it by wetting the cobs and rotting the grain.

In the case of the MNR/N after the four-week S, between 148 and 131 days, 148.47 mm cried, then two weeks without rain, without showing effects of water deficit in the plants, since there was humidity in soil. In the end, between 146 and 159 dde it rained 30.57 mm that could be grained. In this plot it was where he obtained more rain (414.31 mm) and the EmJil had under favorable humidity conditions. Here, plants have no mechanism to evade or resist any adverse condition effects, such as S (Loomis and Connor, 2002).

The current genetic improvement looks for short flowering stages, that is, a short time between EmPa and EmJil, which shows a corn crop blooming almost at the same time. However, when MN does not flowering all at the same time, they can effectively confront the phenomena of S, because they affect when it occurs, it will impact differently to the early, intermediate or late ones within the same MN. Also, we can use varieties of different cycles to face the magnitude of rainfall between corn producing areas (Luna et al, 2005), but when the FF is short, if it coincides with the drought, the yield loss can be total.

Conclusions

The amplitude in the stage of male and female flowering in native maize allows us to confidently face the adverse effects of the drought, as it does not cause equal damage to all the plants within the population, since it will only affect those that affect pre flowering and flowering.

Abstract

Grass-legume mixtures are important crops in the production of quality forage. Soil acidity is one of the factors which limit growth of many legumes and grasses. The aim of the study was to analyze the effect of liming (control – without CaO; 3 t ha^{-1} CaO; 6 t ha^{-1} CaO) an acid soil with a pH of 4.8, on the forage yield, hay yield, the proportion of red clover, Italian ryegrass and weed in the total hay yield. The experiment was performed in the period 2014-2016. The trial was set in a randomized block design with three replications and with a plot size of 5 m^2. Sowing was done on 20 cm row spacing of. In the 2014 and 2016 analyzes were carried out on three and in the 2015 on two obtained cuts, due to drought. The total hay yield of grass-clover mixture for all of the three years in control was 36.0 t ha^{-1}, in the treatment with 3 t ha^{-1} of lime, the yield was 39.607 t ha^{-1} and in the 6 t ha^{-1} of lime, the yield was 37.279 t ha^{-1}. Soil liming had an impact on the forage and hay yield in the first cut in the second and third year of production. In drier periods of the year, soil liming influenced the significant increase in the weight ratio of Italian ryegrass. However, in the wet times of the year, the stronger impact of soil liming was reported for the development of red clover.

Keywords: *forage yield, Italian ryegrass, liming, red clover, weeds.*

Introduction

The precondition for intensifying livestock production is to produce sufficient quantity of high quality forage. Average hay yields in meadows in the Republic of Serbia are low and range between 1.5 - 2.0 t ha^{-1}. One of the main reasons for low and unstable yields and poor forage quality is the lack of application of agro-technical measures (Dubljević, 2007).In present days, there are tendencies of reducing energy consumption and environmental pollution, intensifying systems of sustainable agriculture and biodiversity preservation. For this purpose, among the other things, the inclusion of forage legumes into grass mixtures should be carried out. The introduction of legumes in systems of forage crops production reduces the use of nitrogen fertilizers possibility of losing nitrogen from the soil by leaching or emission in form of gasses, is reduced (Ledgard et al., 1999). Symbiotic fixation of nitrogen in legumes is the basic process for maintaining fertility of the soil and productivity of organic systems of cultivation (Vinther and Jensen, 1999). By cultivating legumes and grasses in mixture, a more viable production and better quality of forage is achieved (Nešić et al., 2007). Also, the share of weeds in the total yield of grass-leguminous mixtures is considerably smaller as compared to clean grass or leguminous crop (Sleugh et al., 2000).

Acidity of soil is one of the factors that makes it difficult to cultivate grass and legumes (Wheeler, 1998). Soil reaction affects all of the stages of plant development, resistance to disease, resistance to low temperatures, life span, forage yield and quality. Acidic soils, with addition to the lack of calcium, are distinguished by the high presence of easily mobile forms of Al, Fe, Mn and reduced content of easily accessible P, K and Mo (Su and Evans, 1996). Problems of acidic soils can be successfully solved by the introduction of lime fertilizers

(Grewal and Williams, 2003). Considering that acid soils occupy significant areas in the Republic of Serbia, the aim of the research was to investigate the effect of liming on such the soil on the yield of grass-leguminous mixture of red clover and Italian ryegrass.

Materials and methods

The field trial was set up in 2014 in Čačak (43°54'39.06" N, 20°19'10.21" E, 246 m a.s.l.) on a leached vertisol with acid reaction (pH_{H2O} 4.8), which contains 3.18% organic matter, 0% $CaCO_3$, 22.08 mg P_2O_5, 30.0 mg K_2O 100 g^{-1} of soil. Before the basic cultivation of the soil and after the end of vegetative periods, fertilization was carried out with 300 kg ha^{-1} $N_{15}P_{15}K_{15}$ or how many kg of each element per ha. The trial was set up on a completely random block system in three replications, with the experimental plot size of 3 m^2 (3x1 m). The analyzes were carried out on the grassy leguminous mixture of red clover (variety Kolubara – Institute of Field and Vegetable Crops in Novi Sad) and Italian ryegrass (Tetraflorum – Slovenian tetraploid cultivar). The research covered three levels of soil liming (control – without CaO, treatment with 3 t ha^{-1} CaO and treatment with 6 t ha^{-1} CaO). The introduction of lime material was done by surface application immediately before the pre-seeding preparation of the soil. The sowing was carried out at a distance of 20 cm between rows (Italian ryegrass and red clover were sown in the same rows), with a seed quantity of 12 kg ha^{-1} of red clover, and 12 kg ha^{-1} of the Italian ryegrass. The crop was grown without the use of irrigation. The analysis were carried out on three obtained cuts in 2014, two cuts in 2015 (due to the pronounced drought periods) and on three cuts in 2016. Mean annual air temperature in 2014, 2015 and 2016 was 13.15°C, 13.14°C and 12.4°C respectively, and the annual rainfall was 902 mm, 547 mm and 767 mm respectively (Table 1). The average annual air temperature for many years (1992-2002) is 11.97°C, and the average annual precipitation is 680.3 mm.

Table 1. The amount and distribution of rainfall by month (P) and mean monthly temperatures (T) for 2014, 2015, 2016 and the period 1992-2002.

Month		I	II	III	VI	V	VI	VII	VIII	XI	X	XI	XII	$\bar{x}$ i $\sum$

Mowing was carried out in the stage of budding of red clover. The forage yield was determined by measuring the total biomass from the plot immediately after mowing. From the measured sample (1000 g), after drying at room temperature, the hay yield (t ha^{-1}) was calculated and the weight ratio of the Italian ryegrass, red clover and weeds in the hay was determined. The obtained results were processed using the analysis of variance (ANOVA) in SPSS 4.5 software. The significance of the difference in mean treatment values was tested by the LSD test.

Results and discussion

Soil liming did not have an impact on the forage and hay yield in the first year of growing grass-legume mixture of red clover and Italian ryegrass (Table 2). The average hay yield in the first cut was 10.01 t ha^{-1}, in the second 4.376 t ha^{-1} and in the third 1.41 t ha^{-1}. Simić et al. (2011) was determined lower yields of grass-legume mixture of red clover and Italian ryegrass in the first year of production, which is a result of less precipitation during the vegetation period.

Table 2. Influence of soil liming on the forage yield, hay yield, proportion (%) of Italian ryegrass-red clover and weeds in the total yield in 2014

Cut	Liming	Forage yield ?	Hay yield?	Ryegrass weight ratio (%)	Clover proportion weight ratio (%)	Weed proportion weight ratio (%)
1	ø	27.31	9.83	88.7	8.3 b	3.01
	3 t ha^{-1}	29.88	11.38	84.8	11.9 a	3.31
	6 t ha^{-1}	26.42	8.82	93.3	3.6 c	3.03
2	ø	12.18	3.78	61.0 a	33.2 c	5.8
	3 t ha^{-1}	16.78	4.57	50.1 b	42.1 b	7.8
	6 t ha^{-1}	16.19	4.78	41.3 c	50.9 a	7.8
3	ø	5.18	1.16	32.0 a	61.6 b	6.45 a
	3 t ha^{-1}	6.25	1.35	10.0 b	88.8 ab	1.27 c
	6 t ha^{-1}	7.07	1.72	0.1 c	95.2 a	4.73 b

The values denoted with different small letters within columns are significantly different ($p \leq 0.05$) in accordance with the LSD test.

In the first cut in 2015, on the treatment with 6 t ha^{-1} of lime, a significantly lower forage yield was obtained as compared to the control and treatment with 3 t ha^{-1} of lime, while the hay yield did not differ significantly (Table 3). The reason for this is the impact of liming on the change in the floristic composition of the grassland. Liming had a more positive impact on the red clover, which caused its weight ratio in the mixture to increase, and the weight ratio of the Italian ryegrass reduced get lower?, thus reducing the overall yield. In the second cut there was no effect of soil liming on forage and hay yield. The average hay yield in the first cut in 2015 was 8.01 t ha^{-1}, and in the second cut 4.573 t ha^{-1}.

Tabela 3. Influence of soil liming on the forage yield, hay yield, proportion (%) of Italian ryegrass, red clover and weeds in the total yield in 2015

Cut	Liming	Forage yield	Hay yield	Ryegrass proportion weight ratio (%)	Clover proportion weight ratio (%)	Weed proportion weight ratio (%)
1	ø	34.43 a	8.13	76.0 a	24.0 c	-
	3 t ha^{-1}	30.88 ab	8.35	47.1 b	52.9 b	-
	6 t ha^{-1}	26.42 b	7.54	6.2 c	93.8 a	-
2	ø	13.6	3.89	43.2 a	56.1 b	0.74 a
	3 t ha^{-1}	15.2	4.24	20.7 b	79.2 a	0.10 b
	6 t ha^{-1}	21.2	5.59	17.0 b	82.4 a	0.85 a

The values denoted with different small letters within columns are significantly different ($p \leq 0.05$) in accordance with the LSD test.

In the third year of production, there was no Italian ryegrass, and the weight ratio of weeds was very high, especially in the first cut (Table 4). The forage and hay yield in the first cut was significantly reduced in the treatment with 6 t ha^{-1} as compared to the control, while in the second and the third cut the forage and hay yield did not significantly depend on the liming of the soil. The hay yield in the first cut was 0.646 t ha^{-1}, in the second 5.987 t ha^{-1} and in the third 2.485 t ha^{-1}.

Tabela 4. Influence of soil liming on the forage yield, hay yield, proportion (%) of Italian ryegrass, red clover and weeds in the total yield in 2016

Cut	Liming	Forage yield	Hay yield	Ryegrass proportion weight ratio (%)	Clover proportion weight ratio (%)
1	ø	3.933 a	0.746 a	11.7 ab	88.3 ab
	3 t ha^{-1}	3.544 ab	0.705 ab	7.0 b	93.0 a
	6 t ha^{-1}	2.867 b	0.489 b	19.0 a	81.0 b
2	ø	14.76	5.51	31.5 ab	68.5 ab
	3 t ha^{-1}	16.28	6.36	26.0 b	74.0 a
	6 t ha^{-1}	15.93	6.09	38.6 a	61.4 b
3	ø	9.51	2.552	35.8	64.2 a
	3 t ha^{-1}	9.81	2.652	57.1	4.9 c
	6 t ha^{-1}	9.17	2.250	57.0	43.0 b

The values denoted with different small letters within columns are significantly different ($p\leq0.05$) in accordance with the LSD test.

The total hay yield in 2014 was 15.797 t ha^{-1}, in 2015 12.58 t ha^{-1} and in 2016 9.118 t ha^{-1}. Higher yield in the first year in relation to the second is the consequence of higher precipitation, especially in the second period of vegetation. The total yield for the three years in the control treatment was 36.00 t ha^{-1}, in the treatment with 3 t ha^{-1} of lime 39.61 t ha^{-1}, and on the one with 6 t ha^{-1} 37.28 t ha^{-1}.

In the second and the third cut during the first year of exploitation, the liming of soil affected positively and significantly the weight ratio of red clover in mixture, at the expense of reducing the weight ratio of Italian ryegrass and weeds. However, in the first cut, the weight ratio of red clover was decreased with the application of liming, due to the increase in the weight ratio of the Italian ryegrass. The reason for this inconsistent impact of liming on the change in the weight ratio of clover and ryegrass can be a different amount of precipitation. In drier periods of the year, liming has influenced a significant increase in weight ratio of the Italian ryegrass, as confirmed by the results of Tomić et al. (2013). Thomas (1984) pointed to the similar results, according to which in the conditions of drought, the competitive ability of the Italian ryegrass was more expressed in relation to the red clover. However, in the wet times of the year, the stronger impact of soil liming was noted for the development of red clover, and then the weight ratio have increased.

In 2015, in the first cut, the weight ratio of red clover was increased significantly with the increase in the amount of lime applied, at the expense of reducing the weight ratio of Italian ryegrass. Due to very strong competitive ability and rapid space for growth of red clover and Italian ryegrass, there were no weeds. In the second cut, the weight ratio of red clover was significantly higher and the weight ratio of Italian ryegrass was lower in the treatments as compared to the control, while there was no difference between the treatments. The weight ratio of weeds in the second cut was below 1%. Živanović-Katić et al. (2008) state that the application of liming leads to a change in the floristic composition of plant communities, in way of achieving larger density of crops and reducing the weed weight ratio .

In the third year of production, there was no Italian ryegrass, the weight ratio of red clover was smaller, and the weight ratio of weeds was high. Therefore, the weight ratio of red clover and weeds in all three shots did not differ significantly in treatments, as compared to the control.

Conclusion

Soil liming did not have any effect on forage and hay yields except in the first cut in the second and third year of production, when significantly less forage yield as compared to the control was obtained for the treatment with 6 t ha^{-1} of lime. The hay yield did not change significantly during the second year in the first cut under the influence of liming, while in the third year on the treatment with 6 t ha^{-1} was significantly lower as compared to the control. The total hay yield for all three years was for control 36.0 t ha^{-1}, for treatment with 3 t ha^{-1} of lime the yield was 39.607 t ha^{-1} and for treatment with 6 t ha^{-1} it was 37.279 t ha^{-1}.

The impact of soil liming on the weight ratio of the Italian ryegrass and red clover in the forage was inconsistent. The reason for this is a different amount of precipitation during certain periods of the year. In drier periods of the year, soil liming has influenced a significant increase in the weight ratio of the Italian ryegrass. However, in the wet times of the year, the stronger impact of soil liming was recorded on the development of the red clover, and then its weight ratio increased. In the third year of production there was no Italian ryegrass, the weight ratio of red clover was smaller, and the weight ratio of weeds was high.

Abstract

The influence of the length of the one-year-old branches (under 5 cm, 13-17 cm and above 25 cm) and the catkin position on these branches (basal, middle and terminal) to the number of staminate flowers per catkin, the number of stamens per staminate flower and the number of stamens per catkin was studied. The number of staminate flowers per catkin amounted to 56-123 (average 95.4). From the base to the top of the branch, the number of staminate flowers per catkin increased. The highest average number of stamens per staminate flower was found in catkins on the branches 13-17 cm long (20.8), and the smallest in the branches under 5 cm long (17.8). In the catkins at the base of the branches, the staminate flowers contained the smallest number of the stamens (on average 17.8), while in the catkins in the middle and the terminal zones of the branches the staminate flowers contained an average of 19.4 and 19.9 stamens respectively. The number of stamens per catkin ranged from 1120 to 3075 (average 1825.6). The largest number of stamens per catkin was determined on the branches 13-17 cm long (2001.6), and the branches up to 5 cm in length had the fewest stamens per catkin (1617.4). From the top of the branch to its base, the average number of anthers per catkin decreased from 2084.5 to 1503.3.

Keywords: *Juglans regia, stamen, male inflorescence, plant reproduction*

Introduction

The family Juglandaceae consists of seven genera, comprising about 60 tree species. The genus *Juglans* contains circa 20 species, of which the Persian walnut (*Juglans regia* L.) is the most widely cultivated and economically important species of edible nuts in the temperate regions of the world (McGranahan and Leslie 1990).

Persian walnut is the main nut crop in Serbia. The total production of walnuts in a shell from 2012 to 2017 in Serbia has varied from 12276 tonnes in 2017 to 18336 tonnes in 2013. The total walnut production area in Serbia in 2017 was 3307 ha, and the average yield from 2012 to 2017 was 3712 kg/ha (FAO, 2017).

Walnut is a monoecious, wind-pollinated, and self-compatible fruit tree. Staminate flowers are borne on catkins, usually 10 to 15 cm in length, which emerge from lateral buds on the wood from the previous season's growth (Figure 1).

The individual flowers lack petals and consist primarily of a whorl of green sepals that surrounds up to 40 pollen-bearing stamens on each flower. Each stamen terminates in a pollen-bearing organ, the anther (Polito, 1998).

In the previous studies, the authors have recognized that the main causes of morphological differences in the structure of catkins are the walnut genotypic specificities of the species and cultivars (Molina *et al*., 1996; Mert, 2010; Sütyemez, 2007; Ozcan *et al*., 2017), and that the position of staminate flowers on the axis of catkins is the basic factor determining number of stamens in staminate flowers (Germain *et al*., 1975; Impiumi and Ramina, 1967).

The establishment of staminate catkins in the walnut buds takes place during the spring of the year preceding their flowering, on about the 25th day after the initiation of leaf sprouting (Šebánek *et al*., 1991). The young meristems of walnut buds may develop in three different ways as stamen primordia, as vegetative buds or as terminal buds with pistillate flowers (Sladký, 1972). The origin of three different types of buds on the branches of fruitful walnut trees gives the impression that the course of this differentiation is most probably affected by endogenous regulators (Langrova and Sladky, 1971). According to Atsmon and Galyn (1962), the pattern of primordia development is regulated hormonally with a strong modifying influence exerted by the adjacent leaf.

The aim of this paper is to draw attention to the need to determine the factors expressing the regulatory function in the process of formation of reproductive organs in walnut. One of the unknowns in this process is the way in which the length of one-year-old branches, as well as the position of catkins on these branches, affects the number of staminate flowers in catkins, the number of stamens in flowers, and the number of stamens in catkins.

Materials and methods

This study was carried out in 2014 and 2015 on Serbian walnut cultivar 'Šampion'. Plant material has been collected from walnut trees grown in an orchard situated near the town of Kraljevo (Central Serbia).

Samples of flower branches with catkins were collected from different parts of the crowns and were classified according to length in three groups: 1) up to 5 cm in length, 2) from 13 to 17 cm and 3) over 25 cm. Each group contained 30 branches that were taken from five trees of each variety examined. One catkin from the basal, middle and terminal part of each bearing branch was taken as a sample. The number of staminate flowers per catkin, the number of stamens per staminate flower and the number of stamens per catkin was studied. Since the number of stamens in staminate flowers decreases from the base to the top of catkins, the number of stamens per male flower is determined as an average of three flowers in the middle of the catkin.

Counting of staminate flowers and stamens was performed under a stereoscopic microscope, model STM-9 Pro (Nanjing Microtech Scientific Instrument Co., Jiangsu, China) at a magnification of 10-60 times. Photographing of samples was performed with Canon EOS 700D (Canon Inc., Tokyo, Japan). The number of stamens per catkin was calculated by multiplying the number of staminate flowers per catkin with an average number of stamens in the three flowers in the middle of the catkin.

The data obtained are processed by the statistical method of the analyses of variance. The significance of differences between mean values is determined by Tukey´s test at $P = 0.05$.

Results and discussion

The number of staminate flowers per catkin

The number of staminate flowers per catkin in the two-year research period ranged from 56 to 123, with an average value of 95.4. These results are in agreement with the findings of other authors. Germain *et al*. (1975) stated that catkins of the walnut contain about 100 to 160 staminate flowers, spirally arranged along the axis of the catkin. According to Molina *et al*. (1996), depending on the genotype, walnut catkins contained 95-300 staminate flowers. Sütyemez (2007) examined the production of pollen in 32 genotypes in Turkey and found that the number of staminate flowers in catkins ranged from 109-148. Ozcan *et al*. (2017) state that the catkins of four varieties of walnuts contained 117 to 140 staminate flowers.

The factor year had a significant impact on the number of staminate flowers per catkin. In 2014, the average number of staminate flowers per catkin was 90.2, while in 2015 the average value of this parameter amounted 100.7. Janković (2016) states that the average number of

flowers per catkin over the three-year study period was 120.1. On this parameter, a significant influence had the genotype, year and the interaction between genotype and year.
As the length of branches increased, the number of staminate flowers per catkin increased. The number of staminate flowers per catkin at branches shorter than 5 cm (90.5) was significantly lower than the number of staminate flowers per catkin at branches longer than 25 cm (99.6). The number of staminate flowers per catkin on 13-17 cm long branches did not differ significantly from the value of this parameter to the other two categories of branches. Oparnica and Vulić (2006) concluded that the number of male and female inflorescences in hazelnut, as well as their arrangement at the bearing branches, are in direct dependence on the length of bearing branches.
From the base to the top of the branches, the number of staminate flowers in catkins increased. At the top of the branches, the average number of staminate flowers per catkin was 104.3 and significantly differed from the value of this parameter on the middle and basal part

Table 1. Effect of length of the one-year-old branches and catkin position on the number of staminate flowers and stamens

Factors	Factor levels	Number of staminate flowers per catkin	Number of stamens per flower	Number of stamens per catkin
Length of the branches (A)	< 5 cm	90.5 a*	17.8 a	1617.4 a
	13-17 cm	96.2 ab	20.8 b	2001.6 b
	> 25 cm	99.6 b	18.5 a	1857.7 b
Catkin position on the branch (B)	top	104.3 a	19.9 a	2084.5 a

*** – the differences are significant at p < 0.001

of the branches, and was 97.2 and 84.7, respectively.

Number of stamens per flower
The number of stamens per flower ranged from 13 to 24, with an average value of 19.1 (Table 1). The number of stamens per flower did not differ significantly over the years. According to Krueger (2000), Californian walnut genotypes contain an average of 40 stamens per flower, while Molina *et al*. (1996) state that in their researches the number of stamens per flower was

9-23. Sütyemez (2007) found that the number of stamens per flower among the 32 walnut genotypes ranged from 16-22. According to Ozcan *et al.* (2017), in the four studied walnut genotypes, the number of stamens per flowers was from 17 to 18.
Significantly more stamens had flowers on branches 13-17 cm long (20.8) than those on branches up to 5 cm (17.8) and over 25 cm (18.5). In the catkins at the base of the branches, the staminate flowers contained the smallest number of the stamens (on average 17.8), while in the catkins in the middle and the terminal zones of the branches the staminate flowers contained an average of 19.4 and 19.9 stamens, respectively. According to Germain *et al.* (1975), staminate flowers, depending on the location of the catkin, can have 2-32 stamens. The number of stamens in the flowers decreases from the base to the top of the catkins. In the studies carried out by Impiumi and Ramina (1967), the male flowers that were at the base of the catkins had an average of 18 stamens, and flowers at the top of the catkins 13 stamens.

Number of stamens per catkin
The number of stamens per catkin ranged from 1120 to 3075 (average 1825.6) (Table 1). In 2015, catkins contained significantly more stamens (1922.9) than in 2014 (1728.2). The highest number of stamens per catkin had the branches 13-17 cm long (2001.6), and the branches up to 5 cm in length had the fewest stamens per catkin (1617.4). The difference in this parameter between the branches belonging the largest and the lowest length category was not significant. From the top of the branch to its base, the average number of anthers per catkin decreased significantly from 2084.5 to 1503.3.

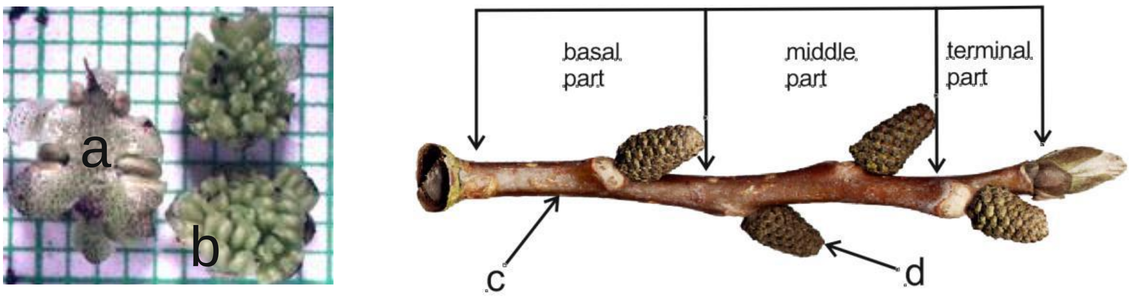

Figure 1. Appearance of staminate flowers, stamens and a bearing branch with catkins in walnut: a - staminate flower; b – stamens; c – bearing branch; d - catkin

In a shoot with multiple flowers, the shoot meristem becomes converted into an inflorescence meristem, which can form one or more floral meristems, each of which develops into a single flower. The floral organ primordia, from which the individual parts of the flower develop, arise in the floral meristem by patterned cell division followed by cell differentiation and enlargement (Wolpert *et al.* 2002). The young meristems of walnut buds may develop in three different ways: as stamen primordia, as vegetative buds or as terminal buds with pistillate flowers (Sladki, 1972). The origin and the development of single buds on the walnut branches is a gradual process. First 2 or 3 basal buds originate from primordia of staminate catkins following 3 to 4 vegetative buds, and only towards the end of the budding period primordia of pistillate flowers are differentiated in terminal buds. This succession in differentiation is analogous, to a certain extent, with the differentiation of staminate and the pistillate inflorescence of maize **(**Langrova and Sladky, 1971). The transition from vegetative to inflorescence shoot meristem is controlled by environmental signals including photoperiod and temperature (Laibach, 1951; Gregory and Hussey, 1953; Napp-Zinn, 1985), by intrinsic growth regulators such as the gibberellins (Napp-Zinn, 1969; Langridge, 1957; Wilson *et al.*, 1992), and by a system of flowering time genes (Martínez-Zapater, 1994).

The establishment of staminate catkins in the buds takes place during the spring of the year preceding their flowering, on about the 25th day after the initiation of leaf sprouting (Šebánek, 1991). The data given by Sladki (1972) show that spraying walnut shoots with 0,2% IAA or 0.1% MH in the period prior to 1 May may reduce the number of staminate buds and increase the number of vegetative buds.

Conclusions

As a monoecious species, in which male and female reproductive organs are separated in different blooms on the same tree, walnut is characterized by a complex sexual process, and thus quite different from most other fruit trees. Since the biology of reproductive organs is not sufficiently studied, many questions about sexual reproduction in walnuts have not yet been answered. Among numerous issues, it is of particular importance to define factors that regulate the process of transferring vegetative meristem into the generative phase of development, that is, to define the conditions that lead to the induction of male and female inflorescences.

Abstract

The research was carried out in 2014 and 2015. The influence of temperature (10°C, 15°C, 20°C, 25°C and 30°C) on pollen germination of two walnut cultivars (G139 and Elit) was examined. Cultivar and temperature both showed a significant effect on pollen germination. Conversely, the year did not affect germination. The least germination of pollen in both cultivars was at 10°C. The average pollen germination rates over the two years were 5% and 11.6% for G139 and Elite cultivars, respectively. The highest pollen germination rates were at 25°C, with G139 cultivar having 34.1% and Elite 44.4% germinated pollen grains. The influence of temperature on pollen germination of studied walnut cultivars is presented in the form of graphics of fitted cubic functions, based on the average values over the two years of research. The results highlight the issue of temperature impact on walnut pollen germination, emphasizing that the minimum temperature for walnut pollen germination is not 14°C (as commonly accepted) and suggesting the possibility that there are genotypes of walnut whose pollen can germinate at temperatures lower than 10°C.

Keywords: *Juglans regia, Geisenheim 139, Elit, temperature, cubic function*

Introduction

The Persian walnut (*Juglans regia* L.) is a wind-pollinated, monoecious, herkogamous plant (McGranahan and Leslie,2009). Walnut is self-fertile, but in most genotypes the period of pollen shedding and pistillate flower receptivity does not sufficiently overlap. Therefore, commercial walnut orchards should necessarily be co-planted with pollenizers (Polito, 1998). An important criterion to consider when choosing pollenizers, as well as the male parent for hybridisation in walnut breeding is pollen viability.

Information on pollen viability and germination is important for the study of reproductive biology of walnut and for the development of its genetic improvement program. Various methods can be used for estimation of pollen viability and germinability in horticultural crops. Two different approaches can be taken to estimate pollen viability: staining pollen with dyes and *in vitro* germination assay. Staining techniques aim to determine pollen enzymatic activity and membrane integrity. *In vitro* germination determines the actual germination ability of pollen under suitable conditions (Shivanna *et al*., 1991; Dantas *et al*., 2005; Tuinstra and Wedel, 2000), anditisthemostwidelyusedmethodof testing pollen viability in breeding programs (Marcellán and Camadro, 1996).

In vitro pollen germination is influenced by several factors, such as species, culture medium, temperature and time of incubation, and flower development stage at the time of sampling, in addition to storage conditions (Stanley and Linskens, 1974).

Temperature is one of the most important environmental factors that affect pollen performance during the progamic phase (Hedhly *et al*., 2005). Threshold and optimum temperature requirements for pollen germination are species-specific and, often, cultivar-

specific (Luza *et al*., 1987; Polito *et al*., 1991; Loupassaki *et al*., 1997; Rosell *et al*., 1999; Hedhly *et al*., 2004).
Cardinal temperatures for germination of pollen are usually in high correlation with average temperatures that prevail at the time of flowering, as evidenced by many authors, including: Griggs and Iwakiri (1975), Egea *et al*. (1992), Pirlak (2002), Mellenthin *et al*. (1972), Luza *et al*. (1987).
Polito *et al*. (1991) detected adaptive responses of walnut pollen germination to temperature during pollen development: optimal temperatures for pollen germination whose formation went under regular environmental conditions were lower than for pollen taken from the branches that were held at temperatures of 16-17°C from the beginning of February until the time of catkins shedding.
In spite of several studies conducted in the previous period to determine the minimum, optimal and maximum temperatures for germination of walnut pollen, no accurate answer has been given to this day. This study aimed to determine the cardinal temperatures for *in vitro* germination of the pollen of two walnut cultivars.

Materials and methods

Studies of temperature effects on in *vitro pollen* germination were performed over the two years, from 2014 to 2015.For the experiments, pollen of two walnut cultivars, G139 and Elit was selected. These cultivars are recommended for cultivation in Serbia in areas with the greater risk of late spring frosts due to the later start of their vegetational period (Mišić, 1989). Additionally, cultivar G139 is considered an efficient pollinator for other cultivars with the late start of the vegetational period (Cerović *et al*., 2003).
Pollen was germinated on media comprising: 0.7% agar, 15% sucrose, 300 ppm boric acid and 50 ppm calcium chloride. Five incubation temperatures were studied: 10±1°C, 15±1°C, 20±1°C, 25±1°C and 30±1°C. The temperature was recorded at three-hour interval as a mean value collected from the three thermometers whose accuracy is ±1^{o}C.
Pollen samples were collected between 8 and 10 a.m., at the time the catkins began to shed their pollen. The catkins were sampled from different parts of the crown of each experimental tree at the start of anther dehiscence. Under laboratory conditions, the catkins were laid out on black paper to release their pollen for three to four hours. Six hours after the catkins collection, pollen grains were inoculated onto germination media.
The pollen was germinated in sterile 35-mm-diameter Petri dishes, each containing 3 ml of medium. According to Taylor (1972), Petri dishes with germination media were exposed to a temperature of 4^{o}C for 24h to achieve optimal agar gel solidification before pollen inoculation. This prevents pollen grains from getting immersed too deep into the medium, which could interfere with the germination process or lead to intensive bursting of pollen tubes due to high hydration. The pollen was deposited by a fine brush to ensure even distribution of pollen grains on the surface of the medium. The importance of uniform pollen distribution on media surface was described by Giulivo and Ramina (1974), who discovered that pollen germination rates were higher in the areas with higher pollen grain density. Pollen grains were incubated in the dark for 24 hours at a temperature of 20°C. Upon incubation, the Petri dishes containing the germinated pollen were deep-frozen at -18°C to hold back pollen tube growth and preserve the material until further evaluation. The day before planned pollen observation under the microscope, Petri dishes were transferred from the freezing chamber to refrigerator to 4^{o}C for defrosting, as described by Hedhly *et al*. (2005).
The numbers of germinated and nongerminated pollen grains were counted under a light microscope at 100 x magnification. The pollen grains were considered germinated when the pollen tube length exceeded its diameter. Fifteen fields of view randomly selected from

different parts of the Petri dishes were examined per dish, each containing 20-50 pollen grains. About 400-600 pollen grains were observed per dish.

The association between pollen germination and independent variables was tested using ANOVA. Significant differences among treatments were computed after Tukey's HSD test at $P < 0.05$. Germination rate responses to temperature and maximum seed germination were analysed using linear and nonlinear regression methods for all genotypes in two experimental years.

Results and discussion

Temperature had a significant effect on pollen germination in all cultivars in both experimental years (Table 1), which is in accordance with the results other authors reported for other plant species (Griggs *et al*., 1975; Luza *et al*., 1987; Sukhvibul *et al*., 2000; Pirlak, 2002; Hedhly *et al*., 2005).

Pollen germination rates for both walnut cultivars were lower in 2014 than in 2015, although the differences were not significant. Janković (2016) studied temperature effect on pollen germination of five walnut cultivars and showed the existence of interactions between the walnut cultivar and the year in which measurements were made. In our study, this was not confirmed. The strong influence of ecological conditions in the time of pollen formation and catkins shedding on the functional ability of pollen is described by Beineke *et al*. (1977) in black walnut and Beyhan and Serdar (2008) in chestnut.

Table 1. Effects of temperature, cultivar and year on pollen germination of walnut

Cultivar (B)	G139	19.6 a
	Elit	28.8 b
Year (C)	2014	21.9 a
	2015	26.4 a
ANOVA		
Factors		p
Cultivar (A)		**
Temperature (B)		***
Year (C)		NS
A × B		NS
A × C		NS
B × C		NS
A × B × C		NS

The lowest pollen germination rates were obtained at 10° C, although germination still occurred in both cultivars. The pollen of G139 (Figure 1 - a) had lower germination rates at 10°C (3,9% in 2014 and 6,1% in 2015) compared to the one from Elit cultivar, which had the germination rates of 11,1% in 2014 and 12,1% in 2015. With further temperature rise, the percentage of germinated pollen grains in both cultivars also increased (Table 1). The highest pollen germination rates for Elit and G139 cultivars were recorded at temperature of 25°C in both studied years (Figure 1 - b). Temperature rise to 30°C had a negative influence on pollen germination. The effect of interactions between cultivar type and temperature on pollen germination was not significant. Conversely, Janković (2016) found a significant influence of genotype on walnut pollen germination at cardinal temperatures. Also, other authors reported the existence of interactions between genotype and temperature in the pollen germination process (Pfahler *et al*., 1997; Mckee and Richards, 1998; Song *et al*., 1999; Sukhvibul *et al*., 2000; Hedhly *et al*., 2004).

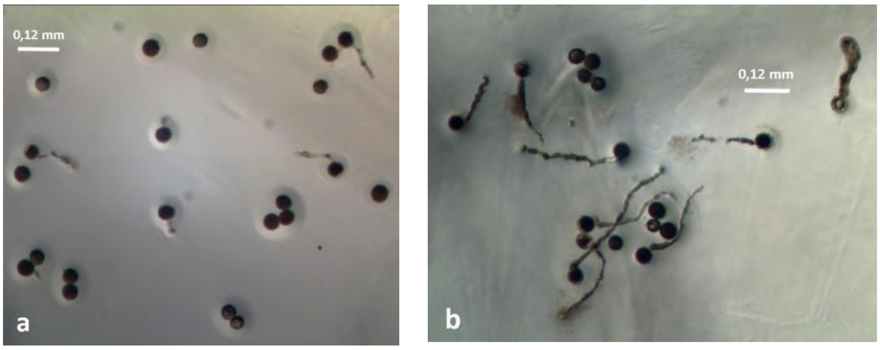

Figure 1. a - pollen of G139 walnut cultivar after germination at a temperature of 10°C; b - pollen of G139 walnut cultivar after germination at a temperature of 25°C

Luza *et al*. (1987) showed that none of the 12 studied Juglans regia and three Juglans nigra cultivars produced pollen that germinated at temperatures below 14°C, and at 14-15°C only pollen from early blooming cultivars germinated.. After their experiments, there were no other studies on cardinal temperatures for walnut pollen germination, so these results are often cited as proof that these cultivars have higher demands regarding heat during pollen germination. Pollen of some almond, sweet cherry and apricot cultivars starts germination already at 5°C (Griggs and Iwakiri, 1975; Egea *et al*., 1992; Pirlak, 2002), while pollen of some pear and mango cultivars can germinate at 10°C (Mellenthin *et al*., 1972; Sukhvibul *et al*., 2000). According to Janković (2016), pollen of all five studied walnut cultivars germinated at 12°C.

Table 2. Equations to describe temperatures' (T) influence on pollen germination rate: T_{opt} - optimal temperature for maximal pollen germination; R2 - regression coefficient

Cultivar	Fitted cubic equations	T_{opt} (°C)	R^2
	2014		
G139	$Y_1 = -0.022T^3 + 1.147T^2 - 16.173T + 73.127$	24.9	0.96
Elit	$Y_2 = -0.019T^3 + 0.949T^2 - 12.660T + 61.740$	24.1	0.92
	2015		
G139	$Y_3 = -0.019T^3 + 0.935T^2 - 11.911T + 51.073$	24.2	0.96
Elit	$Y_4 = -0.019T^3 + 0.919T^2 - 10.901T + 48.527$	24.4	0.92

Results of our study indicate that there are walnut genotypes whose pollen could germinate at temperatures even below 10°C. Among the linear and nonlinear regression models tested, the cubic function best described the response of pollen germination to temperature (Fig. 1) and was used to estimate the optimal temperatures for pollen germination of all genotypes in two experimental years (Table 2).

According to Janković (2016), between pollen germination at a temperature of 12°C and time of cultivar blooming, there were no significant correlations. Mert (2009) studied pollen germination in six walnut cultivars at three temperatures (16°C, 19°C and 27°C) and obtained the highest pollen germination rate at 27°C, and the lowest (1.97-8.92%) at 16°C. Wu *et al*. (2008) reported that the optimal temperature for germination and tube growth of walnut pollen was 25°C. Luza *et al*. (1987) obtained maximum pollen germination at 28°C in *J. regia* and at 32°C in *J. nigra*. In this experiment higher optimum temperatures for pollen germination were associated with later blooming cultivars, that was also observed in our study.

Conclusion

Temperature is an important factor in walnut pollen germination process, especially regarding cardinal values. Opposed to the generally accepted opinion that walnut pollen doesn't germinate at temperatures below 14°C, our results show that germination is possible even at 10°C. During the walnut pollen germination process, a significant effect also display genotypes and environmental factors that affected the process of pollen formation. It can be concluded that under specific ecological conditions, some walnut genotypes can produce pollen with the ability to germination at temperatures even below 10°C, indicating the need for further studies regarding this topic.

Abstract

Initial studies related to cytoplasmic male sterility (CMS) were performed by Rhoeds in 1931. CMS is used in maize to enhance efficiency of seed production with simultaneous cost redaction. The majority of studies showed positive effects of CMS on maize grain yield. Grain yields recorded male sterile plants were higher by 5-10% than the ones in female fertile plants. Seven maize inbred lines of different origin and growing season were analysed. Each inbred was analysed in five variants: original inbred (N), CMS-C, RfC, CMS-S and RfS. The aim of this study was to compare grain yields and yield components of original inbreds and their CMS and Rf variants. The highest yields of observed inbreds (5.303 and 5.197 t/ha) were recorded in those with C and S cytoplasm, respectively. According to the LSD test, at significance levels of 0.05 and 0.01, the longest ears of 15.57, 15.56 and 15.46 cm were detected in inbreds with original, S and C cytoplasm, respectively. The highest kernel row number (12.98) at both significance levels was established in inbreds with C cytoplasm. The highest number of kernels per row (33.92) at both levels of significance was recorded in inbreds with S cytoplasm. The greatest kernel depth (0.8212 and 0.8196 cm) at both significance levels was established in inbreds with C and S cytoplasm, respectively. The greatest 1000-kernel weight at both levels of significance was detected in inbreds with normal cytoplasm. The highest number of kernels per m^2 (2716 and 2676) was recorded in inbreds with C and S cytoplasm, respectively.

Keywords: *maize, yield, male sterility, inbred lines.*

Introduction

The revolution in maize production began with the discovery of heterosis and the cultivation of hybrids, during 1930s in the United States (Duvick, 2005). Maize is the first plant species in which heterosis is used to produce commercial hybrids. The use of the hybrid F_1 generation leads to an increase in yield by 25-30% compared to free pollinating varieties (Vančetović et al., 2007).

The first research on cytoplasmic male sterility (Cytoplasmatic Male Sterility-CMS) was performed by Rhoeds in 1931. In maize CMS is used to increase seed production efficiency and reduce its cost. The majority of studies showed positive effects of CMS on maize grain yield. Grain yields recorded in male sterile plants were higher by 5-10% than the ones in female fertile plants. Nowadays, production of maize hybrid seed in some parts of the world is increasingly based on using CMS in order to reduce costs of detasseling (Stevanovic *et al.*, 2013). The majority of studies (Stamp *et al.*, 2000; Weingartner *et al.*, 2002; Kaeser *et al.*, 2003) showed a positive effect of CMS on maize grain yield, especially under unfavourable drought conditions (Bruce *et al.*, 1966)

There are three types of CMS known so far in maize (Luo *et al.*, 2002; Shuanggui *et al.*, 2006):

1. CMS-T
2. CMS-C
3. CMS-S

The C and S type are used in commercial production in Serbia. CMS-T type is not used due to its specific susceptibility to the fungus Helminthosporium maydis race T that caused epiphytotic disease in USA during the 1970s (Duvick, 1972).
The aim of this study was to compare grain yields and yield components of original inbreds and their CMS and Rf variants

Material and Methods

Seven maize inbred lines (designated ZPL1, ZPL2, ZPL3, ZPL4, ZPL5, ZPL6 and ZPL7) of different origin and maturity group (FAO 300-500) were used in the trial. All original inbreds have been developed at the Maize Research Institute Zemun Polje. Each inbred was observed in five variants:

1. Original inbred (N)
2. CMS-C
3. Rf-C
4. CMS-S, and
5. Rf-S

Cytoplasmic male sterile and restorer versions have been developed at the Maize Research Institute Zemun Polje by conversion of inbreds with normal cytoplasm.
The trial, set up according to the randomised split-plot design, was carried out in three locations (Zemun Polje and Školsko dobro within the experimental fields of the Maize Research Institute Zemun Polje and in Srbobran) during two years (2010 and 2011). The location of Školsko dobro was rejected in 2011 due to a poor crop stand. The three-replication trail was set up in five sets (blocks). Each block represented one type of the observed inbreds:

I block – N (normal) cytoplasm, i.e. original inbreds
II block – CMS-C inbreds
III block – RfC inbreds
IV block – CMS-S inbreds and
V block – RfS inbreds.

Plots within each replication were composed of four rows. Two border rows represented original inbreds in all five blocks, which was especially important in CMS blocks, since N inbreds were pollinators for their sterile counterparts. Plants from inner rows (avoiding the effect of a border hill) were used for the analysis of grain yield and agronomic traits. Between spacing was 70 cm. The elementary plot size amounted to 7.28 m^2, while the crop density was 71.429 plants ha^{-1}. The yield was calculated in tones per hectare (t/ha) at grain moisture content of 14%.
Least significant difference (LSD) was used to compare original inbreds and converted inbreds at the 0.05 and 0,01 significance levels for yield an yield components. The MSTAT-C software package (MSTAT Development Team, 1989) was used for performing the LSD test.

Results and Discussion

In this study, comparisons were made between original and converted inbreds. The estimation of significance of differences between average values was done by LSD test at the 5% and 1% level.
Table 1 presents results of LSD test for grain yield, kernel rows number and number kernels per row. We detected the highest grain yields across all the seven studied inbreds for both significance levels in variants with C and S cytoplasm (5.303 and 5.197 t/ha, respectievly). In inbreds with the RfS type we detected the lowest yield (4.662 t/ha). LSD-test between inbred lines showed the highest kernel rows number in inbreds with RfC type of cytoplasm (12.98),

and the lowest with N type (12.67) for both investigated levels of significance (0.05 i 0.01). The highest number of kernels per row was observed in S inbreds (33.92), while the lowest number of kernels per row was determined in RfC inbreds (31.45) for both significance levels.

Table 1. Least significance difference test for the grain yield, kernel rows number and number kernels per row

LSD-test (Table 2) between inbred lines showed the highest ear lenght in inbreds with N, S and C type of cytoplasm (15.57, 15.56 and 15.46 cm respectievly). The lowest ear lenght was detected in inbreds with RfS and RfC type of cytoplasm 14.98 and 14.85 cm respectievly. In inbreds with N type of cytoplasm we detected the highest weight of 1000 kernels (261.3g). Lowest value of this parameter was recorded in inbreds with RfS cytoplasm (253.9g). The highest number of kernels per m^2 was observed in C and S inbreds, 2716 and 2676 respectievly, and the lowest with RfS type 2496.

In our research inbreds with C and S type of CMS achieved a higher grain yield than the inbreds with N type. Our results are in accordance with the results if previous studies (Stamp *et al.*, 2000; Weingartner *et al.*, 2002; Kaeser *et al.*, 2003). Previous studies showed also a positive effect of CMS on maize grain yield, especially under unfavourable drought conditions (Bruce *et al.*, 1966).

The impact of sterile analogs on the yield components should be positive because less nutrients and water are consumed and plants do not form pollen.It can not be concluded that there is a significant influence on the ear length, depending on the type of germplasm. Adding new genes in the cytoplasm leads to an increase in the kernel rows number. For the number kernels per row can be said that it is higher in the lines with the S and C type of cytoplasm. The mass of a thousand kernels did not differ on the level of significance 0.01, while at the level of significance of 0.05 the highest value of this parameter was achieved by genotypes with normal germplasm , which is in agreement with the results of Lim et al. (1974), but these studies were done on hybrids where the normal and T genotypes were compared. Weingartner et al. (2002) observed minimal changes in this indicator between genotypes with normal and T-type cytoplasm, while Munsch et al. (2009) showed that T and C cytoplasm negatively affect these parameter. When the number of grains per square meter is concerned, the highest values are recorded in the lines with S and C type of cytoplasm at both levels of significance. This is very important and positive for seed production on a CMS basis. Results Weingartner et al. (2002) show a significant influence of C cytoplasm on the value of this parameter. Also, Munsch et al. (2009) shows similar results.

Conclusions

It can be concluded that inbreds with C type of cytoplasm have better performances compared with inbreds with N ad S type for following traits: grain yield, kernel rows number and number of kernels per m^2. Sterile analogues were not only better when grain yield was concerned, but also when it comes to almost all other yield components.

Grain yield is the most important trait for the seed production. In this study, inbreds with C type of cytoplasm had best results.

In the period since the seventies of the last century, until now, cytoplasmic male sterility in maize hasn't received much attention from the researchers. The reduced intensity of the research is due to the epiphytosis of the mushroom *Helminthosporium maydis* and for this reason the use of CMS in maize production is considered to be very risky. Just because of all the above research on this topic, it should be continued and found out how new (modern) lines behave if in seed production we use their sterile analogues.

Abstract

Reduced tillage has impact on the economical agricultural production. The secondary effect is manifested through the effective implementation of the basic frameworks of sustainable agricultural production. Support to the above concept in the field is represented by applied precision farming systems in accordance with the principles of good agricultural practice. The entire agricultural production technology is supported by agricultural machinery, which exploitation is a pillar of sustainability. Using precision agriculture technologies, it opens up new opportunities in analyzing the quality of sowing of row crops. An analysis of sunflower seeding was performed. The random sample system extracted data from big data records collected from over 18 parcels and an area greater than 380 ha. The average seed population had a coefficient of variation from negative 23% to positive 60% in relation to the given seed rate. The average number of well-planted seeds (single seeded seed, ISO index) ranged from 86.6% to 94.6%. The average number of double seeds (ISO Multiple index) ranged from 1.7% to 8.6%, and the average number of blank places (ISO Miss Index) ranged from 1.4% to 7.1%. Due to the large deviation and the characteristic cyclic repetition of the error in a big data sample, it was concluded that the sowing did not meet the required planting quality standards. The cause of the unacceptable planting quality is caused by poor exploitation of the soil tillage machine. The advantage of using precision farming systems, acquisition and then Big Data analysis is significant from the aspect of profitability of agricultural production. The registered error at the beginning will ensure the quick and effective detection and removal of the cause.

Keywords: *planting, precision agriculture, reduced tillage, sunflower, big data*.

Introduction

The growing need for food, has led to the development of agriculture primarily relying on the use of mechanization and chemicals. As one of the responses to established sowing practices, precise agriculture can offer a variety of techniques and technologies, which can successfully overcome existing problems and shortcomings of the classical production technology (Kutter, T, 2011). Precision agriculture is based on the application of information technologies, satellite navigation, sophisticated control tools and the ability to align agricultural machinery with the desired direction of production management (Pedersen, S.M. 2004). With the help of various sensors, real-time production process parameters can be determined and recorded based on which the reasons for effective / inefficient operation can be determined (McBratney, A, 2005). The collected information is used to create maps showing the variations of the observed parameters such as yield, weeds, soil fertility, seed quality, disease development, and so on. The complete effect of applying precise agriculture is evident through the cost-effectiveness of production, optimizing the costs of engaged inputs in production, and rationalizing the engagement of agricultural mechanization and human resources, timely and effective decision-making, and most importantly, making decisions

based on detected and provable information that has not been available so far (Dillon CR, 2009; Oparnica S, 2018a; Oparnica S, 2018b).
Implementation of precise agriculture has become possible thanks to the development of sensor technology in combination with procedures for mapping variables in the appropriate agro-technical scale in the production area, such as plowing, sowing, fertilization, herbicide and pesticide application, harvesting and livestock breeding (Sarantis, M; Roland B). The key feature comes from a positioning system, primarily global navigation satellite systems (GNSS), which are the main enabler of "precision". It is present in major agricultural producers, especially in large farms and areas of mainly growing regions of Europe, the USA and Australia, and where the business model is the main driver in order to increase profitability (Plant, RE 2000; Daberkow, SG 2003; Fountas, S., 2005). Controlled Traffic Farming (CTF) and auto-pilot systems are the most successful forms of application in arable land that show clear advantages in almost all cases. For the Variable Rate Application (VRA) method, such as the optimization of seeds, fertilizers or pesticide applications (the success varies according to specific application factors which is manifested through the yields by zones (yield sensors - mapping yields by zones). For example, section control implies the exclusion of sections of seeders, spreaders and nozzles outside the boundaries of the plot or on the already treated part of the plot, a double passage (Velandia M, 2013).
Using these systems, some savings are expected. For example, savings were achieved on average 2.24 eur/ha using the aggregate guidance system (Abidine, 2002;). This resulted in savings of 18-48 eur/ha in wheat production. The variable application of the norm can save 10-25 eur/ha depending on the crop and reduce the use of 10-15% nitrogen without affecting the yield reduction. As for the use of sensors in the application of pesticides, usage can be reduced by an average of 13% (Shockley, 2015). If cereals are grown, which have more treatments, it is possible to save over 12 eur/ha for just one pesticide application. Using precision agriculture in irrigation leads to a 25% reduction in the use of water, resulting in a final cost reduction of 44 eur/ha directly. Section control saves between 3% and 5% of the seed.
The application of precise agriculture can be through determining the compaction of the plot and pulling resistance, determining the presence of characteristic parts of the plot and the appropriate selection of the crop production technology. The most important point in production is the quality of sowing (Zarco-Tejada, P 2014; Jensen, H.G. 2012; Hörbe, T.A.N. 2013). The sown represents the crucial point of production because the soil tillage technology is on checking. Although the emergence also depends on the availability of moisture in soil and precipitation, the final plant density and the uniformity of crops depend on land cultivation. After sowing, follow the care measures that will keep the crops at the same level as to prevent the competition of other plants and diseases. Therefore, sowing together with agro technical measures keeps a crucial place in the production of sunflowers and other crops.
Seeding with multiple seeders with the assistance of precision farming systems, automatic management and reduction of human and machine labor costs are the task of this paper. Using the system of precision agriculture does not lead to the necessary emergence of cost-effectiveness of production and its efficiency, it can very easily cause negative effects whose presentation is the goal of this paper.

Material and method

Sowing were done with 4 seeder. All of them are seeder with 12 seeding mettering unit mechanically powered, with vacuum pressure and pneumatically section control. Inter row spacing is 0,7 m. There are some differences between two pairs of them which is presented in figures and text.

Fig. 1. First type of seeding unit

Fig. 2. Second type of seeding unit with more pressure on parallelogram linkage

Seeding units are presented at figure 1 and 2. The heavy-duty parallel linkage (fig. 1-1 and fig. 2-2) with a large travel is mounted on interchangeable bushings. Two springs stabilize the metering unit with additional shock absorber (fig. 2-3). Each metering unit is equipped with an audible safety clutch system (fig. 1-2) with automatic clutching for optimal protection of the metering system. Both of them were powered by electric motor, not with mechanical powered system (fig. 2-1). The adjustment of the clod removers is precise (12 positions) and rapid due to the adjustment system with locking pins. In order to suit different planting conditions, the clod removers are rapidly interchangeable with the trash wheels and this with no tool (fig. 1-3 and fig. 2-5). The planting system is made up of two large diameter discs (380 mm) mounted on sealed ball bearings (fig. 1-4 and fig. 2-6). Together with the inner shoe, this system ensures a constant depth control and planting quality no matter what the planting conditions. Large depth gauge wheels (110 mm) ensure an efficient and uniform depth control (fig. 1-5 and fig. 2-7). Resting on the ground directly in line with the seed drop ensures the unmatched depth consistency (fig. 2-8). The bracket arms of the gauge wheels (fig. 1-6 and fig. 2-9) are assembled on interchangeable bushes. They are helically fluted for a good grease distribution. Scrapers are standard assembly on the gauge wheels. The open rear press wheel unit (fig. 1-7) gives better clearance in sticky conditions. The off-set adjustments and the spacing of the 2 press wheels enable optimal furrow closing no matter what the conditions (stones, trash, hard soil, …), fig. 2-10. The depth adjustment is easily made using a hand wheel (fig. 1-8 and fig. 2-10). This type of adjustment (fig. 1-9 and fig. 2-11) ensures a great control precision of the planting depth even for small seeds at a shallow depth. The hopper in high resistance, transparent plastic has a capacity of 52 liters. The cover locks so will not close during filling, even in windy conditions (fig. 1-10 and fig. 2-12). The front facing of the metering unit integrates the passage of the vacuum hose and the seed monitor and signal kit cables (fig. 1-11).

Sowing quality was checked in accordance with ISO 7256-1: 1984 / Sowing equipment - Precision drills on certain sections of the seeders, and based on this the conclusion on the overall quality of sowing was carried out. By connecting the seeder to the navigation device, the density population is recorded, the percentage of double places, the percentage of empty places on the whole plot area (Figure 3).

In this case, the "point" on the map is the working width of the seeder, 8.4 m and the length of 20 m until the control of the sections is done. Sowing quality parameters are given in common for all seed sections for the given point. On average, 59 points / ha were obtained. When section control turns off/on each section, a new point is created with entered parameters.

Based on the data from the map, a conclusion can be given on the quality of the sowing quality on the entire sown surface, the condition of the seedlings and the conditions that affected the sowing quality.

For each recorded individual layer, the processing and analysis of data in the software provides graphical information, statistics for the entire parcel, as well as a histogram with a partition of surfaces with a certain parameter ranking.

When the answer to the question about the size of the yield is requested after harvest, by overlapping the yield map with the sowing map, it can show the impact of sow quality on the yield.

The research was carried out in the sunflower sowing on 18 plots on a total area of 380 ha. The sowing was done in the last decade of March (south Backa) and the first decade of April (north of Backa).

Results and discussion

Sowing is an operation in which the advantages of the navigation systems are best seen. Sowing along an ideal straight line makes it easy to carry out the next operations and makes them more productive due to the possible higher speed of movement and making less damage to the crop. By using the control of seedling sections, the use of seed can be reduced to up to 5%. The shape of the plot is incorrect, savings are greater. A system of precise agriculture in which the combined seedling and drive aggregate recognize the already sown surface or plot boundary and exclude individual sections. In a wide variety of cultures, the seed that sown and emerges in the corded area is later cut down in between row cultivation. If it remains, in that part there is a larger plant population and one companion for light, nutrition and water.

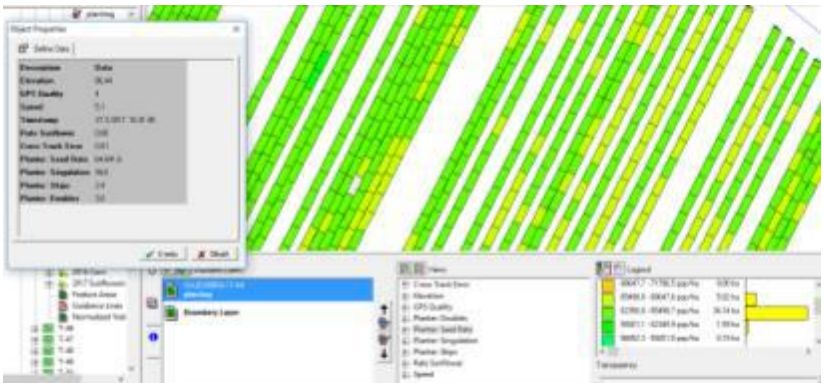

Fig. 3. Sowing map quality

The sowing of multiple seed aggregates on one plot during the day is a challenge, and almost impossible to realize during the night. Simply, operators are not able because of poor visibility to register the sown area. If each sowing unit is on a separate plot, it is often necessary to provide logistics on each plot because they are interchangeably distant, which is required by an additional telehandler, additional worker, a transport unit for seeds and fertilizer for each plot. If one sowing plant sow large plots, an area of more than 200 ha, it takes 2 to 3 days to complete the sowing of that parcel. The consequence of such a method is the uneven emergence. With the use of "Vehicle Sync" technology, up to 6 machines can be connected on a single plot that exchanges information on the finished surface. In this situation, this technology has enabled 4 seeders to work on one plot, with only one telehandler, one assistant worker and one transport unit. In addition, the working time coefficient was about 82.5% with a standard deviation of 2.5%, that is, the seedlings work effectively 19.2 hours - 20.4 hours per day. With a smaller number of seeders and lesser

logistics, larger areas are sown and no more sowing units are needed (Oparnica S, 2017a, Oparnica S, 2017b)
Modern seeders are equipped with sensors that are tasked with tracking the seeded population and to alarm problems with deviation from the norm. Typically, the alarm level is ± 10% to 15% of the current standard. Theoretically there is the possibility that the whole seedling season of the seeder will eject 9% more / less seed, and the alarm will not be activated.

The random sample system extracted data from big data records collected from over 18 parcels and an area greater than 380 ha. The average seed population had a coefficient of variation from negative 23% to positive 60% in relation to the given seed rate. The average number of well-planted seeds (single seeded seed, ISO index) ranged from 86.6% to 94.6%. The average number of double seeds (ISO Multiple index) ranged from 1.7% to 8.6%, and the average number of blank places (ISO Miss Index) ranged from 1.4% to 7.1%. Due to the large deviation and the characteristic cyclic repetition of the error in a big data sample, it was concluded that the sowing did not meet the required planting quality standards.
Benefits of using the various systems for control in the technology field of precision farming systems obviously require constant control and validation of work. Now when it is clear that the problem exists due to unsatisfactory results of sowing, it was present to find reasons.
Based on the conducted observations when measuring the seedlings in a row, the depth of sowing was very different. The range of change ranged from 15% to over 35% (random sample). In the case of NH seeder (Figure 2), the deviations were smaller, while more extensive dilations were recorded in the NG seeder (Figure 1). The reason for these differences in sow depth can be seen in the following photos. First, Figure 4a shows the direction of soil tillage. The tillage direction was about 30^{o} in a negative mathematical direction from the sowing direction (the angle closing right 1 and 2 in Figure 4a.).

Fig. 4a. Line1 marks direction of sowing and line 2 marks direction of tillage

Fig 4b. Marks A and B for formed different tillage zones

Secondly, two seeders are designed for direct planting of crops, while the other two are for sowing after conventional soil treatment. In Figure 4b two seeding zones are observed. The first zone is marked with A and the other with B. Two seeding zones were observed that differ in the fact that zone A, zone of compacted soil (untreated) and zone B, zone of loose tillage soil. These zones are formed in soil tillage with a combined low-speed soil compacting machine consisting of a short discs (two separate segments) and tins (on elastic supports).
Another factor that affected the poor sowing is caused by the depth of tillage. The tillage depth did not exceed 0.1 m in zone A, and in Zone B, it was usually 0.05 m. The consequence of shallow treating particularly caused problems on plots where there were a lot of harvest residues. Changing the depth of sowing and the appearance of zones of different depths is shown in Figure 5.

Fig. 5. Differences and variance of tillage depth

An analysis of the impact of each seed quality parameter on the average yield was made. In this case it turned out that the population has the greatest impact on yield. Therefore, it is necessary to direct future research and analysis towards the direction of dependence and correlation between plant and yield strata.

Tab. 2. Coefficients of correlations between obtained data and yield

Correlation	**Yield**
Population	-0,23604

Double	-0,04551
Empty	0,0168

Conclusion

The advantage of using precision farming systems, acquisition and then Big Data analysis is significant from the aspect of profitability of agricultural production. The registered error at the beginning will ensure quick and effective detection and removal of the cause.

Given collected and processed sowing data are obtained:

• Precise information on the quality of the operation performed on the entire surface;

• Mapping gives right information about the proper layout of the seed over the surface, or a trap of an average population without a variation information is avoided;

• There is accurate and precise information about the quality of sowing and business decisions are not made on the basis of assumptions about sowing quality.

In order to achieve the positive effects of the application of precision agriculture, different challenges must be overcome both in terms of both, material and psychological nature. The material challenges are very defined, the size and shape of the parcel, the type of machine to be used, the technology of land processing and ultimately the defined cost of purchasing navigation equipment and sensors. Challenges of psychological nature are the most difficult to overcome. It is difficult to implement training in which operators will change their habits and move from their comfort zone. Although the benefits of applying the new concept are very clear, irrational resistance is created in people who need to apply them in practice. It requires multidisciplinary involvement of agronomists from all areas of agriculture in order to demonstrate all the benefits of using modern technologies of precision agriculture.

THE EFFECT OF DIFFERENT FERTILIZER APPLICATIONS ON PLANT DEVELOPMENT AND FLOWERING OF DEMRE PEPPER

Fikret YASAR*, Ozlem UZAL

Van Yuzuncu Yıl University, Faculty of Agriculture Department of Horticulture, 65080 Van, Turkey
*Corresponding author: fyasar@yyu.edu.tr

Abstract

In the Study Demre pepper variety was used. The study was carried out in the Physiology Laboratory, Faculty of Agriculture, Van Yuzuncu Yıl University (Van city Turkey), in a climate room where normal atmosphere was provided. The main purpose of the normal atmosphere in the experiment was to ensure that salt stress effects occur under normal conditions. The study was carried out under controlled conditions in a light / dark photoperiod of 16/8 hours, climate room of 25^{o}C and 70% humidity. The study aimed to investigate effect of some commercial fertilizers which have a big market share in the world and Turkey. Nine different commercial fertilizer applications were made to the pepper plants. Base fertilizers were applied to the groups to be applied to the soil before planting seedlings. Other fertilizer applications were applied in 10-15 days intervals according to the instructions of the company. In addition, the group watered with distilled water only (control) and groups with only ½ second Hoagland nutrient solution of irrigation, fertilizer application constituted control of these commercial applications. The fertilization plan was made in accordance with the size of the company said. In this study, plant height, stem diameter, the first flowering date, number of flower, plant internodes length, number of stems; were examined. When the data obtained were evaluated in terms of plant growth; It was remarkable that Bestline fertilizer had the highest values in terms of all the developmental parameters examined except for the plant nodes distance.

Introduction

The pepper plant belong to the Capsicum genus of Solanaceae family. Capsicum genus contains 25 species. Among these species 5 are commercially produced C. annuum L., C. frutescens L., C. baccatum L., C. chinense Jacq., ve C. pubescens Ruiz & Pav. The most widely grown and economically important species of these are Capsicum annuum L. (Pernezny et. al., 2003).

World pepper production in 2016 was 34,497,462 tons. Around 3% of the world's vegetable production is pepper production. 2016 Turkey pepper production was 2,457,822 tons. In 2017, production increased by 6.1% and reached 2,608,172 tons. Turkey produces 7.5% of the world pepper production. (Anonim, 2018a).

Pepper was not as advantageous as tomato and eggplant in terms of exploiting foods due to its hairy root structure and depth. According to them, the root and hairy structure is less deep. If this feature is not taken into account in pepper cultivation, various malfunctions arise due to deficiency of plant nutrients. These also lead to premature deaths, reduced yields and poor quality.

Fertilizer is one of the most important inputs in agricultural production. If it is not applied sufficiently, it causes significant losses in yield and quality, but if it is applied more, it causes pollution of bottom and surface waters, especially with washing of nitrogen and phosphorus fertilizer, and emission of nitrogen oxide (NO, N2O, NO2) and air pollution (Güler, 2004).

The rapid increase in human population necessitates the increase in yield and quality in crop production. Correct fertilization is very important in order to increase yield and quality in crop production. Today, agriculture is still maintained in many places with traditional fertilizer use habits. Unconsciously one-way and large amounts of fertilizer applications without being based on soil analysis bring some yield and quality problems. In addition, this situation has reached the dimensions that threaten human health through nutrition. There are many commercial fertilizers on the market. In this study, the effect of commercial fertilizers on yield and quality criteria in pepper plant which has a large share of the World and Turkey market was investigated.

Material and Methods

The experiment was carried out in a split air-conditioned climate room where normal atmosphere was provided. Demre pepper variety was used in the study.
A mixture of perlite, peat and barn manure (1: 2: 4) was used as growing medium.

Pepper seeds were placed in plastic germination containers filled with pumice, after which 100 seeds were planted and watered with tap water. Seeds were planted in the pumice and covered with paper at a temperature of 24-26 0C and left to germinate in the air conditioning room and watered at intervals of 1 day. After germination started, the papers were removed and grown until they had 2 true leaves in a 16/8 hour light-dark photo period. After having 2 real leaves; 1: 2: 4: ratio of perlite, peat and manure growing medium with a size of 9x15 cm 570 ml volume of large six-hole and each cup of 1 seedling in each cup of 12 glasses were confused for each application.
The fertilization plan is based on the dimensions specified by the company. 9 different commercial fertilizer applications were applied to the plants. Base fertilizers applied to the groups were applied to the groups to be applied to the soil before planting seedlings. Other fertilizer applications were applied in 10-15 days intervals according to the instructions of the company. In addition, there are two different groups that constitute the control application of the study. The control group (the group irrigated with pure water only) and the groups made with only 1/2 Hoagland nutrient solution (Hoagland and Arnon, 1938) of irrigation were the control application of these commercial fertilizer applications.
In this study, plant height (cm), stem diameter (mm), length between plant nodes (cm), number of branches (number), first flowering date (day), number of flowering (number) were examined.

For all the properties studied, a randomized trial design (Random Plots) was used to test the differences between the groups. In case of significant differences between the groups ($p < 0.05$), Duncan multiple comparison test was applied to the relevant data to test which group had significant difference from the other. For this purpose, SAS (1985) statistical package program (SAS Institute Inc., Cary, NC) was used.

Results and Discussion

The study lasted 137 days after planting pepper seedlings. The first flowering after planting was observed after 47 days and in the application of 10-25-20 + 20 (SO3) + Zn. This was followed by 20-20-20 applications after 13 days. Among the applications, the latest flowering was observed in TSP application.

As a result of measurements in pepper plant, the longest length was obtained from Bestline fertilizer with 33,909 cm. According to the control practices of Bestline fertilizer (Control and Hoagland) it is seen that it creates differences in plant height. The lowest plant height was obtained from 13-24-12 + 10 (SO3) + Fe + Zn fertilizer application (28.600 cm) (Table 3).
As a result of the measurements, it was obtained from plants grown with Hoagland nutrient solution with 0.494 cm of the plants having the highest stem diameter. However, it is noteworthy that UAN and 10.5.40 fertilizer have statistical differences in terms of stem diameter of plants grown with Hoagland nutrient solution. Among the fertilizer applications, the maximum body diameter was measured as Bestline (0.490 mm) (Table 3).
According to the data obtained, the lowest inter-node distance was obtained from Control plants (0.975 cm) while the highest inter-node distance (1.500 cm) was obtained from 10.5.40 fertilizer. The applications in the same statistical group as 10.5.40 application, respectively UAN, 13-24-12 + 10 (SO3) + Fe + Zn, 10-25-20 + 20 (SO3) + Zn, 20-20-20, 10 -30-10 (Table 3).
It was determined that the application with the highest branching was Bestline and there was a statistically significant difference with this fertilizer. The lowest number of branches among fertilizers is Potasmag fertilizer. (Table 3).
The number of flowers varies between 13.416-19.545 pieces. Bestline fertilizer with 19.545 pieces has the highest number of flowers. TSP fertilizers and 13-24-12 + 10 (SO3) + Fe + Zn

fertilizers with 13,600, 13,416 units have low values from control applications (Control, Hoagland) (Table 3).
Koca (2013), potassium sulphate application, plant vegetation growth character (longest plant, the highest number of leaves, fresh dry weight of the whole plant, average weight, average weight, as well as total onion yield per unit, onion diameter) was found to be the highest. In a similar study El Bassiony (2006), the effect of potassium fertilizer on the growth, yield and quality of onion plants in the study of the best growth (plant height, number of leaves / plants) highest yield and onion quality 20 kg / ha by applying potassium sulfate to the soil obtained. Again in Aisha and Taallab (2008), the highest vegetation growth character (longest plant, maximum number of leaves, maximum fresh dry weight of the whole plant, average weight as well as total onion) using chemical forms of K as potassium sulfate. yield and onion diameter) were determined. In the study conducted by Bozkoylu (2008), the effect of chemical fertilizers on plant growth was investigated and it was found that chemical fertilizers were more effective than organic fertilizers.

Conclusion

The first flowering after planting was observed after 47 days and in the application of 10-25-20 + 20 (SO3) + Zn. This was followed by 20-20-20 applications after 13 days. Among the applications, the latest flowering was observed in TSP application. When the data obtained were evaluated in terms of plant growth; It was remarkable that Bestline fertilizer had the highest values in terms of all the developmental parameters examined, except the distance between the plant nodes. Especially in terms of the number of flowers which are among the yield criteria, it was determined that the application of fertilizer which had close values with Bestline was 10-30-10 fertilizer. It can be said that Bestline and 10-30-10 fertilizers yield more positive results on yield compared to other fertilizers.

Abstract

The secondary metabolism of plants is very sensitive to the environmental factors. In the processes of physiological adaptations of plants, an important role belongs to the phenolic compounds. The total content and the ratio of phenolic components depend on the nature of stress factors. Thus, the latter can be considered as stress markers and used in the phytoindication of the levels of anthropogenic transformation observed in the forest and park ecosystems. The biochemical markers were studied using the referent species *Acer platanoides* L., *Carpinus betulus* L. and *Sambucus nigra* L., sampled in the National Nature park "Holosiivskyi" (Kyiv, Ukraine). For the studied species, the highest phenolic content was observed in leaves of plants growing on insignificant elevations and slopes. The content of phenolic compounds such as flavonoids and catechins decreased in plants growing on plots with relatively high level of recreation pressure. The content of phenolic compounds and anti-oxidants was comparatively high in *Carpinus betulus*. The plants of *Acer platanoides* were significantly sensitive to the environmental factors. In their leaves, the concentration of phenolic compounds changed almost by half depending on the habitat conditions. In contrast, the leaves of *Sambucus nigra* plants varied more by their qualitative and quantitative composition of flavonoids. The chlorogenic acid, also, was shown to be highly informative, according to the analysis of principal components. That phenolic compound has high anti-oxidative potential. The ratio of chlorogenic acid to the total content of the identified phenolic compounds is a relative index of the plant's physiological state. Hence, the ratio value can be considered a biochemical marker of stress in the indicator plants.

Keywords: *forest ecosystem, marker, phytoindication, phenolic compound, stress*

Introduction

The functions of phenolic compounds in plants are diverse and mostly unstudied (Keech, 2005; Mattner, 2006). These compounds act as components of the electron transport chains of respiration and photosynthesis, and as regulators of growth and development (Cheynier, 2013). They also participate in various redox processes and ensure functions of low molecular weight antioxidants, etc. (Blokhina, 2003).

Phenols are important in the formation of constitutional and induced plant resistance to stress factors (herbivores, pathogens, herbivores, unfavorable temperature and pH, UV radiation, heavy metal stress), in regulation of symbiotic relationships (Nichols S., 2015; Zhu, 2016; Naikoo, 2019; Kidd, 2001). Phenolic compounds in a plant organism are predominantly synthesized by the shikimate pathway, which also involves the formation of aromatic amino acids (Tzin, 2010; Randhir *et al.*, 2004). The initial stage of phenol biosynthesis is the formation of oxycoric acids by the enzymatic conversion of *L*-phenylalanine. The flavonoids are obtained from chalcones with the participation of chalcone synthase (CHS) (Cheynier, 2013). Flavonoids are found in almost all plant tissues and organs, which points to their exceptional role in the regulation of physiological processes and adaptation of plants (Nichols, 2015; Mierziak, 2014). A large group of unreduced flavonoids, such as leukoanthocyanidins and anthocyanins localized in epidermal cells, is known to actively absorb ultraviolet radiation (280-320 nm) (Logemann *et al*., 2000). High selective ability to absorb ultraviolet determines their protective role in the functioning of the photosynthetic apparatus of plants, especially in the early stages of ontogeny (Liu, 1995). In addition, some aglycone flavonoids (quercetin, campferol) significantly affect the transport of auxins, interacting with membrane proteins that are involved in transmembrane transport of growth regulators (Brown, 2001). The structures of many flavonoid groups with antifungal, antiviral and antibacterial activity have now been identified. In addition, several flavonoid groups showed synergistic effects. At the same time, reports of the antibacterial activity of flavonoids are quite contradictory, possibly due to variations in testing conditions and individual sensitivity of study objects. Phyto-antibiotic activity particularly that associated with inhibition of DNA gyrase has now been confirmed for quercetin (Cushnie, 2005). A few mechanisms of action of other flavonoids, including myricetin, apigenin, rutin, etc. are also known (Cheynier, 2013). Taking into account the important role of secondary metabolites in the regulation of plant metabolism, the present work aimed at biochemical profiling and determining the impact of recreational pressure on the quality content of phenolic compounds in leaves of plants, which are widespread in the territories of different biotopes of the National Nature park "Holosiivskyi".

Material and Methods

The research was conducted in 2017–2018 in the hornbeam stands of the largest (1052 ha) green area in southwestern Kyiv (Ukraine), Holosiivskyi mixed deciduous forest. Six sites (S_1–S_6), 2500 m^2 each, were selected for the study. The general condition of trees and shrubs was determined visually. S_1 was located near university building, S_2 was chosen near playgrounds with relatively high recreational pressure, S_3 was chosen in area with average recreational pressure (30 m alongside a city road), S4 was established near Golosijevo ski complex, S_5–S_6 were chosen in Holosiivskyi Forest at areas with low recreational pressure, hardly visited by the city residents.

Acer platanoides L., *Carpinus betulus* L. and *Sambucus nigra* L. plants up to 10 years old were used as indicators of the state of the park ecosystem. The leaves of Norway maple and hornbeam were collected randomly from the lower branches. Elderberry leaves were collected from the middle branches. Samples were stored in a container during field studies. Within one experimental area, leaves were collected from five plants. The extraction was carried out in methanol (1:10 – v/v).

Biochemical profiling of methanol extracts was performed with HPTLC on G60 silica gel plates (Merck). The separation of flavonoids and phenol carboxylic acid conjugates was carried out in a solvent system: ethyl acetate, ethyl methyl ketone, methanol, water – 30:20:5:5 (v/v/v/v) (Reich, 2007). Chromatographic extract volume was 3 μl. Chlorogenic and caffeic acids (1 mg/ml) were used as standards. To obtain individual products and to determine the chemical nature of compounds, the chromatogram after drying was treated with 0.5 % NP reagent in ethyl acetate and 5% polyethylene glycol 400 in dichloromethane. The plate was kept for 5 min at 100 ºC. The chromatogram was visualized at λ=365 nm. R_f indices of the individual compounds were determined photodensitometrically using the *Sorbfil TLC* software.

The biochemical profiles of indicator plants were analyzed using the principal component method in Statistica 7.0.

Results and Discussion

Biochemical profiling of leaf extracts showed that the qualitative composition of phenolic compounds is species-specific and depends on the habitat conditions. The total concentration of phenols, as well as the content of individual components, is a sufficiently informative indicator of the effect on plants of external factors.

The Norway maple was quite sensitive in this aspect among the studied plant species. Under unfavorable conditions the concentration of phenolic compounds, including flavonoids, decreased almost twice in its leaves. On the contrary, both the qualitative and quantitative compositions of flavonoids were variable in the elderberry leaves.

The qualitative composition of phenolic compounds in the hornbeam leaves was quite conservative. Only at the S2 site with high anthropogenic pressure, an additional product was formed in the leaves (Rf~0.43). The product, treated with NP reagent, released a bright blue fluorescence, characteristic of phenolecarboxylic acid conjugates. However, this phenolic compound was not detected in other biotopes.

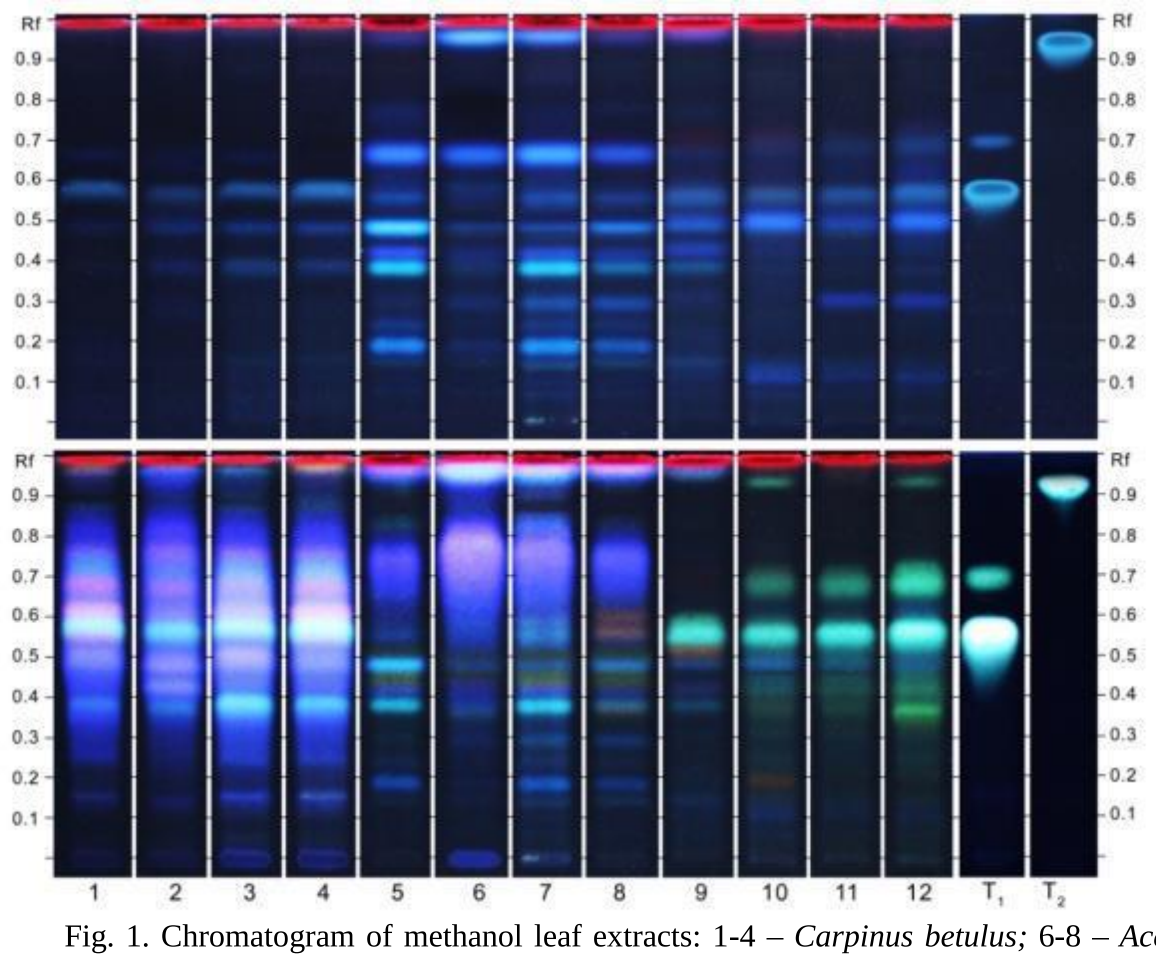

Fig. 1. Chromatogram of methanol leaf extracts: 1-4 – *Carpinus betulus;* 6-8 – *Acer platanoides*; 9-12 – *Sambucus nigra* in different biotopes of National Nature park "Holosiivskyi"; T_1 – chlorogenic acid; T_2 – caffeic acid (lower chromatogram was made after leaf plate was treated with NP reagent (1 % diphenylboryl oxyethylamine) and 5% PEG 400, and then heated to 105 $^{\circ}$C for 3 min).

As a result of photodensitometric analysis of the individual compounds, six phenolic compounds with intense auto-fluorescence (UV excitation 365 nm) were detected in the hornbeam leaves. At the same time, the qualitative composition of this class of substances

was quite variable. The full range of substances was identified in the leaves of trees growing on the S_2 site (Table 1).
According to the fluorescence brightness and Rf~0.58, the hornbeam leaves contain chlorogenic acid or one of its isomers. The highest concentration of chlorogenic acid is found in plants from the S5 site, which is farthest from the major highways, utilities and buildings.
For Norway maple, the range of substances on the chromatograph was wider. The chromatographic profile revealed 14 individual compounds (Table 2). Similarly to the hornbeam leaves, the profile with most of the separated components was seen for plants from the S_3 and S_5 sites. Under these conditions, up to 11 compounds are synthesized in leaf. It should be noted that territorially, these sites are closer to each other. The biochemical profiles of plants from S_1 and S_2 sites were somewhat less wide.

Table 1.
The ratio of individual compounds in the extracts of *Carpinus betulus* leaves according to fluorescence intensity (λ = 365 nm)

Peak	$R_f \cdot 100$	Peak area, S×1000, c.u.

	Σ	74.55	89.26	164.90	170.24

* S_1, S_2, S_3, S_4 – study sites.

Nine compounds were found in the leaves of plants from the first site (S_1), and only seven compounds were determined from leaves of plants from S_2. Lower number of individual phenolic compounds, which are cytoprotectants with high antioxidant potential, in the biochemical profile may indicate a decreased potential ability of leaf tissues to protect macromolecules and membranes from stress-related reactive oxygen species (ROS). Typically, an increase in the total amount of phenolic compounds in plants occurs under the action of external factors that cause a protective reaction. In the hornbeam under considerable recreational pressure, the total number of phenolic compounds has decreased almost twice, according to the results of chromatographic analysis. That response may be explained by the depressed state of the plants, which leads to a decreased metabolic activity, or to the activation of other mechanisms of adaptive responses that require separate studies.
The content of phenolic compounds in the leaves is somewhat different for *Acer platanoides*. Thus, under conditions of recreational pressure (S_1), content of the phenolic compounds increased by 1.4 and 1.7 times, respectively, compared to the not visited areas (S_3-S_4) (Table 2).

Table 2.
The ratio of individual compounds in the extracts of *Acer platanoides* leaves according to fluorescence intensity (λ = 365 nm)

Peak	$R_f \cdot 100$	Peak area, S×1000, c.u.

12	76	23.56	0	0	5.07
13	85	0	0	11.36	0
14	96	0	0	0	22.83
	Σ	683.53	244.11	489.32	409.71

At the same time, the qualitative composition of individual products and the total content of phenolic compounds twice decreased in the highly visited recreational area (S_2). Such a feature of metabolic activity coincides with the response of *Carpinus betulus* plants. The content of phenolic compounds increased in *Acer platanoides* leaves in S_1 and decreased in S_2, possibly indicating the relatively greater protective potential of the substances, and confirming that phenylpropanoid synthesis is inhibited under prolonged exposure to stress factors.

Analysis of the individual compounds by the principal component method revealed that the greatest contribution to the overall dispersion is made by substances with Rf~0.66, as well as three substances 0.19; 0.38; 0.48 (Fig. 3).

The compound with Rf~0.66 was found in all leaves. According to fluorescence intensity, its highest concentration is found in the leaves from the study site S1, the lowest concentration in leaves from S_5.

The ratio of this substance to the sum of all identified compounds by the area of peaks on the photodensitogram (K) was an informative indicator of the plant's condition and we consider it a marker of their physiological state, even if the obvious visual signs of damage or inhibition of plants are not observed. The coefficient is calculated by the formula:

$$K = \frac{SRf_{\text{к}}}{\sum_{i=1}^{n} SRf_i},$$

where SRf_{κ} – peak area on photodensitogram of the marker product, $\sum_{i=1}^{n} SRf_i$– sum of peak areas of (*n*) products on a chromatogram of one sample.

The calculated ratios were then put on the map of the study area (Fig. 4). It is shown that the calculated coefficient decreases with the level of anthropogenic pressure by the distance of plant habitat from the main buildings, popular recreational areas and high-traffic highways. For S_2 site, the coefficient was 0.43, for S_3 and S_5 sites, it was 0.24 and 0.22, respectively.

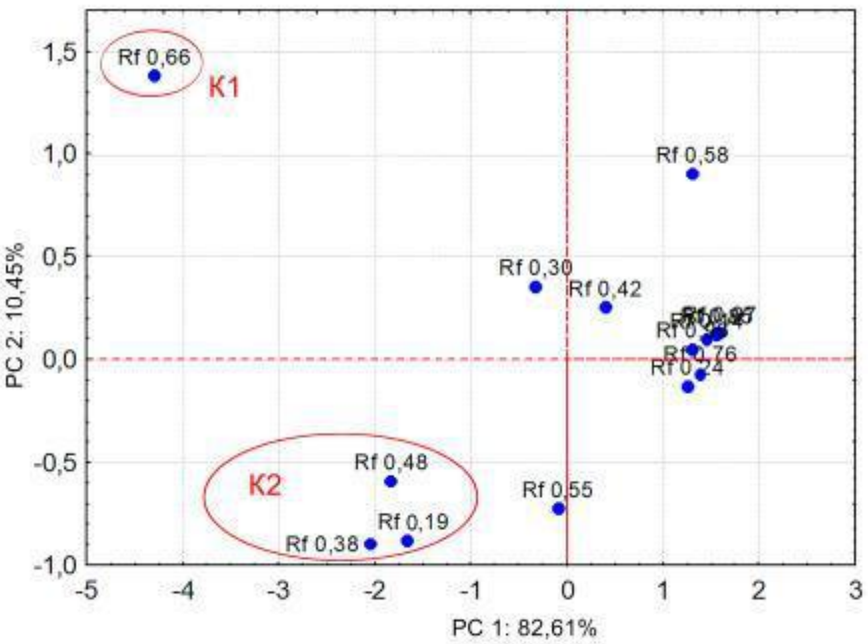

Fig. 3. Principal components analysis of biochemical profiles of *Acer platanoides* leaves

In the studied model, this biochemical marker made the greatest contribution to the overall dispersion and is therefore a highly informative feature. In our opinion, this substance should be considered as one of the key response signs of *Acer platanoides* to the state of the ecosystem.

Fig. 4. Indexes of physiological state of *Acer platanoides* plants by biochemical markers in different habitat of the National Nature park "Holosiivskyi"

Chromatography of *Sambucus nigra* leaves revealed a significant amount of chlorogenic acid (CA) and its derivatives. In this chromatography system, CA has an Rf of 0.56, and a bright blue fluorescence at UV 365 nm.

In addition, 12 phenolic compounds were isolated from elderberry leaves. Several of them are of some interest in terms of the possible chemo-indication of anthropogenic and biotic pressure. CA, as a fairly powerful antioxidant, is one of the key compounds involved in providing systemic protection to the plant organism (Manquian-Cerda, 2018). Photodensitometric analysis made it possible to compare the CA content of plants from different biotopes.

The content of this compound in the leaves was quite variable. At the same time, not only its quantitative content but also its ratio to other phenolic acid conjugates may be important.

Table 3.

Σ		264.98	200.18	263.86	379.92

CA is one of derivatives of the cinnamic acid (cinnamate), which are common in higher plants, mainly in the form of conjugates. After hydrolysis they form phenolic acids such as caffeic (3,4-dihydroxycarboxylic), ferulic (3-methoxy-4-hydroxycarboxylic), mustard (3,5-dimethoxy-4-hydroxycarboxylic), and p-coumaric (4-hydroxycarboxylic). CA reduces the level of malondialdehyde due to its high antioxidant potential. It reduces the prooxidant activity of free radicals in plant tissues under oxidative stress, as evidenced by the decreasing concentrations of lipid peroxidation products and of hydrogen peroxide (H_2O_2). At the same time, CA enhances the enzymatic activity of the antioxidant system (SOD, catalase and glutathione peroxidase).

The most represented plant profiles in the elderberry leaves, were those of the first section (10 compounds), and the second section (5 compounds) was the least represented. This coincides with the data obtained for the hornbeam and Norway maple.

Principal component analysis confirmed the high importance of CA (Rf~0.56). Another potential marker for assessing the plant's physiological state is a prominent substance with Rf~0.49 (Fig. 5).

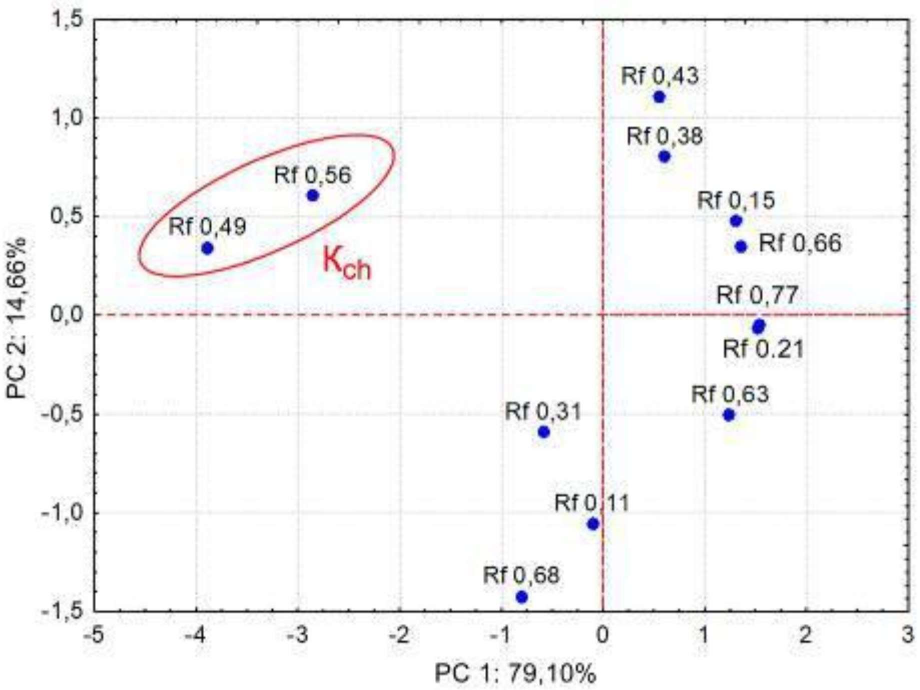

Fig. 5. Principal components analysis of biochemical profiles of *Sambucus nigra* leaves

The ratios and fractions of substances in the total amount of phenolic compounds, analyzed with the above method, also showed this ratio (Kch) value to increase correspondingly with higher recreational pressure on forest and park ecosystems (Fig. 6).

Fig.6. Indexes of physiological state of *Sambucus nigra* plants according to biochemical markers in different habitats of the National Nature park "Holosiivskyi"

Thus, it is established that high sensitivity of certain chains of phenylpropanoid synthesis and formation of individual phenolic components are characteristic of the Norway maple and elderberry plants. Some of the individual compounds, in particular CA, are considered sensitive biochemical markers of plant physiological status, as well as indicators for determining the levels of recreational pressure on forest and park ecosystems.

Plants are an important component of environmental monitoring as indicators of the state of the ecosystem (De Temmerman *et al*., 2001, Mehlhorn, 1991, Micieta, 2000, Batic, 1999, Lorenzini, 2000). At the same time, not all plant species can be used as indicators of anthropogenic pressure. Choosing the indicator species depends on the factors on which the monitoring is focused. They should occur in all monitoring areas and have characters sensitive to environmental changes. According to the data obtained in the forest-park urban ecosystems in the zone of mixed forests, leaves of *Sambucus nigra* and *Acer platanoides* plants were quite sensitive to recreational pressure. These species are typical representatives of forest ecosystems, sufficiently resistant to adverse factors, such as acid soils with increasing free aluminum content. They also are shade-resistant and resistant to recreational pressure. A wide range of phenolic compounds, with variant and conservative components, contained in the leaves of studied species allows using them as markers of the physiological state of plants (Manquion-Cerda K., 2018).

Conclusions

The content of individual phenolic compounds is related to the general process of phenylpropanoid synthesis. Hence, not only the synthesis of individual compounds, but also their ratios in the total phenol content are informative. Using variable components of phenolic synthesis with high antioxidant potential and their ratios to the total phenol amount are an important element in the evaluation of the general physiological state of plants. These biochemical parameters are not suitable for rapid analysis of the state of forest ecosystems, but can be used for studies of stress factors. The specific absorption spectrum of UV radiation of phenolic compounds (in particular chlorogenic acid) may have wide prospects for remote spectral studies of forest and park ecosystems, as well as agroecosystems.

Abstract

The objective of this study was to evaluate antioxidant activities of vegetable extracts *Dancus carota* L., grown in Serbia. Different experimental models have included the determination content of total phenolics, total flavonoids and antioxidant activities of extracts. From the same material, two extracts were obtained by various methods: maceration and ultrasonic extraction. The highest content of phenolic compounds was detected in *D. carota* L. 50.42 mg GAE/g, ultasonic extract. The lowest content of phenolic compounds shown *Dancus carota* L. macerat, 17.45 mg GAE/g. The obtained antioxidant activities are in correlation with the content of phenolic components. On the basis of the results obtained, extract of were found to serve as a potential source of natural antioxidants due to their marked activity. The obtained results may be useful in the evaluation of new dietary and food products.

Keywords: *D. carota L, maceration, ultrasonic extraction, phenolic compounds*.

Introduction

Different parts of plants (roots, leaves, flowers, fruit, stem, bark) have been successfully used to treat numerous diseases (Beninger and Hosfield, 2003). Owing to their antioxidant activity, they can influence a number of physiological processes, thus protecting the organism from the damaging effect of free radicals and inhibiting the development of unwanted microorganisms. Several studies have pointed out the possibility to use essential oils and/or their components in medical and plant pathology as well as in the food industry for the control of microorganisms pathogenic to consumers and/or responsible for food spoilage (Yanishlieva *et all.*, 2006). Our body is exposed to a large number of foreign chemicals everyday . The most of which are man-made and our inability to properly metabolize them negatively affects our health by the generation of free radicals. Free radicals are also generated during normal metabolism of aerobic cells. The oxygen consumption inherent in cells growth leads to the generation of series of oxygen free radicals. Highly active free radicals and their uncontrolled production are responsible for numerous pathological processes such as cell tumour (prostate and colon cancers) and coronary heart diseases. Antioxidants can significantly delay or prevent the oxidation of easily oxidizable substances (Macheix and Fleuriet, 1998). Natural antioxidants are classified according to their mechanism of action as chain-breaking antioxidants which scavenge free radicals or inhibit the initiation step or interrupt the propagation step of oxidation of lipid and as preventive antioxidants which slow the rate of oxidation by several actions but do not convert free radicals. However, synthetic antioxidants, such as butylated hydroxyltoluene (BHT) and butylated hydroxyanisole (BHA), known for their ability to terminate the chain reaction of lipid peroxidation, have been proven to be carcinogenic and to cause liver damage (Prieto *et all.*, 1999). The use of plants in the food industry in place of synthetic preservatives, antioxidants or other food additives has significantly increased over the last few years due to their ability to produce biologically active substances (Merken and Beecher, 2000). There is growing interest toward natural antioxidants from herbal sources (Beninger and Hosfield, 2003).

Material and Methods

All chemicals and reagents were of analytical grade and were purchased from Sigma Chemical Co. (St Louis, MQ, USA), Aldrich Chemical Co. (Steinheim, Germany) and Alfa Aesar (Karlsruhe, Germany). The plant material used in the experiment included is grown under plastic-covered greenhouse conditions in Cacak.

Spectrophotometric measurements were performed using an MA9523-SPEKOL 211 UV-VIS spectrophotometer (ISKRA, Horjul, Slovenia).

Plant materials (20 g) were macerated in a mixture of 95% ethanol (250 ml) and 0.5% glacial acetic acid at room temperature for 24 hours. The resulting macerate was filtered and the maceration procedure was repeated once. The extracts obtained were combined and concentrated until dry in a rotary vacuum evaporator to produce the (E_1) extract [5]. The (E_2) extract was obtained by ultrasound-assisted extraction using a Brason B-220 ultrasonic bath (Smith-Kline Company, USA).

The typical procedure involved ultrasound-assisted extraction of crushed plant material with 95% ethanol over a period of 1 hour.

Total phenols were estimated using the Folin-Ciocalteu method (Duh *et all.,* 1999). Plant extracts were diluted to a concentration of 1 mg/mL, and aliquots of 0.5 mL were mixed with 2.5 mL of Folin-Ciocalteu reagent (previously diluted tenfold with distilled water) and 2 mL of $NaHCO_3$ (7.5%), (Yan *et all.*, 2006). After heating for 15 min at 45˚C, the absorbance was measured at 765 nm in a spectrophotometer against blank sample. Total phenols were determined as gallic acid equivalents (mg GA/g extract), and the values are presented as means of triplicate analyses (Hsu *et all*., 2008). The method used by (Brighente *et all*., 2007), was adopted with suitable modifications from (Daker *et all*., 2008). DPPH (8 mg) was dissolved in C_2H_5OH (100 mL) to obtain a concentration of 80 mg/mL. Serial dilutions were carried out with the stock solutions (1 mg/mL) of the extracts. Solutions (2 mL each) were then mixed with DPPH (2 mL) and allowed to stand for 30 min for any reaction to occur, and the absorbance was measured at 510 nm. Ascorbic acid (AA), gallic acid (GA) and butylated hydroxytoluene (BHT) were used as reference standards and dissolved in methanol to make a stock solution at the same concentration (1 mg/mL), (Yanishlieva *et all.,* 2006). Control sample was prepared containing the same volume without test compounds or reference antioxidants (Tandon *et all*.,1995). Ninety-five percent ethanol was used as blank. The DPPH free radical scavenging activity (%) was calculated using the following equation:

% inhibition = $[\,(A_c - A_s) / A_c]\ 100$.

Results and Discussion

The total phenolic content of the (E_1) ultrasonic extraction 50.42 mg GAE/100g of sample, and that of the (E_2) maceration extract was 17.45 mg GAE/100g of sample. The results obtained were calculated as average values of five parallel measurements. High values of antioxidant activity were identified, being 92.67 % and 89.67 % for the E_1 and E_2 extracts, respectively. Figures 1. and 2. show graphic presentation of the antioxidant activity of the E_1 and E_2 extracts.

Fig. 1. Antioxidant activity of the E_1 extract

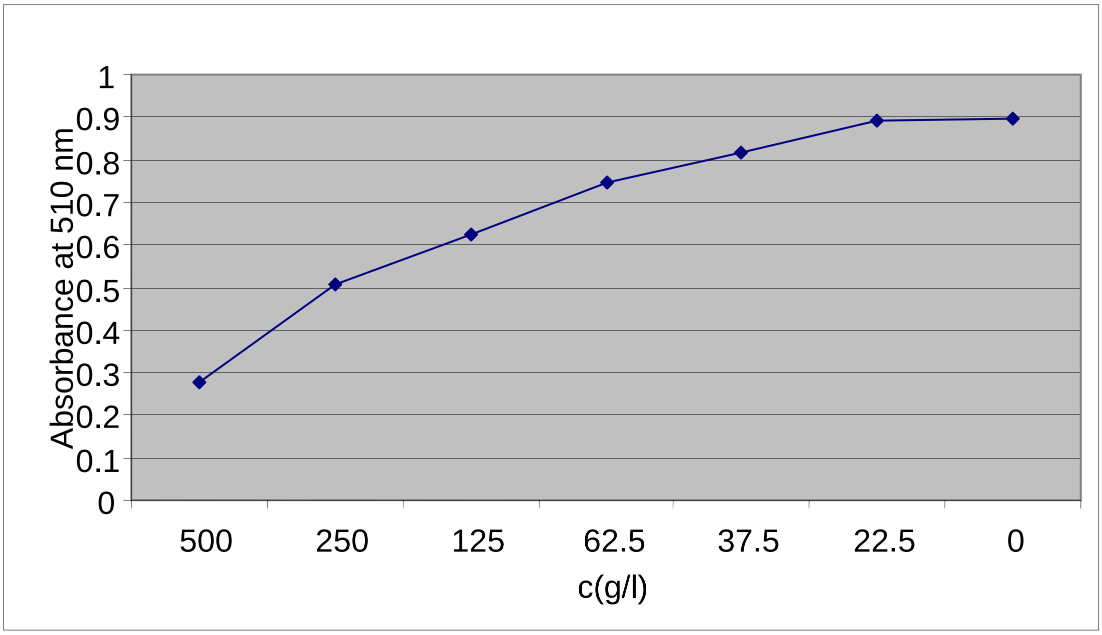

Fig. 2. Antioxidant activity of the E_2 extract

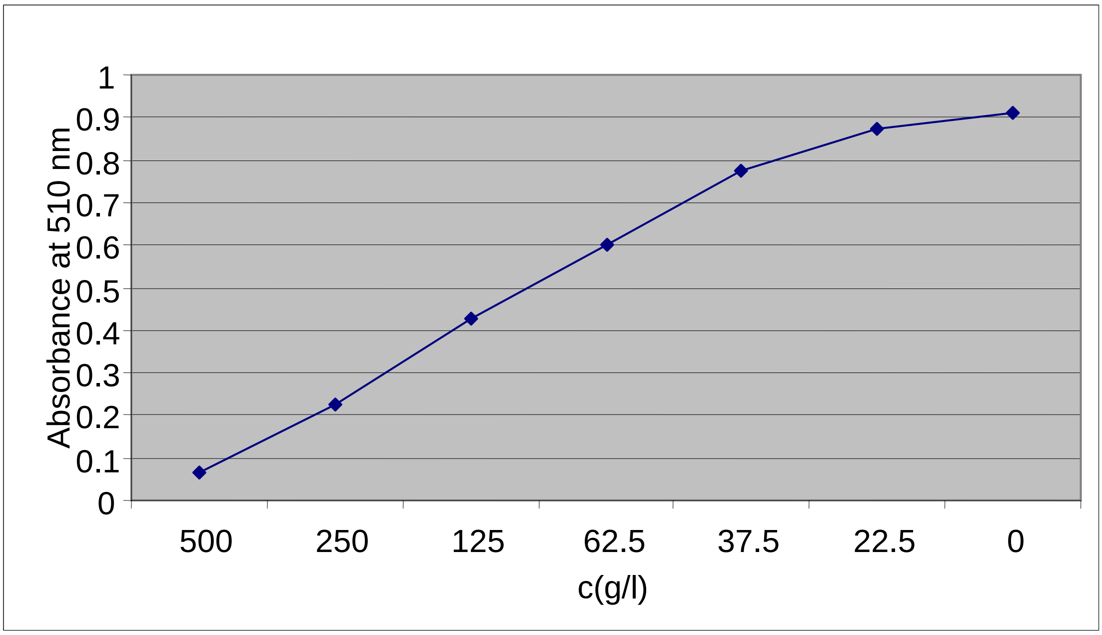

The DPPH capacity values were calculated relative to rutin, trolox and quercetin (Table 1). The values were calculated based on the graph representing dependence between standard concentration (mg/g DPPH) in the X-axis and capacity of DPPH radicals (%) in the Y-axis.

Rutin c= (% DPPH- 1.29481) / 0.37472
Troloks c= (% DPPH- 0.24856) / 0.38094
Quercetin c= (% DPPH- 12.09185) / 5.2032

Table 1. DPPH mg/g relative to rutin, trolox and quercetin

extract	mg/g DPPH	standard
Ethanol E_1	0.24385	Rutin
Ethanol E_2	0.24118	Rutin
Ethanol E_1	0.24261	Trolox
Ethanol E_2	0.23999	Trolox
Ethanol E_1	0.01549	Quercetin
Ethanol E_2	0.01529	Quercetin

Conclusions

The importance of this study lies in a preliminary examination of whether carrot extracts can be used as a source of natural preservatives in the food industry. Results show significant antioxidant activity in the vegetable extracts tested. Moreover, the E_1 and E_2 extracts were found to have significant antioxidant activity which correlated with the total phenolic content. Total phenols, hence and antioxidant activity, are dependent upon the method and time of extraction, which is most likely due to their instability. Therefore, this fact should be considered when selecting and obtaining natural antioxidants.

Abstract

Fennel is a plant belonging to the *Apiacea* (*Umbelliferae*) family, and used by humans for a long time for medicinal purposes. In order to evaluate the influence of different materials on germination and seedling growth of three cultivars of fennel, an experiment was conducted in 2018. There cultivars of fennel were Isfahan, Yazd, and Shiraz in main plots, and three materials including 100% soil, 50% diatomite + 50% soil, and 100% diatomite in subplots, were analyzed in a split plot experiment based on a randomized complete block design (CRBD) with three replications. The highest total germination percentage, coefficient of velocity of germination, coleoptile length, fresh coleoptile weight and dry coleoptile weight was related to Isfahan. The maximum speed of germination, mean germination time, fresh length and dry leaf weight was achieved in Shiraz cultivar. The higher values of total germination percentage, speed of germination and mean germination time were related to 100% soil, while application of 50% of soil + 50% of diatomite had obtained the maximum values of radicle length, coleoptile length, fresh coleoptile weight, dry leaf weight and dry coleoptile weight. The maximum values of coefficient of velocity of germination and fresh leaf weight was achieved in application of 100% diatomite. It seems that application of 50% soil + 50% diatomite and Isfahan and Shiraz cultivars have a great potential of seed germination of seedling growth.

Keywords: Fennel, Diatomite, Germination, Seedling Growth

Introduction

The aromatic and medicinal plants are important in all over the world (Heidari et al., 2014; Ogbaji et al., 2018; Shahrajabian et al., 2018; Shahrajabian et al., 2019a; Shahrajabian et al., 2019b; Shahrajabian et al., 2019c; Soleymani and Shahrajabian, 2018). Fennel (*Foeniculum vulgare Mill*.) had aromatic, medicinal and flavouring properties, and it is rich in various biological active ingredients (Ozcan and Chalchat, 2010; Soleymani and Shahrajabian, 2012a;Badgujar et al., 2014; Gama et al., 2014). It is cultivated in different parts of the world such as Europe, the middle east and Asia (Sadeghpour et al., 2015). Inappropriate seed germination is a common phenomenon which may cause a great concern for crop production, especially medicinal and aromatic crops (Khoshkharam et al., 2010; Shahrajabian et al., 2018).Seed vigor can be defined as the ability of the seed to germinate and become established under less than optimal conditions, or to survive a series of environmental stresses during germination (Soleymani et al., 2011; Balla et al., 2012; Soleymani et al., 2013). Diatoms are the most diverse group of phytoplankton ranging in the size from a few micrometers to a few millimetres and exist either as single cells or chains of cells (Aksakal et al., 2013; El-Sherif et al., 2018). Huang et al. (2012) concluded that diatomite is a siliceous sedimentary rock with a porous structure, low density, high surface area and excellent thermal resistance, and it is readily available and environmentally friendly in sustainable agriculture.

El-Sherif et al. (2018) found that diatomite can improve the growth and mitigate the negative effects of salinity stress, and also reduce the negative effects of water stress. Yong et al. (2018) mentioned that favourable temperatures and water supplies are the most important conditions required for germination and seed emergence. Unfortunately, in Iran the available researches and studies on diatomite and application of this technology for medicinal crop cultivation is limited. Therefore, the aim of this research was to evaluate changes of seed germination and seedling growth characteristics of fennel cultivars in centre of Iran to different managements of diatomite application.

Materials and methods

Diatomite and three varieties of fennel were obtained from Agricultural Research Centre, Isfahan, Iran. There cultivars of fennel were Isfahan, Yazd, and Shiraz in main plots, and three materials including 100% soil, 50% diatomite + 50% soil, and 100% diatomite in subplots, were analyzed in a split plot experiment based on a randomized complete block design (CRBD) with three replications in a green house at Mojgan Agricultural Company, Mahmood abad, Isfahan, Iran (Latitude 32 $^{o}52^{/}$ N, Longitude $51^{o}34^{/}$ E and 1660 m elevation) in 2018. 50 seeds per pots were planted. Germination percentage, germination speed (GR), mean germination time to complete germination (MGT), and coefficient of velocity of germination (CVG) were measured with equations number 1, 2, 3 and 4, respectively.

Germination percentage= Number of germinated seed /100 (1)

GR= $\Sigma \frac{N}{\Sigma(n \times g)}$ (2)

Where, n is the number of germinated seed on growth day and g is the number of germination seeds.

MTG= $\Sigma \frac{NiDi}{N}$(3)

N: total seed number, Ni: number of germinated seed per day, and Di: the number of required days for germination.

CVG= $\frac{1}{MTG}$ (4)

Germinated seeds were carried out by using three replicates of 50 seeds and other seeds were cultured to determine dry matter. Radicle and coleoptileof germinated seeds were measured for length and weight characteristics. To this purpose, 10 seeds were chosen randomly, within those germinated first. The selected seedlings were oven-dried for 48 hours at 65 ^{o}C for dry weight measurement. Analysis of variance (ANOVA) was used to evaluate the significant differences. The Multiple Range Test of Duncan performed the separation means ($P<0.05$). All statistics was performed with the SAS statistical software.

Results and discussion

The influence of cultivar was significant on total germination percentage, speed of germination, radicle length, coleoptiles length, fresh leaf weight, fresh coleoptile weight, dry leaf weight and dry coleoptile weight. Except fresh coleoptile weight, dry leaf weight and dry coleoptile weight, all experimental characteristics namely, total germination percentage, speed

of germination, mean germination time, coefficient of velocity germination, radicle length, coleoptile length and fresh leaf weight was significantly influenced by material components.
The highest total germination percentage (75.99%) was belonged to Isfahan cultivar which had meaningful differences with other cultivars. The total germination percentage in Yazd and Shiraz cultivar was 59.86% and 63.82%, respectively. The appropriate seed germination is very important for final successful productions of crops (Shahrajabian et al., 2011; Soleymani and Shahrajabian, 2017). The higher speed of germination was related to Shiraz cultivar, followed by Yazd and Isfahan. Although, there was a significant difference between Isfahan and Shiraz, both of these cultivars had no significant differences with Yazd. The maximum and the minimum mean germination time was achieved in Shiraz and Isfahan cultivar, respectively. Uniformity and increase percentage of seedling emergence in direct seedling planting significantly influence the yield and quality of crops (Khoshkharam et al., 2010; Soleymani and Shahrajabian, 2012b; Soleymani and Shahrajabian, 2012c; Ogbaji et al., 2013; Shahrajabian et al., 2013; Soleymani et al., 2016). Although, the higher value of coefficient of velocity of germination was obtained for Isfahan cultivar compare to those of other cultivars, no significant differences were found between treatments. The higher radicle length was related to Yazd (2.60 cm), followed by Isfahan (2.50 cm), and Shiraz (2.43 cm). On the one hand, Isfahan had significant difference with Shiraz; on the other hand, its difference with Yazd was not significant. The highest and the lowest coleoptiles length was related to Isfahan (6.50 cm), and Yazd (3.66 cm), respectively, which had meaningful differences with other. The higher fresh leaf weight was related to Shiraz (0.55 g), followed by Isfahan (0.51 g), and Yazd (0.31 g), respectively. Although, there was no significant difference between Isfahan and Shiraz, both of these cultivars had meaningful difference with Yazd. The maximum and the minimum fresh coleoptile weight were belonged to Isfahan and Yazd cultivar, respectively. Fresh coleoptile weightin Isfahan, Yazd and Shiraz was 0.60 g, 0.38 g, and 0.47 g, respectively. The maximum and the minimum dry leaf weight was related to Shiraz and Yazd, respectively, which had meaningful difference with each other. However, no significant difference was found between Isfahan and Shiraz cultivar. The higher dry coleoptile weight was achieved in usage of Isfahan, followed by Shiraz and Yazd, respectively. All differences between treatments were significant (Table 2). The maximum and the minimum total germination percentage and speed of germination were achieved in usage of 100% soil, and 100% diatomite, respectively, which had meaningful differences with each other. The highest and the lowest mean germination times were related to 100% soil, and 50% soil + 50% diatomite, respectively. All differences between treatments were meaningful. Application of 100% soil had obtained the lowest coefficient of velocity of germination and radicle length which had meaningful differences with other treatments. Delayed and reduced germination and seedling emergence which cause non-uniform and establishment, therefore seedlings subject to soil-borne pathogens (Nourimand et al., 2011; Shahrajabian and Soleymani, 2017; Shahrajabian et al., 2017; Abdollahi et al., 2018). The higher values of coefficient of velocity of germination and radicle length were observed in 50% soil + 50% diatomite and 100% diatomite, respectively. The maximum and the minimum coleoptile length was related to 50% soil + 50% diatomite and 100% diatomite respectively. All differences between treatments were meaningful. The higher values of fresh leaf weight was related to 100% diatomite, followed by 50% soil + 50% diatomite and 100% soil respectively, which had significant differences with each others. Application of 50% soil + 50% diatomite had obtained the highest values of fresh coleoptile weight, dry leaf weight and dry coleoptile weight. There were not any significant differences for fresh coleoptiles weight, dry leaf weight and dry coleoptile weight between treatments. The minimum fresh coleoptile weight and dry coleoptiles weight were achieved in 100% of application of soil (Table 2).

Table 2. Mean comparison for total germination percentage (%), speed of germination, mean germination time, coefficient of velocity germination, radicle length (cm), coleoptile length (cm), fresh leaf weight (g), fresh coleoptiles weight (g), dry leaf weight (g), and dry coleoptile weight (g).

Conclusion

Recently, growing and cultivation of medicinal plants is an important sector in agriculture and is the main source of extracting and producing materials for manufacturing current drugs. Germination ability and percentage of medicinal crops are of fundamental importance, influencing the viability of the plants developing from the grains. Diatomite (DE) is a sedimentary rock primarily composed of the fossilized remnants of unicellular fresh water plants known as Diatoms. Fennel has a long history of herbal uses as not only medicine, but also food. Fennel also is a widespread annual, biennial or perennial medical herb and it depends on the variety. The highest total germination percentage, coefficient of velocity of germination, coleoptile length, fresh coleoptile weight and dry coleoptile weight was related to Isfahan. The maximum speed of germination, mean germination time, fresh length and dry leaf weight was achieved in Shiraz cultivar. The higher values of total germination percentage, speed of germination and mean germination time were related to 100% soil, while application of 50% of soil + 50% of diatomite had obtained the maximum values of radicle length, coleoptile length, fresh coleoptile weight, dry leaf weight and dry coleoptile weight. The maximum values of coefficient of velocity of germination and fresh leaf weight was achieved in application of 100% diatomite. All in all, on the basis of results, it can be concluded that application of 50% soil + 50% diatomite and Isfahan and Shiraz cultivars have a great potential of seed germination of seedling growth.

Abstract

Seed dormancy is one of the major problems in agricultural studies, especially for medical plants. Anise (*Pimpinella anisum L.*) is an important medical plant with dormant seed and it is established and distributed only in its natural habitats. In order to evaluate the effects of some pretreatment factors on primary growth and germination characteristics of Anise, an experiment was conducted as Factorial layout within completely randomized design with four replications. Pre-chilling treatments were 0, 15, 30 and 45 days treatments and hormone treatments were GA_3 (Gibberellic Acid), BA (Benzyladenine), KI (Kinetin), GA_3+BA, GA_3+KI, BA+KI, GA_3+BA+KI, KNO_3, H_2SO_4 and distilled water as a control treatment. Prechilling treatment effects on coleoptile and radicle length, seedling length, germination percentage, mean time for germination, germination rate and seed vigor index were meaningful. Different hormone treatments had significant influence on coleoptile and radicle length, seedling length, germination percentage, mean time germination, germination rate and seed vigor index. The highest germination percentage and germination rate was related to usage of BA+KI. The higher values for radicle length and uniformity of seed germination were achieved in application of BA and KI, respectively. Moreover, application of GA_3+BA+KI had obtained the highest seed vigor index. It seems that application of endogenous GA_3+KI and BA+KI concentration, which is provided mostly by chilling treatment, is the most effective factor for breaking the seed dormancy. On the basis of the results, usage of 45 days moist prechilling accompanied with application of GA_3+KI and BA+KI in Esfahan cultivar was appropriate.

Keywords: Seed dormancy, Seed germination, Seedling growth, Anise.

Introduction

Plants, herbs and their secondary metabolite constituents have a long history of use in traditional and modern western medicine (Soleymani and Shahrajabian, 2012; Ogbaji et al., 2013; Ogbaji et al., 2018; Shahrajabian et al., 2019a; Shahrajabian et al., 2019b; Shahrajabian et al., 2019c). Anise (*Pimpinella anisum L.*) is a flowering plant in the family Apiaceae native to the eastern Mediterranean region, west and Southwest Asia (Ibrahim Doaʾa Anwar, 2017). Anise is also famous in traditional Chinese medicine (TCM), Ayurveda and Unani medicine. Anise has been used for different purposes in traditional medicine of Iran (Shojaii and Abdollahi Fard, 2012). Seed priming treatments have been employed to accelerate germination, seedling growth and yield in most seeds under normal and stress conditions (Shahrajabian et al., 2011; Soleymani and Shahrajabian, 2012; Shahrajabian et al., 2013; Mahdavi, 2016; Soleymani et al., 2016). Seed germination can be controlled by many factors like natural germination and growth inhibitors (Bhardwaj et al., 2016; Shahrajabian et al., 2017; Shahrajabian et al., 2018; Soleymani and Shahrajabian, 2018). These are the derivatives of gibberellic acid (GA_3), abscisic acid (ABA), cinnamic acid, kinetin (KI), bonzyladenin (BA), coumarin, jasmonic and etc. The variation in seed dormancy and seedling emergence are controlled by environmental conditions. The origin of research into Gibberellins can be traced to Japanese plant pathologists who were investigation the causes of the bakane (foolish seedling) disease that seriously lowered to the yield of rice crop in Japan, Taiwan and some other Asian countries (Patel and Mankad, 2014). Gibberellic acid is a plant growth hormone that has important role in seed germination (Patel and Mankad, 2014). It has been reported that the stimulating effects of GA_3 on seed germination are not similar in all crop species (Bell et al., 1995). GA_3 has been also reported to promote growth in cotton, rice and in some halophytes under saline conditions (Lin and Kao, 1995). Tsygankova et al. (2016) confirmed specific auxin-like, cytokinin-like and minor gibberellins-like effect of synthetic heterocyclic compounds on cell division, cell proliferation, cell elongation and cell differentiation that are the basic processes of plant growth and development. Gibberellins eliminated the chilling requirements of peach and apple seed and increased their germination (El-Barghathi and El-Bakkosh, 2005). Primed with plant hormones such as gibberelin could improve quality of seeds and germination in seeds (Shekari et al., 2015). Liopa-Tsakalidi et al. (2011) also suggest that germination and seedling growth of 11 species responded differently to different levels of GA_3. Fernandez et al. (2002) revealed that cold stratification has a direct influence on production of gibberellins (Gas) in seeds of *Arabidopsis thaliana*. Exogenously applied GA overcomes seed dormancy in several species (Hassan and Fardous, 2003). Hormone priming increased antioxidant enzyme activity and decrease amount of reactive oxygen space (Shekari et al., 2015). Sharifi and Pouresmael (2006) concluded that only cold treatments such as gibberellic acid, cytokinin, potassium nitrate, washing and light treatments are not useful. It has been reported that GA is effective in breaking seed dormancy in snowberry (Rosner, 2002). Nkomo and Kambizi (2010) noted that prechilling followed by exposure to a temperature higher than 30^{o}C encourages germination of *C. Olitorious* seeds. Rouhi et al. (2010) concluded that applying 500 ppm concentration of GA_3 and 0.1 of KNO_3 resulted in higher germination in waterlily dormant seeds. Plant hormones are used in breaking seed dormancy (Gupta et al., 2008). Cytokinin and auxin are the most common plant growth regulators used in in vitro culture of plat tissues (Eudes et al., 2003; Abu-Romman et al., 2015). Cytokinins constitute a major class of plant growth regulator that is involved in a wide range of physiological processes (Davies, 1995). Cytokinins have a stimulatory or an inhibitory role in different development processes, such as control of apical dominance in the shoot, root growth and branching, leaf senescence, and chloroplast development. In spite the fact that Anise is an important and expensive medicinal and spice plant, not enough information is available on the effects of moist pre-chilling and application of hormones on different cultivars of it. So, the aim of this study is survey the certain effects of different treatments to stimulate seed germination and seedling growth of Anise.

Material and Methods

In order to evaluate the influence of some pretreatment factors on primary growth and germination characteristics of anise (*Pimpinella anisum L.*), an experiment was conducted as Factorial layout within completely randomized design with four replications at Research laboratory of Mojgan Agricultural Company, Mahmood abad, Isfahan, Iran (Latitude 32 ^{o}52$^{/}$ N, Longitude 51^{o}34$^{/}$ E and 1660 m elevation).

Pre-chilling treatments were 0, 15, 30 and 45 days treatments and hormone treatments were GA_3 (Gibberellic Acid), BA (Benzyladenine), KI (Kinetin), GA_3+BA, GA_3+KI, BA+KI, GA_3+BA+KI, KNO_3, H_2SO_4 and distilled water as a control treatment. First, seeds were surface sterilized in 1.5% (w/v) sodium hypochlorite solution for 15 minutes and then rinsed three times sterile distilled water. For each treatment, 4 Petri dishes were used and 30 seeds were put into each of them, then, each Petri dish were covered with 10 mm of each specific treatment. In the first trial, seeds were chilled for 15, 30 and 45 days, and after that, seeds were soaked and treated with 10 hormone treatments. In the second experiment, seeds were treated without pre-chilling treatments. In the thirds experiment, seeds treatments were done with poly ethylene glycol. Equation number one and number two was used to calculate germination percentage and germination rate, respectively.

Germination percentage= Number of germinated seed / 100 (1)

1) $GR = \Sigma \frac{N}{\Sigma(n \times g)}$ (2)

Where, n is the number of germinated seed on growth day and g is the number of germination seeds Analysis of variance (ANOVA) was used to determine the significant differences.
Uniformity of seed germination and mean time for seed germination (MTG) was evaluated by equation number 3 and 4. Seed vigor index was calculated by equation number 5.

Uniformity of seed germination= $\dfrac{1}{\dfrac{\sum (D-\bar{D})^2 \times N}{\sum N}}$ (3)

$MTG = \dfrac{\Sigma(nd)}{\Sigma n}$ (4)

n: The number of germinated seed in the specific day.
d: The number of days from the beginning of germination.
∑n: The total number of germinated seed.

Seed vigor index: Germination percentage × mean of seedling length (mm)(both coleoptile and radicle) / 100 (5)

The Multiple Range Test of Duncan performed the separation means ($P<0.05$). All statistics was performed with the SAS statistical software.

Results and Discussion

Prechilling had significant impact on coleoptile length, radicle length, seedling length, germination percentage, mean time for germination, germination rate and seed vigor index. All experimental characteristics expect of uniformity of seed germination was affected by hormone treatments. The highest coleoptile length was related to 45 days chilling (2.45 mm) which had meaningful differences with other treatments. Although, the higher value of radical length was obtained for 45 days (0.8485 mm) chilling, its difference with 30 days chilling was not meaningful. The minimum coleoptiles (0.7536 mm) and radical length (0.6819 mm) was related to control treatment. The higher values of seedling length (2.98 mm), and germination percentage (70.02%) was obtained for 45 days of chilling followed by 30 days, 15 days and control treatment. There were significant differences in seedling length and germination percentage between 45 days of chilling and other treatments. Control treatment had obtained the highest mean time for germination (11.18) which had meaningful differences with 30 days and 45 days pre-chilling, although, its difference with control treatment was not meaningful. The maximum value for uniformity of germination rate (5.87%), and seed vigor index (2.244) was achieved in 45 days pre-chilling which had meaningful differences with other treatments. Both germination rate and seed vigor index was increased significantly from control treatment to 45 days pre-chilling. The maximum and the minimum uniformity of seed germination was related to control treatment (0.2165), and 15 days pre-chilling (0.1075), which had no meaningful differences with each other (Table 1). Gupta et al. (2008) reported that prechilling treatment also improved seed germination in Isabgol. Shekari et al. (2015) concluded that GA_3 priming treatment had a significant effect on germination percentage and number of normal seedlings. The highest coleoptiles length (1.663 mm), and seedling length (2.574 mm) was related to application of GA_3+KI and the minimum one was observed in KNO_3. Patel and Mankad (2015) concluded that low concentrations of GA_3 influence all developmental and physiological processes in plants. The maximum and the minimum radical length was related to application of BA (1.7232 mm), and KNO_3 (0.5286 mm), respectively, which had meaningful differences with each other. Benzyladenine (BA) at a high concentration was also shown to be effective in shoot regeneration in *P. vulgaris* (Malik and Saxena, 1992). Application of BA + KI had obtained the highest value for germination percentage (66.33%) and germination rate (4.126%), which had significant differences with other treatments. Sawan et al. (2000) demonstrated that kinetin application improved seed viability and seedling vigour as shown by lengths of the hypocotyls, radical and the entire seedling, as well as seedling fresh weight. Gibberellic acid is also known to play an essential role in seed germination, stem elongation and flower development (Sharma et al., 2006). The maximum and the minimum mean time for germination was achieved in usage of BA + KI (66.33), and KNO_3 (25.45), respectively. Narra et al. (2010) also found that the seedling under the GA_3 influence showed enhanced germination, seedling elongation and dry weight accumulation on *Trachyspermum ammi*. Although, the higher value for uniformity of seed germination was related to KI (0.1523), followed by other treatments, there were no significant differences between treatments. Application of GA_3+BA+KI had obtained the highest seed vigor index (1.545), and the minimum one was related to application of distilled water (0.4076) (Table 1). Gupta et al. (2008) concluded that GA has shown promising effect in breaking seed dormancy with accelerated seed germination (speed of germination, vigor index) and seedling growth (seedling dry weight).

Conclusion

Seed germination is a complex physiological processes that response to environmental signals such as light, water and other factors. Also, Seed germination is very important to know the germination pattern of a plant, especially the medicinal plants. Prechilling treatment effects on coleoptile and radicle length, seedling length, germination percentage, mean time for germination, germination rate and seed vigor index were meaningful. Different hormone treatments had significant influence on coleoptile and radicle length, seedling length, germination percentage, mean time germination, germination rate and seed vigor index. Prechilling treatment for 45 days had obtained the highest coleoptile and radicle length, seedling length, germination percentage, germination rate and seed vigor index. While control treatment had obtained the maximum mean time for germination and uniformity of seed germination. Application of GA_3+KI had obtained the highest coleoptile length, seedling length, and mean time for germination. The highest germination percentage and germination rate was related to usage of BA+KI. The higher values for radicle length and uniformity of seed germination were achieved in application of BA and KI, respectively. Moreover, application of GA_3+BA+KI had obtained the highest seed vigor index. All in all, in conclusion, it was shown that GA_3, KI and BA had greatly enhanced the germination parameters in terms of germination percentage, seedling elongation and other characteristics.

Abstract

Sustainable agricultural system is the best way to provide needs of people today and future generations. In sustainable agricultural system, agricultural yields increase with intercropping due to higher growth rate, reduction of seeds, pests and diseases and more effective use of resources. Intercropping is a one of the most important way to increase diversity in an agricultural ecosystem. Intercropping has a long history. Intercropping systems could be more stable systems of agricultural practices than mono cropping. The most important advantages of intercropping are increasing production, greater use of environmental resources, significant reduction of pests, diseases and weeds damage, improve soil fertility and increase in nitrogen, stability and uniformity yield. Integrated use of synthetic and organic fertilizers may lead to development of sustainable crop production. This method also can increase the efficiency of chemical fertilizers and of course reduce their use. Green manures are legume crops like clover and others that are able to add nitrogen by fixation to the soil and then reduce the need for commercial nitrogen. Moreover, planting green manures is an effective means of adding nitrogen to the agricultural land. The biological nitrogen fixation is also play an important role in sustainable agricultural systems. In sustainable agricultural system, fertilizers, livestock manure and cover crops are important parameters in productive agricultural systems to have stable food. All in all, in sustainable agricultural system, intercropping included, fertilizers, livestock manure and cover crops are important parameters in productive agricultural systems to have stable food.

Keywords: *Intercropping, Chemical Fertilizer, Manure, Sustainable Agriculture, Stable System.*

Introduction

The rapid increases in human population and exploitative use of non-renewable resources have worsened food shortages (Amini et al., 2012; Esfandiary et al., 2012; Soleymani et al., 2012a,b; Shahrajabian et al., 2017a; Shahrajabian et al., 2012b,c,d; Ogbaji et al., 2018; Shahrajabian et al., 2018; Soleymani et al., 2018; Yong et al., 2018; Shahrajabian et al., 2019a,b,c,d,e,f,g). Chemical fertilizers play a dominant role in agriculture development (Shahrajabian and Soleymani, 2017a,b). Most scientists believe that increasing yield per ha is a major way for increasing crops yield (Ogbaji et al., 2013; Soleymani et al., 2016; Soleymani and Shahrajabian, 2017; Yong et al., 2017). Due to high costs and poor accessibility of inorganic fertilizers to resource-poor farmers, other inputs are oftentimes proposed as alternatives (Shahri et al., 2011; Soleymani and Shahrajabian, 2012d; Shahrajabian et al., 2013). It is believed that much of deficient plant nutrients could be supplied to soils through organic matters while short falls are made up with mineral fertilizers (Ogbaji et al., 2013). Farmyard manure (FYM) contains very small amount of major nutrients and even difficult to obtain required quantity of FYM and also involve large transportation. It also maintains the soil physical and chemical condition and improves the overall ecological balance of the crop production system. It also reduced use of external inputs and implies on reliance on self regulating ecosystem process. When the livestock fodder is scarce, results in impaired livestock nutrition and health condition. In forage production, considering chemical position of forage crop is so important.

Intercropping

Intercropping is known as a practice, which can improve the utilization of available resources and cause yield advantages and increases yield stability compared to sole cropping (Soleymani et al., 2011g; Soleymani and Shahrajabian, 2012a,b). Intercropping is a sustainable practice used in many developed and developing countries and an essential element of agricultural sustainability. Symbiotic N_2 fixation (SNF) in legumes is a fundamental process for maintaining soil fertility continued productivity of organic cropping systems. One of the benefits of intercropping is, having high potential to extrapolated crop combinations. Intercropping legumes with non legume crops is a common practice in the world. Sole annual legumes, cereals and intercropping mixture of annual legumes and cereals are intensively cultivated in the world for forage production. Recently intercropping gained an increasing interest in an attempt to substantiate functional biodiversity for agriculture production and to reduce chemical inputs use. The introduction of a living cover crop during a cash crop growth cycle (relay intercropping) may help to preserve biodiversity, increase soil organic matter content and carbon sequestration and provide nutrient recycling. Soil organic matter associated with microbial activity plays a major role in the nutrient cycling process in soil leading to enhanced nutrient availability. Soleymani et al. (2012c) reported that there has been a rapid increase of fertilizer application in recent years to achieve high yields in Iran, but studies showed that intercropping cause yield advantage and better nutrition uptake. They have found that intercropping of berseem clover and forage corn in low input farming system, nitrate accumulation in clover was suitable for animal 's grazing. They concluded that mix cropping legumes with cereal and grasses species had been applied to enhance nutrition value, supply energy and protein on both crops; mixture of cereal and legumes offer a sustainable alternative to maintain efficient farming systems with reduced environmental impacts. Soleymani et al. (2012d) mentioned that green manuring is an age-old practice used for supplying the nitrogen to crop plants; the intensive cropping system, heavy input technology, environmental degradation and other related problems again encouraged its re-inclusion in plant nutrient supply system. They did conclude that residue burning accompanied with usage of triticale as a green manure was the best choice to achieve high quality, but for obtaining the most fresh forage yield and biological yield of forage corn, triticale plantation can be replaced by barley cultivation.

Fertilizer

Low-input farming systems such as arable organic farming, often have limited access to nitrogen, and this often limits the productivity of these systems (Soleymani et al., 2010; Soleymani et al., 2011f; Soleymani and Shahrajabian, 2012e; Soleymani et al. 2012a; Shahrajabian et al., 2020). Minimal or no fertilizer input had caused serious nutrient depletion, which coupled with the low fertility status of soil and it is the major limiting factor to crop production. Nitrogen supply increases plant growth such as increasing nitrogen supply enhances both shoot and root, and plant growth inhibited by low nitrogen (Soleymani and Shahrajabian, 2011; Shahrajabian et al., 2011). Supplemental nitrogen application, is needed to optimize plant production and minimize production cost (Soleymani et al., 2013), however, the application of excessive amounts of nitrogen can cause the accumulation of toxic levels of nitrate (NO_3^-) in plants (Khoshkharam et al., 2010; Soleymani and Shahrajabian, 2013). In most commercially available fertilizers, the concentrations of fertilizer active ingredients rapidly diminish prior to sufficient plant uptake due to degradation (e. g. chemical, photochemical and biological), volatilization, leaching, adsorption or land immobilization (Broumand et al., 2010). Nitrate toxicity in forage plants can pose chronically or acute in livestock.

Manure

Organic farming, which evolved in 1980s, is one way to solve the current farming problems, in this method, manure and green manure use instead of chemical fertilizers (Soleymani et al., 2011b; Soleymani et al., 2011e; Soleymani et al. 2012b). Manures are very variable products, often difficult to apply accurately and release nutrients in the soil at a desirable rate. Some studies have shown that farmyard manure applied alone or in combination with inorganic fertilizers was effective in maintaining soil fertility under continuous cultivation. Applying farm manure increased cation exchange capacity (CEC), organic carbon and water holding capacity of the soil and nutrient availability. Dairy manure is an excellent source of nitrogen for crops and can easily fulfill the nitrogen requirement. To get satisfactory results well-composted manure must be used, because it is usually free of weed seeds and has a better nutrient balance. It has been noted that application of organic manure has a more lasting beneficial residual effect that can remain significant up to four seasons when compared with inorganic fertilizers whose residual benefit do not last beyond season.

Green manure

The typical organic production is characterized by extended rotations involving leguminous crop green manure and organic amendments utilization (Lynch et al., 2008). Canali et al. (2010) noted that supply of nitrogen from the soil, which consist of nitrogen mineralized from organic soil matter and crop residue is an important and variable contributor of nitrogen to potato crop production. Without organic farming, food security will be hampered (Sarker and Itohara, 2010). Legumes are often grown for incorporation into soil as a green manure providing benefits such as off season soil cover, stimulated soil biological activity and improved plant nutrition (Soleymani et al., 2011d). Most interests has been attached to the legume 's ability to furnish subsequent crops with readily available nitrogen (N).

Conclusion

Sustainable agriculture means a shift from monoculture to intercropping. In another word, intercropping means the agricultural cultivation of two or more crops in the same space and at the same time. Sustainable farming also means self-sustaining, low-input and energy-efficient agricultural systems. Biodiversity is the main key and strategy for sustainable agriculture. In intercropping system, there is normally one main crop and one or more added crops, with the main crop being primary importance for food and forage production. The most important aim and advantage of intercropping is to produce a higher yield on a given piece of land by appropriate use of the available growth resources that may not be utilized by each single crop grown alone. There are different types of intercropping but the most important types are, row intercropping, strip intercropping, mixed intercropping and relay intercropping. Intercropping system may lead to soil conservation, improvement of soil fertility, and improvement of forage quality, and reduction of pest and diseases. The intercropping systems are old and widespread applications in low-input agricultural systems, and they were common for so many countries before the modernization of agriculture. There are both direct and indirect facilitative interactions of intercropping systems. Intercropping systems can cause more effective use of resources by providing symbiotic nitrogen from legumes or making available inorganic phosphorus fixed in soil because of lowering of pH via nitrogen fixing legumes. Also, more efficient water usage in intercropping systems was suggested by so many researchers. Intercropping practices are the most productive when intercrops of different growth period are used so that their maximum requirements for growth resources occur at different times. Intercropping is the best way of introducing more biodiversity into agro-ecosystems and results have shown that increased crop diversity may increase the number of ecosystem service provided. It is also the best way to ecological balance, more utilization of resources, increase the quantity and quality of agricultural products and significant reduction damage and lost by pests, diseases and weeds. On the basis of multiple advantages of intercropping especially in the terms of sustainable agriculture and organic farming, it is more clear that intercropping is more reasonable than sole cropping systems. Application of organic and synthetic fertilizers to soil would provide multiple benefits for improvement of soil chemical, physical and biological properties leading to improved crop yield. Integrated use of synthetic and organic fertilizers lead to development of sustainable crop production. Also, this may improve the efficiency of synthetic fertilizers and reduce their usage. Integrated use of organic and synthetic fertilizers is a good method to improve crop productivity and sustain soil quality and fertility. In sustainable agricultural system, fertilizers, livestock manure and cover crops are important parameters in productive agricultural systems to have stable food. In this review study, it is informed about the importance and use of the intercropping system, manure and chemical fertilizers in agricultural production to have a stable and sustainable agricultural production.

Abstract

The oriental fruit fly, *Bactrocera dorsalis* Hendel (Diptera: Tephritidae**)** is an invasive pest in many countries across the globe, including Nigeria. The potentials of three food-based lures in mass trapping of *B. dorsalis* on *Chrysophyllum albidum* were assessed during 2019 fruiting season in three selected villages in Osun state, Nigeria. The food lures included: pineapple juice, orange juice, banana juice, Methyl Eugenol (standard check) and control (water). The lures were baited with cypermethrin applied at 40ml/trap/week, while methyl eugenol was applied at 10 ml/trap/week. Data collected were subjected to ANOVA, and significant means were separated using Turkey's Honestly Significant Difference (THSD). The results showed that *B. dorsalis* was trapped on *C. albidum* in all the study sites. The number of *B. dorsalis* trapped was higher during the ripening period of *C. albidum* in all locations. The percentages of trapped flies after 10 weeks were 70.85% - 79.50% (Methyl Eugenol) >7.86% - 11.09% (Orange juice) > 8.95% - 11.05% (Pineapple juice)> 2.52% - 6.41% (Banana juice)> 0.60% - 1.09% (control) at the study sites. There were no significant differences (P > 0.05) on the density of *B. dorsalis* trapped in all locations. However, the densities of trapped *B. dorsalis* significantly (P<0.05) differed among the different treatments in all location. All the food-based lures significantly (P<0.05) trapped higher flies than control. The food-based lures tested had potential in trapping *B. dorsalis,* hence increased dosage and application frequency could be used to control *B. dorsalis* in homestead trees and home gardens.

Keywords: *Fruit fly, attractants, mass trapping, control, African star apple.*

Introduction

Fruit flies are a prevalent pest in most of Africa; affecting domestic and export fruits exploitation (De Meyer *et al.,* 2010). The *Bactrocera dorsalis* (Hendel) (Diptera: Tephritidae) fruit fly complex comprises more than 75 species and is one of the crucial pest complexes in global agriculture (Clarke *et al..*, 2005). *B. dorsalis* is a pest regarded as a significant threat for biosecurity among the fruit fly species (CABI, 2015; EPPO, 2015). The species in the complex are highly polyphagous and invasive in nature enabling them to infest a wide range of fruits (Goergen *et al.*, 2011). The pest is known in association with almost 80 host plant species (De Meyer *et al.,* 2012), but African star apple (*Chrysophyllum albidum*) is one the main host of *B. dorsalis in* West Africa. (Goergen *et al.* 2011). African star apple is an indigenous wild fruit tree with enormous potentials for plantation establishment; the fruit/seed could serve as an alternative carbohydrate or energy foodstuff (Okigbo, 1978; Okafor, 1981). The fruits are good sources of vitamins, irons, flavours to diets and raw materials to some manufacturing industries (Adisa, 2000; Bada, 1997; Okafor and Fernandes, 1987; Umelo, 1997) *C. albidum* is reported to be a renewed tree in the agroforestry system and is cultivated in Nigeria, Uganda, Niger, Cameroon, Ivory Coast republics on a commercial scale (Adewusi and Bada, 1997).

The fruit pulp of *Chrysophyllum albidum* contains 21.8 mg/100 g ascorbic acid and the skin contains 75 mg/100 g while Edem and Miranda 2011 reported 446 mg and 239 mg/100 g for pulp and skin respectively (Adesina, 2000; Achinewhu,1983). In Nigeria, children and pregnant mothers consume *C. albidum* ripe fruits, taking a great advantage from.

Production of quality and safe fruits including *C. albidum* has been hampered by the infestation of the fruit flies, especially the *B. dorsalis* since its arrival in Nigeria.

In most parts of Africa, the smallholder farmers, which are responsible for producing the bulk of the fruits, rarely apply any control measures against fruit flies resulting in significant economic losses.

The use of synthetic insecticides for pest control is, conversely, associated with various environmental problems such as contamination, adverse effects on non-target organisms and the development of resistance (Croft, 1990). Female Tephritids require a post-eclosion protein meal for ovarian development and egg maturation (Drew and Yuval 2000). Consequently, fruit fly detection, monitoring, and suppression strategies have relied strongly on the use of food-based attractants baited with various toxicant.

The bait spray strategy significantly reduces the amount of pesticide needed for fruit fly control and has been used successfully in eradication campaigns (Roessler, 1989). According to Mediouni-Ben *et al*., (2010) the use of the mass trapping technique by female-targeted and male-targeted lures can also be included as a component of an Integrated Pest Management (IPM) program for Fruit flies. Therefore, this study evaluates the potentials of three food base attractants or Methyl Eugenol in mass trapping of *B. dorsalis* on *C. albidum* as a management practice.

Materials and methods

Experimental site

The study was carried out in Ife South, Osun state South West Nigeria during the Chrisophyllum fruiting season of 2019. If South is a Local Government Area in Osun State, It has an area of 730 km² located within latitude 7°11′00″N and longitude 4°42′00″E (GMT) with annual rainfall from about 1.300 mm to 1.500 mm, average relative humidity of about 80 to 85 %, and average yearly temperature of 26.2 °C. Three local sites were selected for the study, and they include; Akerodolu, Agodi and Orisunbare

Preparation of food-based bait:

Pineapple, orange and banana food bait were prepared by peeling 1kg of each the fruit and blending it into a smooth slurry paste using an electric kitchen blender. The juices were extracted separately with 1 litre of water for each and sieved with muslin cloths to obtain a homogenous solution as described by Ugwu *et al.*, (2018). The banana paste was prepared by blending 1 kg of banana with 500 ml of water. The prepared samples were refrigerated until when used.

Experimental setup

Lynfield trap (LT) was used to trap the flies. Lynfield trap is a bucket type trap composed of a cylindrical plastic container with four equidistant holes on the upper third, and the lid of the trap contains a hook to which an ME dispenser such as Invader Lure must be fitted (Copeland, 2012) There were five treatments including control; they include Methyl Eugenol, Pineapple juice bait, Orange juice bait, Banana paste and control (water). Cypermethrin (2 ml) was added to each attractant to knock down the trapped flies.

Placement of traps

Three trees were selected from each location at a distance of 10 m from each other to obtain three independent replicates per site. Five traps were hung per tree in all the sites. Forty milliliters of prepared food baits were taken with the aid of 10 ml injection syringe and carefully dropped on 0.5 gm of absorbent cotton wool and placed at the bottom of the trap while twenty milliliters of Methyl Eugenol were used following the same procedure. Each lure was replicated three times per location in a Complete Randomized Block Design (CRBD) using each tree as a sampling unit. Five traps were hung on each tree at 10 m above the ground within the tree canopy (Ugwu *et al.,* 2018)

Data collection and analysis

Data were collected on the number of fruit flies trapped per trap every week in all the locations for ten weeks consecutively. The trapped flies were taken to the laboratory for counting, identification and sexing. Data collected were transformed using square root transformation (X + 0.5), then subjected to ANOVA and significant mean separated at 5% level using THSD.

Results and discussion

Effects of treatments on the density of *Bactrocera dorsalis* trapped at Akeredolu

The number of *B. dorsalis* trapped at Akeredolu village is shown in Table 1

The result showed that Methyl Eugenol was the most effective attractant for *B. dorsalis* at Akeredolu village. It recorded a mean population density of 65.62 (79.50%) of adult *B. dorsalis* per trap after ten weeks. Methyl Eugenol was followed by pineapple juice bait with a mean density of 7.41 (10.17%) per trap at ten weeks. The weekly catches of flies by the lures per trap revealed that Methyl Eugenol significantly (p<0.01) trapped the highest number of flies throughout the period of the study. The number of trapped *B. dorsalis* increased with the progress of fruit ripening, and a peak was on the 9th week of the experiment. A higher population of flies were recorded in correspondence of *C. albidum* fruit ripening from 7 to 10 week in February 2019

Effects of treatments on the density of *Bactrocera dorsalis* trapped on *C. albidum* at Orisunbare Village.

The number of *B. dorsal*is trapped on *C. albidum* at Orisunbare village is shown in Table 2

The population density of *B. dorsalis* flies recorded at Orisunbare village followed a similar trend with that of Akeredolu village. The highest population of *B. dorsalis* were trapped on Methyl Eugenol with a mean occurrence of 65.92 (73.58%) per trap in 10 weeks. Methyl Eugenol was followed by orange juice bait with a mean number of 9.33(10.41%) per trap in 10 weeks. Methyl Eugenol significantly (p<0.01) caught a higher number of *B. dorsalis* flies from week one to week ten. Orange juice bait trapped a higher number of *B. dorsalis* than other food-based attractants, although it did not differ significantly with the population trapped by pineapple juice bait. All the food-based lures significantly (p<0.01) caught a higher number of flies than control (water). Higher densities of *B. dorsalis* flies were trapped during the peak of *C. albidum* fruit ripening from week 7-10 in February.

Effects of treatments on the density of *Bactrocera dorsalis* trapped on *C. albidum* at Agodi Village

The population density of *B. dorsalis* tapped by the different attractants at Agodi village is shown in Table 3. Methyl eugenol significantly ($p<0.05$) recorded the highest number of *B. dorsalis* flies throughout the study period with a mean density of 79.30 (70.85 %) per trap in 10 weeks, followed by orange juice bait with a mean value of 12.41 (11.09%). There was no significant ($p>0.01$) between the orange juice bait and pineapple juice bait on the density of flies trapped in this location. However, all the food-based attractants significantly($p<0.01$) stuck a higher number of flies than control. *B. dorsalis* density was similarly higher from 7th – 10th week (February) during the study in this location.

Table 3. The population density of *Bactrocera dorsalis* trapped on *C. albidum* at Agodi village

Treatments	1	2	3	4	5	6	7	8	9	10	Mean
Methyl eugenol	6.71a	5.86a	5.06a	5.67a	5.77a	7.88a	10.30a	8.21a	11.97	11.87a	79.30a

Percentage population of *B. dorsalis* trapped on *C. albidum* at the three sites of the study areas

Bactrocera dorsalis were trapped in all the three study sites selected for the study (Fig. 1) There were no significant differences ($p \geq 0.05$) on the population density of *B. dorsalis* trapped in all the locations. However, the highest percentage of *B. dorsalis* flies were caught at Agodi village (39.40%), followed by Orisunbare village (31.54%) while Akeredolu village trapped the least density of *B. dorsalis* flies (29. 06%)

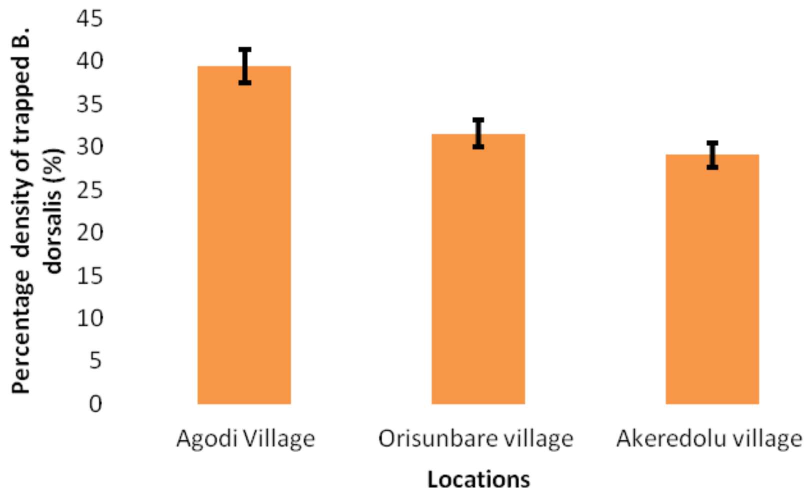

Fig. 1. **Mean percentage density of *B. dorsalis* trapped on *C. albidum* at the three study sites**

Percentage density of female and male *B. dorsalis* trapped on *C. albidum* trees at the three study sites.

Female and male *Bactrocera dorsalis* were trapped in all the study sites (Fig. 2)

Methyl Eugenol trapped only males *B. dorsalis* at the three study sites while food-based lures and control trapped both female and male flies. The percentage density of male *B. dorsalis* trapped by Methyl Eugenol was significantly ($p<0.05$) higher than other treatments All the food-based lures significantly ($p< 0.05$) caught a higher number of females than male *B. dorsalis*.

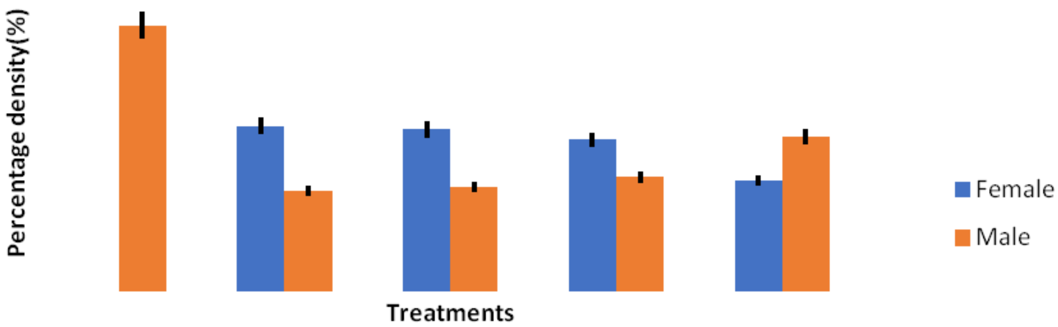

Fig.2. Percentage density of female and male *B. dorsalis* trapped at the three study sites

The study has shown that all the food-based lures evaluated attracted adult *B. dorsalis.* Although there were disparities in the level of attraction by different lures assessed. The results support the earlier findings by Vargas *et al*. (2003) that reported the type of protein in a food-based bait could influence the attractiveness of the lure to fruit flies.

Methyl Eugenol acts as a para pheromone attracting more *B. dorsalis* flies than the food-based lures did. Moreover ME trapped only male flies while food based lures were moderately effective and trapped both male and female *B. dorsalis* This report supports the earlier report by Russell Messing (1999) that parapheromone lures (methyl eugenol, cue-lure, ceralure, trimedlure and latilure) attract males only and every fruit fly species in Hawaii is attracted to a different kind. Methyl Eugenol has earlier been reported to be very effective in mass trapping *Bactrocera* spp. in mango and established to be the most effective technique among the various fruit fly management strategies tested using ME trap plus Bait (Ishaq *et al.* (2004), Stonehouse *et al.* (2005) and Jiji *et al.* (2009).

Correspondingly, Ekesi *et al.* (2014) reported that Methyl Eugenol is a male annihilation lure for *B. invadens*, and it attracts only males. Ugwu and Shuaib, (2018) and Ugwu *et al*., (2018) also reported that methyl eugenol trapped only male *B. dorsalis* while food-based attractants caught both sexes on guava and mango homestead trees

Bactrocera dorsalis were trapped on *C. albidum* trees in all the locations during the study, indicating that *C. albidum* is among the most suitable hosts of *B. dorsalis* complex as reported by Goergen *et al.* (2011) where he listed *C. albidum* among a wild host of *B. dorsalis* complex. In correlation to *B. dorsalis* host rang*e*, it has also been reported that the host range of *B. dorsalis* in Africa consists of more than 72 plant species of both wild and cultivated crops spread across 28 families (Goergen *et al.* (2011; Umeh and Onukwu, 2016)

Protein source is a significant constituent in the food baits, and commercial lures have been used to trap *B. cucurbitae* (Fabre *et al*., 2003) and *B. dorsalis* (Alyokhin *et al*., 2000; Cornelius *et al*., 2000)

Conclusion

This study has contributed to the knowledge about the presence of *B. dorsalis* in Osun state Nigeria. *C. albidum* has proved to be one of the major wild hosts of *B. dorsalis*, and food-based lures have shown potential for trapping of *B dorsalis.* Thus, the study is vital for the development of efficient management strategies against fruit flies, hence increased dosage and application frequency could be used to manage *B. dorsalis* infestations in homestead trees, orchards and home gardens. The study also confirmed the selective and robust response of *B. dorsalis* to Methyl Eugenol and food-based attractants and their ability to infest and develop in *C. albidum* fruits.

Abstract

The development of new assortments of beverages with high biological value and functional effect on human health is a new trend in the industry. Therefore, malt, a major raw material in brewing, is of particular importance. Malt has a high biological value and some of its components (phenolic compounds, catechins, ferulic acid, and etc.) have a high antioxidant capacity. The aim of this study was to investigate the phenolic content and antioxidant capacity of 8 malt types (2 Pilsner, 2 Vienna, 2 Wheat, 1 Munich and 1 Pale ale) and wort produced from them. The total phenolic content, phenolic acid and flavonoid phenolic compounds were determined. The total phenolic content varied between 0.88 and 6.66 mg GAE/g dw for malt and 263.57 and 412.65 mg GAE/L for wort. The results for phenolic acids and flavonoid phenolic compounds were almost equal both for malt and wort. The antioxidant activity was determined by the radical scavenging assay (DPPH) and ferric reducing antioxidant power (FRAP). The DPPH radical scavenging activities varied from 1.21 to 9.31 μM TE/g dw for malt and 492.39-6105.68 μM TE/L for wort, respectively. The results from FRAP assay ranged from 1.35 to 28.56 μM TE/g dw for malt and between 192.08 and 473.76 μM TE/L for wort, respectively. The results obtained were used for a discussion on the possibilities for the production of wort-based functional beverages.

Keywords: *malt, phenolic compounds, antioxidant activity, functional beverages*

Introduction

Beer is the oldest and one of the most consumed alcoholic beverages in the world. It is a natural product prepared from four main ingredients (malt, hops, water and yeast), each of which has a number of benefits for human health (Carvalho et al., 2016).

Malt, which is made mostly from barley through a malting process, is essential for the beer quality. It provides a certain amount of starch, as well as contributes to the organoleptic characteristics and colour of the beer. Malt plays a major role in the oxidative stability of beer, as its various components have antioxidant capacity. Malt can contribute to about 95% and 86% of the antioxidant capacity of dark and pale beers, respectively. The antioxidant capacity of malt is also important for human health by protecting against various diseases - cancer, nervous and cardiovascular diseases (Cechovska et al., 2012; Vanderhaegen et al., 2006; Landete 2013; Carvalho et al., 2016). The antioxidant capacity of malt is not only due to the barley polyphenols but also to a number of components generated during kilning as reductones and Maillard reaction products (MRPs) (Rivero et al., 2005; Carvalho et al., 2016). Different phenolic compounds have been identified in barley and malt, including flavan-3-ols, proanthocyanidin oligomers, hydroxycinnamic acid derivatives, and low amounts of flavonols. The amount of some of them changed during malting but others withstand the process (Dvorakova et al., 2008; Leitao et al., 2012; Carvalho et al., 2016). The higher antioxidant activity of malts was mainly attributed to the formation of MRPs upon heating, which is positively correlated with their color (Chandra et al., 2001; Coghe et al., 2003; Carvalho et al., 2016).

The aim of this study was to investigate main brewing characteristics and antioxidant capacity of different malt types. The results obtained were used for the selection of methods of modeling the mixture composition which will be used for production of wort-based functional beverages.

Material and Methods

Malts

In the present work, eight different malts, produced 2017-2018, were used. Four of them were produced by Weyermann®, Germany - Pilsner, Vienna, Wheat, and Munich 1, (indicated with W) and the other four were produced by Best Malt, Germany - Pilsner, Vienna, Wheat, and Pale Ale (indicated with BM).

Reagents

Folin-Ciocalteu reagent, gallic acid, caffeic acid, quercetin, DPPH (2,2-diphenyl-1-picrylhydrazyl), TPTZ (2,4,6-tripyridyl-*s*-triazine), $FeCl_3 \cdot 6H_2O$, and Trolox (6-hydroxy-2,5,7,8-tetramethylchromane-2-carboxylic acid) were purchased by Sigma-Aldrich. Hydrochloric acid was purchased by Merck, Germany. All the other reagents were of analytical grade.

Main brewing characteristics of malts

The main brewing characteristics of malts (Table 1) were determined according to standard methods of European Brewery convention (Analytica EBC, 2007).

Extraction procedures

Malt extracts were produced by mixing 10 g of malt and 40 mL of 80% (v/v) methanol. After staying overnight the mixture volume was made to 50 mL with methanol, homogenized, filtered (Whattman No.1) and stored at -20 ºC. If it is necessary, extracts were diluted properly with purified water before analyses. Wort was produced by Congress mashing (Analytica EBC, 2007) and stored at -20 ºC before use. Wort was diluted with methanol in proper ratio, left for 30 minutes and filtered (Whattman No.1).

Phenolic content of malt and wort

The content of total phenolic compounds was determined by the Folin–Ciocalteu (FC) method, as described by Dvořáková et al. (2008) with slight modifications. 1 mL of sample, 4 mL of Folin-Ciocalteu working solution, 5 mL of sodium carbonate (7.5%, w/v) were introduced into a test tube. This solution was agitated and left to stand for 1 h. The absorbance at 765 nm was determined in a Shimadzu UV-VIS1800 spectrophotometer (Kyoto, Japan) against blank sample prepared with purified water. The calibration curve was performed with gallic acid, and the results are expressed as mg of gallic acid equivalents (GAE)/g dw for malt and mg GAE/L for wort. The total phenolic compounds, total phenolic acids and total flavonols were determined by modified Glories method as described by Mazza et al. (1999). Briefly, the sample (1 mL) was pipetted in a test tube and 1 mL 0.1% HCl in 95% ethanol (v/v) and 18.2 mL 2% HCl (v/v) were added. The solution was thoroughly mixed and allowed to stand for approximately 15 min before reading the absorbance with a spectrophotometer against blank sample prepared with purified water. The absorbance (A) at 280 nm was used to estimate total phenolic content, $A_{320\ nm}$ was used to estimate phenolic acids, and $A_{360\ nm}$ was used to estimate flavonols. The calibration curves for total phenolic compounds, total phenolic acids and total flavonols were constructed by using gallic acid, caffeic acid and quercetin as standard, respectively.

Antioxidant capacity of malt and wort

The antioxidant activity of malt and wort was measured by DPPH method as described by Dinkova et al. (2014) with minor modifications. Briefly, 250 µL of sample were added to a

2.25 mL DPPH solution in methanol (6×10^{-5} M); the mixture was left for 15 min (kept in the dark at room temperature) so that a reaction could take place, and then the absorbance at 517 nm against blank sample with purified water was read. The control sample was made with methanol. The FRAP assay was done according to Benzie and Strain (1996) with some modifications. The stock solutions included 300 mM acetate buffer (3.1 g $C_2H_3NaO_2\cdot3H_2O$ and 16 mL $C_2H_4O_2$), pH 3.6, 10 mM TPTZ solution in 40 mM HCl, and 20 mM $FeCl_3\cdot6H_2O$ solution. The fresh working solution was prepared by mixing acetate buffer, TPTZ solution, and $FeCl_3\cdot6H_2O$ solution in ratio 10:1:1. Extracts (150μL) were allowed to react with 2850 μL of the FRAP solution for 4 min in the dark condition. Readings of the coloured product were then taken at 593 nm against blank sample prepared with methanol. For both of the analysis for antioxidant activity the results were determined from a calibration curve using Trolox as standard and the results were expressed as μM Trolox equivalents (TE)/g dw for malt and μM TE/L for wort.

Statistical analysis

The results of all analysis were expressed as the mean ± the standard deviation of three replicates.

Results and Discussion

Main brewing characteristics of malts

The results of the analyses of main brewing characteristics of malt are summarized in Table 1.

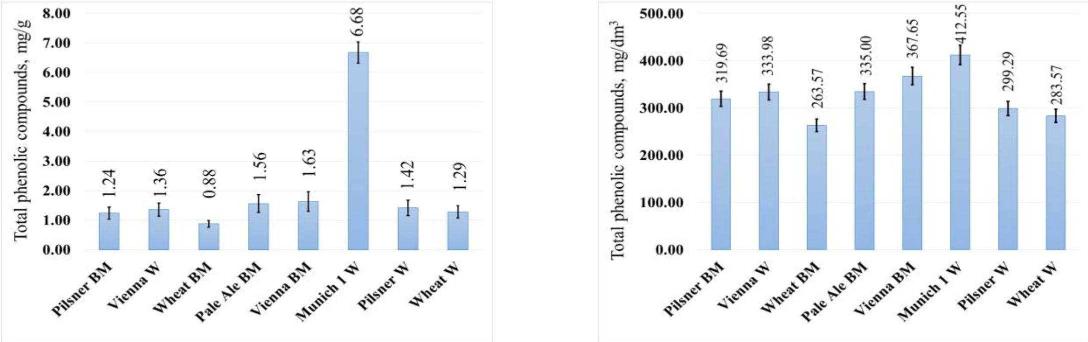
Table 1. Main brewing characteristics of malts

Malt type	Moisture, %	Extract of wort,°P	Extract of malt, %	pH of wort	Color of wort, EBC units
Pilsner W	5.20±0.13	8.69±0.05	80.83±0.58	5.73±0.02	3.2±0.3
Pilsner BM		8.42±0.05	78.09±0.69	5.72±0.02	3.3±0.3
Vienna W		8.50±0.05	78.85±0.61	5.75±0.02	8.1±0.5
Vienna BM		7.75±0.02	71.38±0.85	5.65±0.02	8.0±0.5
Wheat W		8.12±0.03	75.09±0.71	5.6±0.02	5.3±0.4
Wheat BM		8.07±0.03	74.57±0.73	5.62±0.02	5.1±0.4
Pale Ale BM		8.18±0.03	75.70±0.71	5.65±0.02	6.5±0.4
Munich 1 W		8.79±0.05	81.90±0.61	5.63±0.02	12.5±0.7

The results for malt analyzes showed that all malts could be used up to 100% for the production of the different beer types. Wort extract ranged from 7.75 °P to 8.79 °P, which corresponded to malt extract of 71.38% to 81.90%. The pH of wort obtained was relatively high - about 5.6-5.7 units. The color of the wort obtained varied within the range of 3.2-12.5units, depending on malt types.

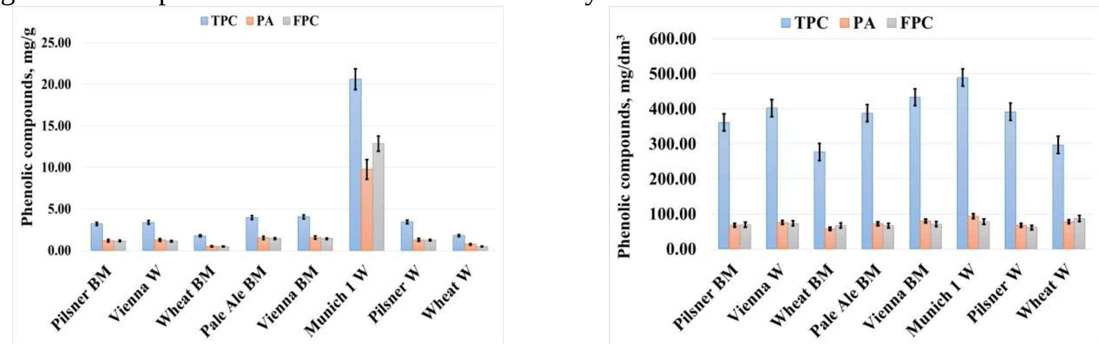
Biological value of malts

The biological value of malts was determined by three main indicators: phenolic compounds content, DPPH radical inhibition and FRAP method. The phenolic compounds content of malt and wort is shown in Figure 1 (determined by FC reagent) and Figure 2 (determined by the modified Glories method). The phenolic compounds in malt determined by FC reagent varied from 0.87 mg/g dw to 1.56 mg/g dw for pale malt types, while the dark malt Munich 1 had a content of 6.66 mg/g dw. The results for total phenolic compounds determined by the modified Glories method were about 3 times higher, as the presence of both oxidized and non-oxidized phenolic compounds was taken into account. Interestingly, the highest results for the phenolic compounds content in Munich 1 were likely to be due to the higher kilning temperature that provoked the release of a portion of the cell wall-bound phenolic compounds or their polymerization (Carvalho et al., 2016).



a) malt b) laboratory wort

Figure 1. Total phenol content in malt and laboratory wort



a) malt b) laboratory wort

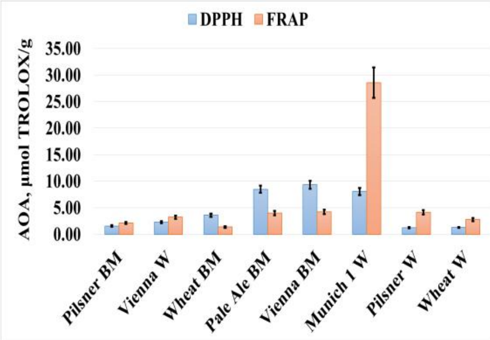
TPC – total phenolic compounds; PA – phenolic acids; FPC – flavonoid phenolic compounds

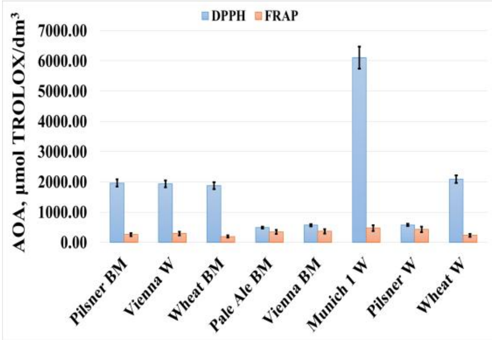
Figure 2. Phenolic compounds in malt and wort

The data for total phenolic compounds in wort in Figure 1 and Figure 2 did not show significant differences. It can be explained that during mashing a part of the phenolic compounds remained bound to the cell walls because of rapid inactivation of enzymes at higher temperatures than 45 ºC (Wannemacher et al., 2018). The data in Figure 2 show almost equal content of phenolic acids and flavonoid phenolic compounds in malt and wort, respectively. The results confirmed the observations made by Szwajgier (2009) that free phenolic acid content in wort was significantly lower than the corresponding free phenolic acid content in malt. The results for antioxidant activities of malt and wort are presented in Figure 3. The data shows that malt had a high antioxidant capacity, which increased with the increase in time and/or kilning temperature. The lowest antioxidant capacity had Pilsen and wheat malts because of relatively low formation of melanoidins which together with phenolic compounds contribute to the malt antioxidant capacity. The highest activity showed Munich 1. Therefore, it can be suggested that the increase in the malt colour (Table 1) had a positive correlation to the antioxidant capacity. During mashing, the components that determine the antioxidant capacity of the malt are extracted into the wort. Here, however, they undergo changes that negatively affect the biological value, as part of the phenolic compounds form precipitates with the proteins. This was the main reason for the observed reductions in the antioxidant activity in some of the laboratory wort (Figure 3b). The low formation of melanoidins during mashing led to the slight increase in the antioxidant capacity in some of the variants. It is interesting to note that all the laboratory wort had greater capacity with respect to the inhibition of the DPPH radical compared to the ferric reducing ability. Again, the highest antioxidant potential showed wort produced by Munich 1 malt.

Possibilities for the production of functional wort-based beverages

The production of new types of beverages requires a systematic approach that combines the knowledge of the process technology and the data on the biological activity of the various malts. Therefore, the best approach is to use a planned experiment for modelling the mixture composition. Mixture design is a very effective method of determining the proportions of variables (ingredients) of a blend. The output varies depending on the proportions but the total remains constant as 1(Buruk Sahin et al., 2016).

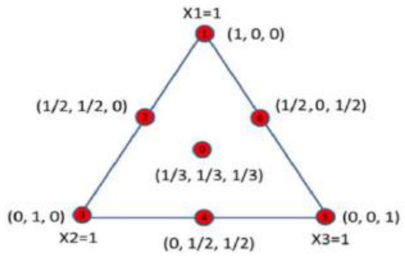


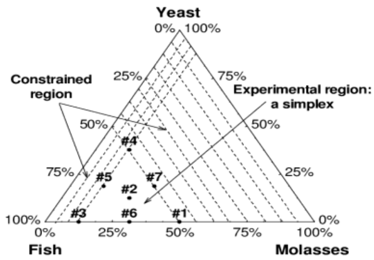


a) malt б) laboratory wort

Figure 3. Antioxidant activity of malt and laboratory wort

A simplex-centroid method with and without constrain is an interesting variant (Figure 4). The method without constrain is suitable for mixtures with 3 or 4 components. The increase in ingredients requires a reduction in the number of attempts, which results in constrains to be used. Constrains may be not only mathematical. In brewing, the main malt used is pale barley malt, which amount has to be over 40%. On the contrary, the wort obtained with higher portions of special malts, which also possess high biological activity, will be very viscous and difficult for lautering. On the other hand, the increase in some special malts portion leads to the problems with beer sensory profile. Therefore, in this study the biological potential of a group of pale and low-coloured malts was investigated and they will be used as the basis for mixtures design. In this case, these malts will be over 40% of the mixtures composition and the other special malts having high biological potential will be limited to such quantities that simultaneously provide a high antioxidant capacity of the beverage and allow the production in a semi-pilot and pilot scale.





a) without constrains b) with constrains

Figure 4. Simplex-centroid method for mixture design

Conclusions

The biological value of eight malts, which can be used up to 100% for brewing, was determined by three main indicators: phenolic compounds content, DPPH radical inhibition and FRAP method. The results showed that the antioxidant capacity increased with the increase in time and/or kilning temperature of malt. Therefore, the increase in the malt colour had a positive correlation to the antioxidant capacity. The results obtained will be used for the mixture design. The mixture will include over 40% of pale and low-coloured malt and the other malts will be dark (specialty) malts with high antioxidant activity.

Abstract

Due to the excessive use of growth promoters in fish production and its possible hazards for humans, our study focusses on monitoring and control attempts regarding their residues in Nile tilapia fish. A total of eighty random samples of Nile tilapia were collected from different Nile canals and markets in El-Menofia governorate, Egypt, for estimation of Methyltestosterone (MT) and Trenbolone acetate (TB) residues by using enzyme-linked immune sorbent assay (ELISA). In the present study, the MT and TB hormone residues were in acceptable levels and without exceeding the maximum permissible limits MPLs (2ppb) of codex (2007) and European Commission "EC" (1999), respectively; except MT residues level in small size farmed tilapia; as 49 % of samples were unacceptable and exceeded MPLs of codex (2007). These results provided no proof for illegal hormones use but did not exclude the possible misuse of hormones. Routine monitoring of these hormones as a food quality and health control measure is needed. Application of various cooking methods (frying and grilling) on Nile tilapia of each category (n =3) exhibited that cooking methods positively reduced residues of MT and TB. The obtained results revealed that the most effective cooking methods for reducing the levels of such hormone residues were grilling (78.8% and 82.05% for MT and TB, respectively) followed by frying (34.8% and 53.85% for MT and TB, respectively).

Key words: *Nile tilapia, methyl testosterone, trenbolone acetate***,** *frying, grilling.*

Introduction

Hormones are common additives, to increase meat production by stimulating the protein synthesis and improving the feed conversion. The most serious potential hazards arising from using of anabolic steroids are tissue residues of these substances and their metabolites, where the effect of these residues is greater on human as it can cause early puberty for girls and boys, liver tumors, cell carcinoma and increase embryo mortality. Also, long-term consumption of anabolic hormones can lead to breast and ovarian cancer. Many countries' regulations clearly define residual limits for these compounds in food. The most common compounds used are the natural anabolic agents(testosterone) and the synthetic anabolic agents (17α-methyl testosterone and trenbolone acetate) which aremale sexual hormones, in low doses also present in females, promote bone/muscle growth and anabolic effects. They are synthetically produced anabolic and androgenic steroid hormones. Ministerial Decree NO. 2655/2003: Prevents the use of"testosterone hormone" in hatcheries for its harm onhealth. Hormones as growth promoters was prohibited for aquaculture in the EU with a strict and limited exceptional use for therapeutic and breeding uses. In other countries such as the US, Canada, Brazil, Australia and New Zeeland hormones are commonly used legally in stock farming (Zhai, et al., 2009 and Commission Regulation, 2010). The determination of anabolic steroid residues faces some difficulties due to their very low concentration in muscle especially after illegal application and their short half life time. So, it needs a powerful, sensitive and efficient method for detection as ELISA (XU et al., 2006). Fish is often treated by various cooking methods before consumption. The cooking process produces fish with desirable sensory qualities, while also minimizing nutrient loss and ensuring the destruction of microbial pathogens. During cooking, the heat treatment and evaporation of water affect the physical and chemical changes in fish, and therefore digestibility is increased due to protein denaturation (Asmah et al., 2014). Cooking processes (frying and grilling) generally decreased the bio-accessibilities of trace or toxic elements or residues. So, fish may be eaten raw, boiled or steamed to improve nutritional values for essential elements and may be eaten fried and grilled to diminish the toxicity and health risk from toxic elements (He et al., 2010). Due to the excessive use of growth promoters in fish industry. Our study focusses on firstly, monitoring of testosterone and trenbolone hormone residues to figure out if these residues fall in the accepted MRLs; and secondly measuring the effect of various popular cooking methods in reducing or elimination of such residues in meat. Moreover, selecting the ideal cooking method for effective reduction of hormone residues in fish prior to consumption.

Materials and Methods

Determination of hormone residues (Manual kits ELISA R-Biopharm AG, Darmstadt, Germany):

Collection of fish samples: Eighty fillet samples of Nile tilapia (farmed and wild, 40 samples of each, 20 large sized fish (205:275g) and 20 small sized fish (90:125g) for each group) were collected from different Nile canals and markets in Al-Menoufia governorate, Egypt, for determination of their contents of hormonal residues level (Methyl testosterone and Trenbolone acetate)based on wet weight (mg/kg). The samples were transported to the laboratory at about 4°C.

Preparation of samples: Skin and scales were removed from fish, and ten grams of the ground muscle was homogenized with 10ml of 67 mM Phosphate buffer (pH 7.2) by mixer for 5 min.

Extraction of samples: Two grams of homogenized sample were mixed with 5ml of tertiary butyl methyl ether (TBME) in acentrifugal screw cap vial and shaken vigorously by shaker for 30-60 min. The contents were centrifuged at 3000 rpm for 10 min. The supernatant was kept and the extraction with TBME was repeated. The supernatants were combinedand evaporated by N_2 evaporator then the dried extract was dissolved in 1mLof 80% methanol. The methanolic solution was diluted with 2ml of 20 mM Phosphate buffer and applied to a RIDA C18 column (solid phase extraction column with C18 end-capped sorbent of an average particle size of 50µm**)** for filtration of the samples then the filtrate was used in ELISA kit.

Test procedures were done according to the chart enclosed in the kits of RIDA^{R} and RIDS screen. R is register trademarks of R-Biopharm AG. Manufacture: R-Biopharm AG, Darmstadt, Germany. R-Biopharm AG is ISO certified.

Application of Heat treatment (Experimental Part): The main purpose of the present work is to investigate the effects of certain common cooking methods (grilling for 15 min. and frying for 10 min.) on the concentration and stability of the hormones in the positive samples. Accordingly, 3 positive samples of fish containing low, medium (around permissible limit) and high concentrations of Methyl testosterone and Trenbolone acetate were subjected to the frying and grilling methods of cooking used at home. Sample weighing 10 g, with thickness 2.5 cm and core temperature of 71.5°C were used. Accordingly, heat treatments as frying in neutral oil at 190°C for 10 minutes and grilling for 15 minutes were applied on the positive samples which proved to be polluted by such hormonal residues to determine the efficacy of each cooking method on the stability of the such dangerous residues (El-Bagory et al., 2017).

Statistical Analysis: The results were statisticallyevaluated by application of student t-test according to Feldman et al. (2003).

Results and Discussion

Methyltestosterone: Fish should be safe and without harmful substances for human health. Anabolic agent used for various purposes in animal husbandry tend to leave residues and this causes some problems in consumer health (Nazli et al., 2005). MT hormone was detected in all samples of wild and farmed Nile tilapia, in which the mean concentration of MT hormone was 0.96±0.08 ppb and 1.52±0.14 ppb in small and large size wild Nile tilapia respectively. On the other hand, the mean concentration of MT hormone was 3.48±0.27ppb and 1.93±0.19 ppb in small and large size farmed Nile tilapia respectively (table 1). These results were agreed with that obtained by Hemmat et al. (2015) and Ezzat (2015) who found the MTmean value 2.057±0.200 ppb and 2.06±0.20 ppb respectively, by using ELISA. Our results were higher than that obtained by Hegazy (2007) and Marzouk et al. (2016) who found the mean testosterone value 0.535±0.03 ppb and 0.753 ppb respectively. On the other hand, higher results were obtained by El-Asaly (2004) and El-Neklawey et al. (2009) who found the meantestosterone value 4.22±1.1 ppband 6.946 ppb respectively, in tilapia farmed fish. The present study takes testosterone level in wild tilapia as a guide to determine the hazard concentration of testosterone in farmed tilapia.

Table (1): Statistical analysis and acceptability of MethyltestosteroneTrenbolone acetate levels
(ppb) in theexaminedsamples of wild and farmed Nile tilapia (n=20).

Size / Fish meat	Small		Large +		°†Acceptability %			
	Mean ± S.E*		Mean ± S.E*		Small		large	
	MT	TA	MT	TA	°MT	†TA	°MT	†TA
Wild Nile tilapia+	0.96 ± 0.08	0	1.52 ± 0.14	0	100	100	100	100
Farmed Nile tilapia	3.48 ± 0.27	0.37 ± 0.03	1.93 ± 0.19	0.18 ± 0.01	51	100	100	100

S.E* = standard error of mean + = Significant differences (P<0.05) as indicated by student t-test. °MPL of Methyltestosteroneaccording to codex (2007) is 2 ppb.
†MPL of Trenbolone according to European Commission "EC" (1999) is 2 ppb.

MT hormonedetected in ourwild tilapia may attributed to normal hormone secreted by fish glands. Also, the MT hormone detected in farmed tilapia may attributed to widely use of synthetic MT in fish production in Egypt (Hegazy, 2007). We must put in our mind that wild Nile tilapia samples have male fish (high testosterone) and female fish (low testosterone) but farmed Nile tilapia samples have nearly all male samples. So, the present study suggests that no public health hazard from consumption of large size farmed Nile tilapia agreeing with Pandian and Kiran Kumar (2003) and Rizkalla et al. (2004) who concluded that no potential hazards from fish feed MT as fries. Long food consumption with MT and TA hormone residues may lead to chronic diseases including breast and prostate cancer, thyroid disease, obesity and diabetes, endometriosis, uterine fibroids, and infertility (Aksglaede, et al., 2009).
Trenbolone acetate: it was not detected in wild Nile tilapiabecause it is a synthetic anabolic hormone added only on fish farms for their benefit of all-male and anabolic properties; while the mean concentration value of TA hormone in farmed Nile tilapia was 0.37±0.03ppb and 0.18±0.01 ppb in small and large size tilapia samples respectively (Table 1). However, all farmed Nile tilapia are accepted and not exceed the MPL of trenbolone stipulated by EC (1999). All wild and farmed Nile tilapia were accepted and fit for human consumption

according to the EC MPLs (Table 1). This result agreed to some extent with results obtained by Hemmat et al., (2015) and Ezzat (2015) who found the mean value of TB as 0.227±0.007ppb and 0.23±0, respectively. TA hormonal residues in tilapia may be attributed to wide use of synthetic androgen (Hotchkiss and Nelson, 2007). Our results proved that hormones residues in small farmed tilapia have high hormonal residue than large one, so they should rear hormone treated tilapia fries to adult size for at least five months to ensure zero hormone residue remains in fish.

Effect of different cooking methods on hormones residues in fish: Different ways of heat treatment is applied to fish in to enhance their flavor, taste and to increase their shelf-life (Oluwaniyi and Dosumu, 2009).Therefore, use of proper cooking processes that have a higher temperature and longer time can lead to the most reduction of residues and can provide an additional safety margin for consumer (El-Bagory et al., 2017). The effect of heat by different cooking methods (frying and grilling) on level of testosterone hormone residues of tilapia flesh proved to be clearly reduced in a ratio of 34.8% with frying from (in three trails). While, by grilling, the level of testosterone hormone decreased with reduction percent of 78.8% (Table2). These results were higher than that obtained by Ezzat (2015) who noted the reduction percent of testosterone hormone by frying were 2.67±0.15 ppb and by grilling to 2.86±0.15 ppb, also by Yassein (2010) with frying to 1.62% and by El-Khaky et al. (2012) with frying to 2.7%. During fish cooking, chemical and physical reactions take place that improve or impair fish value.

Table (2): Effect of different cooking methods on Methyltestosterone and Trenbolone acetate residues level (ppb) in Nile tilapia tissues.

Trial	Control		Frying				Grilling			
			Content		Reduction %		Content		Reduction %	
	MT	TA	MT	TA	MT	TA	MT	TA	MT	TA
1	1.92	0.17	0.63	0	67.2	100	0	0	100	100
2	2.28	0.32	1.47	0.09	35.5	71.9	0	0	100	100
3	5.44	0.69	4.18	0.45	23.1	34.7	2.05	0.21	62.3	69.6
Mean	3.21	0.39	2.09	0.18	34.8	53.8	0.68	0.07	78.8	82.05

Cooking induces water loss, but in turn increases its lipid content and only some fat is lost in case of oily fish. (Sveinsdóttir et al., 2009). The percent of reduction mean of trenbolone residues in hormone containing tilapia after frying were 53.8% for three examined samples and after grilling the ratio reached 82.05%. (Table 2). The best cooking methods to minimize the hormone residues in fish are microwaving, grilling or cooking in oven. However, grilling was found to be the best method (Zeitoun and Ahmed, 2011). We concluded that grilling is the best method of cooking in reduction of hormonal residues.

Conclusion

There are no maximum residue limits (MRLs) established for banned anabolic hormones from fish intended for human consumption in Egypt. However, the situation is more complicated with respect to natural hormones. Synthetic MT and TA hormone residues were not exceeded the MPLs except MT level in small size farmed tilapiawhich exceeded MPLs. So, we suggest that the public health hazard may come only from consumption of small size farmed tilapia. The level of residues of synthetic anabolic steroids should be rationally considering endogenous steroids naturally occurring in fish tissue. Cooking methods (frying and grilling) have positive effects on degrading MT and TB residues; grilling proved to be better than frying as a cooking method. Monitoring system should be introduced to control hormonal residues in fish and ensure consumers safety.

LEGAL REQUIREMENTS FOR PREPARATION AND PRODUCTION OF FOOD IN BOSNIA AND HERZEGOVINA WITH SPECIAL REFERENCES ON THE ENTITY OF THE REPUBLIC OF SRPSKA

Saša LALIĆ[1*], Dragan VUJADINOVIĆ[2]

[1]Ministry of Agriculture, Forestry and Water Management of the Republic of Srpska, Banja Luka, Republic of Srpska, Bosnia and Herzegovina
[2]Faculty of Technology of the University of East Sarajevo, Zvornik, Republic of Srpska, Bosnia and Herzegovina

Abstract

Consumers expect the food they consume to be safe and acceptable to use. Food-borne illnesses are uncomfortable, while in worst cases they may have a deadly outcome. Food-induced epidemics may have a negative impact on trade and tourism, which can lead to a decline in primary producer and processor income, then to an increase in unemployment and ultimately even court proceedings. The food safety area in Bosnia and Herzegovina is currently regulated by legal and by-law acts that are in line with the EU legislation and standards of Codex Alimentarius. In addition, at the level of the Entities of the Republic of Srpska, as well as the Entities of Federation of Bosnia and Herzegovina, there are food laws that are in line with existing state-level laws and EU regulations. The system of good manufacturing practice is implemented in the entire territory of Bosnia and Herzegovina, ie in the Republic of Srpska and the Federation of Bosnia and Herzegovina. These standards are very important in food production and manipulation, as they guarantee quality and safety. In the Republic of Srpska this segment is regulated by the law and the food regulations, which the manufacturers are obliged to implement. The essence of the concept of health security is contained in constant efforts and concrete planning activities to position, define and timely eliminate any dangerous phases or situations in the entire cycle of production of agricultural and food products. The standard has become necessary due to the significant increase in diseases caused by food contamination, both in developed countries and in developing countries. There is a large number of laws and regulations in the territory of Bosnia and Herzegovina that define food production and manipulation. Businesses are required to apply the HACCP standard, and a large number of manufacturers also have the ISO 22000 standard. The main objective of the paper is to define and monitor the application of the HACCP system and the ISO 22000 standard on the territory of Bosnia and Herzegovina, with particular emphasis on the Republic of Srpska entity. In addition, the paper presents a fragmented presentation of the above mentioned system and standards in relation to the European Union with the aim of establishing the position of Bosnia and Herzegovina in the application of the HACCP system and the ISO 22000 standard.

Key words: *consumer, producer, primary production, food regulations, standards.*

Introduction

The application of international standards on the market is an essential element in the process of improving company competitiveness. Customer care, healthy and safe food and environmental standards are just some of the conditions that modern business demands from food manufacturers. (Đorđević et al., 2011) Therefore, it has become an important imperative for food-related companies to implement and implant system management focused on the safety, legality and quality of their products (Verano and Ponce, 2008).

Consumers have the right to expect that the foods they consume are safe and acceptable to use. Food-born illnesses are, in the least, unpleasant, while in the worst cases they may have a deadly outcome. Food-induced epidemics may have many other consequences, such as adverse trade and tourism effects, can lead to a decline in primary producer and processor revenue, then to an increase in unemployment and eventually even to court proceedings. Food spoilage has costly consequences and reduces the confidence of consumers who expect food to be safe and quality (Mačkić et al., 2010).

HACCP represents a systemic preventative approach to ensuring food safety. HACCP is based on the identification and analysis of specific endangered health risks and the establishment of preventive measures in food production and transport that eliminate or reduce the risk to an acceptable level. This system is based on estimates and is embedded in the whole production process (Bunch, 2006). ISO 22000 is a new international comprehensive standard for food safety management systems. It sets a set of general health food safety requirements that apply to all food chain organizations and is recognized globally, these universal standards harmonize key requirements and overcome the difficulties of different standards related to food safety in terms of region, country, activities of organization and types of food (Živković, 2012). In the territory of Bosnia and Herzegovina, or both of its Entities and the Brcko District, the application of the HACCP system is widespread because laws at all levels of government are based on its principles.

The main objective of the paper is to define and monitor the application of the HACCP system and the ISO 22000 standard on the territory of Bosnia and Herzegovina, with particular emphasis on the Republic of Srpska entity. In addition, the paper presents a fragmented presentation of the above mentioned system and standards in relation to the European Union with the aim of establishing the position of Bosnia and Herzegovina in the application of the HACCP system and the ISO 22000 standard.

Integrated processes in food security

The right to safe food is one of the fundamental human rights and the obligation of each country to ensure that the health of its citizens is not endangered by the use of health-defective food products. Food safety today has become a world problem, which is particularly pronounced in the conditions of intense trade in food items on the international market. While sometimes the consequences of food poisoning were mostly limited to the immediate environment of poisoning agents, today the cause may be in one, and victims in many other countries. Extended food supply chains are prolonged, and more and more rapid preparation products are available, without additional heat treatment, further increasing the dangers present. The "integrating" way of thinking is increasingly used not only for food security but also for commercial reasons (Bunch, 2006). Measures to be taken in the process of production, maximum permissible concentrations for certain contaminants, procedures and methods of monitoring the contagion in certain areas, as well as basic elements for legislative regulation in the area of limiting or prohibiting the use of certain resources or processes in the food production process (Milosavljević, 2014). On the basis of such findings, risk management procedures, monitoring and monitoring programs for certain contaminants or groups of landowners, agricultural crops, final products and foodstuffs of plant and animal origin have been prescribed. However, the control of final products, no matter how comprehensive and rigorous, could not prevent relatively frequent incidents and food poisoning not only microbiological but also chemical and physical agents. In addition to the classical nature of the quality control and the health of the final products, it required a lot of time (due to the length of the individual analyzes) and significantly slowed the production process and food turnover (Stojanović et al., 1994). Therefore, in the early 1990s, a wide-ranging application of preventive system approach used in food production as a quality assurance system for food safety was introduced. This concept, known as HACCP, was developed in 1959 for the purposes of space research, and in practical application as an integrated system in the process of producing foodstuffs from "field and farm to market" in most western countries has been introduced since 1991. In essence, the HACCP system is a scientifically based, rational and systematic approach to the identification, assessment and control of risks during the process of production, processing, preparation and use of food, with the aim of ensuring that food is safe for the consumer, that is, unacceptable risk to health. In livestock production, the balance is shifted to integrated systems focusing on preventive and proactive actions, emphasizing the importance of intervention in the places where the cattle are fed, with the aim of providing better hygiene and the quality of meat and milk. In this respect, in Europe, such veterinary actions on farms are being demonstrated by applying HHSP herd health monitoring programs. These programs significantly contribute to protecting people from zoonoses and food-borne diseases. Together with the HACCP system, this program provides maximum health food safety (Pribisic, 2014). The integrated concept of food safety is the only way to achieve the basic goals, a high level of consumer, animal and environmental protection. The key factor is the knowledge of consumers to respect and protect their interests and concerns, not only from the point of view of health, but also to animal welfare and environmental protection. The new philosophy in food inspection that is developing in the European Union is based on self-control. It is accepted that it is in the best interest of the industry to undertake and implement all necessary measures to ensure the health and quality of food at the consumer level. It is therefore expected from the industry to provide, by using a proactive systematic methodology, that the finished product is a reliable pre-established quality and level of health care. All the actions take place in a transparent and documented way, so that they gain consumer confidence and enable them to obtain an official certificate of production and finished products. HHSP at the level of livestock production, and HACCP at the level of processing industry, meet the health-safety criteria, and ISO standards guarantee product quality (Milosavljević, 2014).

The basics of food safety standards in the European Union

Current European legislation requires the use of a proactive and systematic approach to business to ensure food security through the implementation of an appropriate control system. However, very often consumers are exposed to various risks ranging from poisoning, which can lead to more serious health complications and even death. What is the importance of this branch of industry in the European Union territory is the data that the Food and Beverage Industry is leading in the industry sector with annual production of 800 billion euros. This production accounts for 15% of total production, employing 2.8 million workers, of which 30% in small and medium-sized enterprises. Only the agricultural sector generates 220 billion euros annually, which is equivalent to 7.5 million full-time employees. The export of agricultural products, food and beverages to the EU level generates income of 50 billion euros annually. (Coleman et al., 2000). Starting from the importance of food, on 12 January 2000, the EU Commission adopted the baseline and action plan given in the document titled "White Paper on Food Safety". At the beginning of 2002, an "Independent Food Authority" was formed within the European Commission, and a network of National Agencies and Scientific Authorities was set up, whose basic task is to implement the adopted action plan, the compilation of the accompanying laws and food safety standards. At the EU level, the basic principle has been adopted that the law must rest on the aspect of food production and control "from farm to farm", and standards for security must be based on three key aspects (Milosavljević, 2014): economic, social and environmental consequences. The European Union regulated the marketing of food products with many of the most important documents (Bunch, 2006): The European Parliament and Council Regulation and the General Food Law. This law covers all phases of production, processing and distribution of food for humans and animals, except for primary production, preparation, handling and storage of food in households (intended for household consumption and consumption, ie not intended for sale on the market). "Foodstuff" (food) means any substance or product, processed, partially processed or unprocessed, intended for human consumption or is reasonably supposed to be consumed by humans. This includes beverages and any substance, including water, which is intentionally incorporated into food during its production, preparation or processing (Bunch, 2006).

The following institutions are responsible for food safety in the EU (Novaković et al., 2014): **European Commission**, within the framework of the General Directorate for Health and Consumers; **The European Parliament**, in addition to the Committee on Environmental Protection, Public Health and Food Safety (ENVI), includes twenty more committees; **The European Food Safety Agency** is the cornerstone of the European food safety net. It provides scientific counseling services and information on possible and existing risks to nutrition. EFSA is independent and acts separately from the European Commission, the European Parliament and the EU Member States. Within the Agency there is a scientific committee through ten scientific and expert panel groups.

Legal obligations for food preparation and production in Bosnia and Herzegovina with a special reference to the Republic of Srpska entity

According to the Food Act that is implemented in the territory of Bosnia and Herzegovina under the term food, we mean any substance or product that is processed, partially processed or unprocessed, intended for human use or can be expected to be used by humans. The term food includes both a drink, a chewing gum, a nutritional additive, and any other substance intentionally incorporated in food during its production, preparation or processing. In order to introduce a modern integrated system in Bosnia and Herzegovina, it is necessary to draft a new legislation harmonized with EU legislation, ie the *Acquis communautaire*, as well as consumer protection and placing producers in an equal position. In Bosnia and Herzegovina, a number of outdated executive regulations in the field of food that have been taken pursuant to the Decree-Law on the Takeover of Federal Laws and Other SFRY Laws, Applicable as Republic Laws and Other By-Laws, are currently in force. Pursuant to Articles 16 and 17 of the Food Act, the Council of Ministers of BiH, upon the proposal of the Agency, in cooperation with the competent authorities of the Entities and the Brcko District of BiH, issues valid regulations on the application of any process in production, processing, processing and distribution affect the hygiene and health of food and feed. According to Article 72 of the Food Act, the Council of Ministers of BiH, at the proposal of the Agency, shall issue new food regulations, labeling and food advertising regulations, regulations on traditional food reputation, originality and geographic origin descriptions, as well as other regulations from this area. In accordance with the provisions of Article 54 of the Food Act, the Agency initiates, prepares and organizes the drafting and implementation of the provisions of the Act with the aim of: protecting consumer interests, allowing consumers to make choices regarding the food they consume and protect the interests of the producer. The regulations on implementation, based on the said members of the Food Act, establish requirements related to: the obligations of the subjects in the food business with regard to quality; classification, categorization and name of food; organoleptic properties and composition of food; manufacturer specification type and quantity of raw materials, additives and other substances used in food production and processing; technological processes applied in food production and processing; sampling methods and analytical methods to control food quality; additional or specific information that should be included in the food declaration and are of interest to the consumer; marks of traditional food reputation; originality and geographic origin of food; new food, as well as other necessary regulations in this area.

The food safety area in BiH is currently regulated by legal and by-law acts that are in line with the EU legislation and standards of *Codex Alimentarius*. When it comes to the state level, there are two laws on food:

1. The Food Act ("Official Gazette of BiH", No. 50/04),
2. The GMO Act ("Official Gazette of BiH", no. 23/09).

In addition, at the level of the Entities of the Republic of Srpska, as well as the Entities of Federation of BiH, there are food laws that are in line with existing state-level laws and EU regulations. Also, at the state level there is a large number of regulations that determine this sector. There is still a certain number of regulations taken over from the SFRY. The area of veterinary medicines and pesticides in food of animal origin is regulated by the Ordinance on maximum permitted levels of veterinary medicines and pesticides in animal products ("Official Gazette of BiH", No 6/09). In addition to the aforementioned regulations, there are also rule-of-law rules that are aligned with the state level and are fully applicable in both Entities.

The concept of good manufacturing practice (DPP) system in Bosnia and Herzegovina with a special reference to the Republic of Srpska entity

Good manufacturing practice presents a number of recommendations that are desirable to be carried out in the manufacture, processing, storage and supply of food to prevent its microbiological, chemical or physical contamination. In other words, good manufacturing practice points to what needs to be done to prevent food contamination, and when and who should to do it (Mačkić et al., 2010). Good manufacturing practice does not refer to certain harmful factors, and the loss of control will not always and indisputably directly jeopardize the health of consumers but will increase the relative risks.

Areas in which good manufacturing practice is realized are (Henson and Jaffe, 2011):

- staff (including their assignments, job description, organizational structure and hygiene training),
- premises (including location and layout, design, construction aspects, maintenance, work environment, light, temperature, humidity),
- equipment (including shape, maintenance and calibration),
- raw materials for production (including live animals, packaging materials, food ingredients and chemicals),
- product traceability,
- services (including sanitation, waste disposal, supply of electricity, water, cooling steam),
- documentation.

The system of good manufacturing practice is implemented in the entire territory of Bosnia and Herzegovina, ie in the Republic of Srpska and the Federation of Bosnia and Herzegovina. These standards are very important in food production and manipulation, as they guarantee quality and safety. This segment in the Republic of Srpska is regulated by the law and the food regulations, which the manufacturers are obliged to implement.

The concept of good hygenic practice system (DHP) in Bosnia and Herzegovina with a special reference to the Republic of Srpska entity

As part of good manufacturing practice, cleaning and hygiene are of particular importance and are considered to be the main elements of good hygiene practice. Good hygiene practice can be described as a set of procedures to ensure a clean, sanitary environment for the production, processing, storage and supply of food products. Companies to meet these requirements must determine control measures to ensure compliance with the following requirements hygiene requirements, such as hygiene of personnel, facilities, equipment, and specific requirements (Popelka et al., 2005). In other words, good hygiene practice determines what needs to be done in connection with cleaning and hygiene, as well as when and who should perform these tasks. it is necessary to continually perform disinfection or sanitary program, maintain building and equipment maintenance, and conduct cross-contamination control during production, including people, surfaces, air and segregation of raw materials and processed products (Raspor, 2007). The areas covered by the program of good hygiene are (Hayburn, 2014): cleaning of the facility / section and equipment; health and cleanliness of staff performing food-related tasks; purity of raw materials for production, including live animals; ensuring that all means of hygiene and other chemicals are properly packaged, labeled, stored and applied in accordance with their intended purpose and documented procedures.

Healthy food safety is a guarantee that food will not harm the consumer when prepared and / or consumed in accordance with its purpose. According to the new legal regulations of Bosnia and Herzegovina, in compliance with the process of harmonization with the legal regulation of the European Union, the food business operator (The Food Act of BiH) is responsible for the health of food safety. Food monitoring requirements should be met, which means that food business entities must establish such a system that they can identify the "step forward and step backwards" in the chain: the barrel - the manufacturer - the distributor - the consumer. Food business entities must further ensure that all phases of production, processing and distribution of food that they are under their control meet the requirements related to the hygiene prescribed by this Law and the relevant regulations adopted pursuant to this Act. They must also carry out regular controls of hygiene conditions at all stages of production, processing and distribution of food, except at the level of primary production and related activities, in each facility under their control, by carrying out a preventive self-control procedure developed in accordance with the principles of the Hazard Analysis System and Critical Control Points (7 HACCP Principle) (Milosavljević, 2014). For example, a good hygienic practice program for hospitality includes: sanitary technical and hygienic conditions, cleaning, pest control, maintenance of equipment, personal hygiene, occupational health, waste disposal, staff training, supply, delivery and food reception, food storage, food control, food handling in a safe manner, foods that require special attention when preparing, withdrawing products, verifying, controlling health / microbiological food safety (Zdravković, 2014). By introducing and applying the principles of good hygiene practice, good manufacturing practices and self-control systems based on the principles of HACCP system, the quality and safety of food can be ensured and guaranteed. The difference between the code of good hygiene practice and the HACCP system is that the HACCP represents one step more, since the application of this system keeps records and that there is a so-called recall procedure with HACCP, which implies signing up of food from the market is related to large manufacturing systems (Zdravković, 2014).

In the Republic of Srpska, the Ordinance on food hygiene was published in the Official Gazette of Republika Srpska, no. 39 of 10 May 2018. It has defined a number of provisions relating to food business in all phases of production, processing and food traffic under the control of the entity. According to this rule, food hygiene implies the measures and conditions required to control the risk and ensure the eligibility of food used for human consumption in accordance with its purpose. Food business subject to special regulations in the Republic of Srpska is obliged to carry out hygiene measures related to (RS Ordinance on Food Hygiene, 2018): meeting the microbiological criteria for food, the procedures necessary to meet the objectives set out in this Ordinance, the fulfillment of conditions regarding the control of food temperature, maintaining the cold chain, sampling and analysis.

HACCP system

Hazard Analysis and Critical Control Point (HACCP) is a food safety system that is based on the analysis and control of potential biological / microbiological, chemical and physical hazards that are exposed to raw materials, possible hazards to the handling, production, distribution and consumption of end products. Its application implies compliance with the standard operating procedures and instructions that reduce the risks to food safety. HACCP is based on identifying and analyzing specific hazards and identifying preventive measures that eliminate or reduce the risk of production and the emergence of potentially dangerous foodstuffs to an acceptable measure (Bošnjak, 2009). This system has the task of (The Food Security Agency of Bosnia and Herzegovina, 2012): establishing, evaluating and controlling the dangers that could affect food safety, the system manages the quality and safety of food based on prevention, everyone is trained to know what, how, when and why to do it in order to prevent food risks and also their own responsibility so that the end user consumes healthy and safe food. Established hygiene practices are essential for monitoring the situation throughout the entire food chain, from primary production to final product. Its application prevents contamination and provides an adequate food handling environment.

Implementation of the HACCP system in the territory ofBbosnia and Herzegovina with a specific reference to the Republic of Srpska entity

A large number of economic entities in the territory of Bosnia and Herzegovina, ie the Entities of the Republic of Srpska and the Federation of Bosnia and Herzegovina, apply the HACCP system for food production, as manufacturers are obliged to implement them. Thus, according to the food act at all administrative levels of the state, food business entities, in addition to the entity performing the activity of primary production, establishes and implements in all phases of production, processing and food transport a self-control system, based on good manufacturing practice principles and good hygienic practices, risk analysis and critical control points - HACCP. The principles of the HACCP system in the Republic of Srpska are fully applied, as defined by the Republic of Srpska Food Regulations. Companies applying this system, in the territory of the Republic of Srpska, as well as throughout Bosnia and Herzegovina, go through the same procedures as all other entities in the European Union market. For this reason, HACCP is the standard whose settings must meet in order for companies to own it.

Implementation of ISO 22000 in the territory of Bosnia and Herzegovina with a special reference to the Republic of Srpska entity

There is a standardization institute in Bosnia and Herzegovina. The Institute proposes a standardization strategy in Bosnia and Herzegovina, prepares and publishes the standards of Bosnia and Herzegovina, represents and presents Bosnia and Herzegovina in international, European and other standardization organizations, and carries out the tasks deriving from international agreements and membership in these organizations. It participates in the preparation of technical regulations, develops and establishes an information system on the standards of Bosnia and Herzegovina, organizes and conducts specialized training of personnel in the field of standardization. He also deals with publishing and publicity activities in the field of standardization (Popović, 2012). In the field of conformity assessment, it participates in the establishment and maintenance of the certification and homologation system in accordance with the European model. It defends Bosnia and Herzegovina in European and international conformity assessment organizations (EOTC and EUROLAB, etc.) to form an association of test laboratories and associations of calibration laboratories and organizes education in the area of assessment of compliance. Also, it organizes various sourcing assistants for the implementation of ISO standards and the HACCP system.

Standardization is the activity of establishing rules for general and multiple use, which relate to existing or potential problems, in order to achieve optimal degree of regulation in a particular area (Filatov, 2016). Standardization activities consist primarily of preparation, formulation and issuing standards, and enabling standard application. Important benefits of standardization are improving the benefits of products, processes and services for the foreseen purposes, preventing barriers to trade and facilitating technological cooperation (Živković, 2012). In order for a particular economic entity to comply with standardization, it is necessary to officially verify that all requirements related to the standard, as well as company objectives and policies are met. Certification is carried out by an independent international body certification. The certification process is much more complicated than the certification of the HACCP system, with the acquisition of the ISO 22000 certificate giving a great reputation to the company and recognized at international level (Bijelić, 2015). This is a set of international standards that encompasses all organizations in the food chain and defines the requirements of the Food Safety Management System. The ISO 22000 standard is based on the principles of the HACCP system for obtaining the final food product, fully respecting the safety standards: monitoring, studying and describing the production process for preventing or establishing controls in case of food safety risks, conducting analysis, assessing and establishing control, management and disposal resources. For this reason, it is important that business entities from Bosnia and Herzegovina, in addition to the mandatory HACCP system, also approach the implementation of ISO 22000 standard in food production, as it will provide a much better competitive position on the market (Zdravković, 2014).

Conclusion

The essence of the concept of health security is contained in constant efforts and concrete planning activities to position, define and timely eliminate any dangerous phases or situations in the entire cycle of production of agricultural and food products (from primary production of basic and auxiliary raw materials to immediate consumption of finished products). The standard has become necessary due to the significant increase in diseases caused by food contamination, both in developed countries and in developing countries. In addition to health risks, food-borne diseases can significantly increase economic costs, including medical treatment, job absences, insurance payments, and statutory compensation. As a result, several countries have developed national standards for safe food supply, and certain food and beverage companies and groups have developed their standards or programs to control their suppliers (European Commission, 2014). The existence of good hygienic and manufacturing practices, as well as the HACCP system, ISO 22000 standards, have led to a new higher level of food production process. So good hygienic and production practices can be said to be the lowest in the observed set of measures to protect food production. Next, the HACCP system is more comprehensive than the previous two measures. Finally, the most comprehensive is the ISO 22000 standard, which assures the safety and security of food production. There is a large number of laws and regulations in the territory of Bosnia and Herzegovina that define food production and manipulation. Businesses are required to apply the HACCP standard, and a large number of manufacturers also have the ISO 22000 standard. When the Republic of Srpska entity is in question, there is also a large number of laws and regulations defining this area and in compliance with state-level laws and regulations. It is also important to point out that laws and regulations in the production of food are being implemented in the territory of Bosnia and Herzegovina by the European Union. First of all because of its export to its market and the emergence of Bosnia and Herzegovina to become its full member.

Abstract

The stability of food systems is an essential characteristic for determining the quality of products. Freeze–thaw stability is an important property that is used to evaluate the ability of starch to with stand undesirable physical changes occurring during freezing and thawing. We analyzed the effect of different thickening agents on freeze-thaw stability of food systems with modified maize starch. It was made four systems with modified maize starch and combinations of starch and guar gum, starch and xanthan gum, and starch and pectin. The choice of starch quantity and thickening agent originates from the initially uniform viscosity of the resulting systems. The received food systems were storage at 8±1 °C and -18±1 °C for four days. The structural-mechanical properties and stability of the investigated samples were analyzed. The addition of a thickening agent reduced the amount of the used starch and increased the stability of the systems. The sample with 0.09 % xanthan gum and 3 % starch had the best result in regard to shear-resistance, and the worst result was found in sample with 0.14 % pectin and 3 % starch, storage at 8±1 °C. However, the different storage type of the samples influenced on their stability and thixotropic properties, which can be an indicator of choosing the type of storage.

It was measured the value of the separated liquid (in %) of the samples. The results shown that only the sample №1 (only with starch) had a separated liquid. Incorporation of a thickening agent is an indicator of increasing the retrograde stability of the starch.

Keywords: *Food systems, Thickening agents, Structural-mechanical properties, Freeze-thaw stability*

Introduction

Hydrocolloids are water-soluble, high molecular weight polysaccharides that serve a variety of functions in food systems including enhancing viscosity, creating gel-structures, film formation, and control of crystallization, inhibition of syneresis, improving texture, and encapsulation of flavors and lengthening the physical stability (Dickinson, 2003; Anwar et al., 2015). These functional ingredients are widely used in dairy products, canned foods, bakery products, salad dressings, beverages, sauces, soups and other processed foodstuffs to improve textural characteristics, flavor and shelf life (Sahin and Ozdemir, 2004).

The foremost reason behind the ample use of hydrocolloids in foods is their ability to modify the rheology of food system. This includes two basic properties of food system namely, flow behavior (viscosity) and mechanical solid property (texture). The modification of texture and/or viscosity of food system help to modify its sensory properties, and hence, hydrocolloids are used as important food additives to perform specific purposes. Various food formulations like soups, gravies, salad dressings, sauces and toppings use hydrocolloids as additives to attain the desired viscosity and mouth feel. Considering their role in the adjustment of viscosity and texture of food formulations, several studies have been conducted in various food systems employing different hydrocolloids either singly or in combination (Saha and Bhattacharya, 2010). Starch is the most commonly used hydrocolloid thickener, the reason being it is relatively cheap, abundant and possibly it does not impart any noticeable taste if used at a low concentration of 2 to 5%. Further, as starch is a common ingredient of many foods we encounter, addition of starch does not offer any foreign taste which may be true for different gums. It is mainly the hydrocolloid providing a base texture in soups and sauces. Thickening of sweet and sour sauces with various polysaccharide combinations like potato starch-xanthan gum and oat starch-xanthan gum has been studied (Gibinski et al., 2006).

Generally, gums and stabilizers have non-Newtonian rheology and they impart non-Newtonian character to the emulsions even when the amount of the dispersed phase is low (Krstonošić et al., 2015).

Upon freezing, however, water in the foods transforms into ice, often resulting in physical stress to the food matrix. When a frozen food is thawed for consumption, the moisture is readily separated from the matrix and it causes softening of the texture, drip loss, and often deterioration of overall quality (Rahman, 1999). The ability of starch to withstand the undesirable physical changes during freezing and thawing has been commonly termed "freeze-thaw" stability and can be used as an indicator of the tendency of starch to retrograde. When a starch paste or gel is frozen, phase separation occurs with the formation of ice crystals. On thawing, the paste or gel will continue to be composed of a starch-rich and starch-depleted aqueous phase (Karim et al., 2000). Freeze-thaw stability may be simply evaluated by gravimetric measurements (Charoenrein and Preechathammawong, 2012).

In this case it was analyzing the effect of different thickening agents on freeze-thaw stability by their structural-mechanical properties and the value of the separated liquid of the investigated samples. The goal of the research is to make a more freeze-thaw stable sweet-sour system with a lower starch content and determined initial viscosity.

Material and Methods

Preparation and storage of systems

The model systems were produced at the University of food technology`s laboratory in Plovdiv, Bulgaria, by mixing the following basic components: sugar 30%, apple vinegar (6 % solution) 15%, starch in combination with different hydrocolloids in quantity shown in Table 1 and water to 100 %. It was used Acetylated distarch adipate from waxy maize starch E 1422 combined with guar gum (GG), xanthan gum (XG) and pectin (P), to created a product with the same initial viscosity. The control sample (№1) was only with modified starch.

Table 1.Quantity of used thickening agents depending on the sample

Ingredients:	Sample №1, %	Sample №2, %	Sample №3, %	Sample №4, %
Starch	3.4	3.0	3.0	3.0
Hydrocolloids:				
-guar gum	-	0.11	-	-
-xanthan gum	-	-	0.09	-
-pectin	-	-	-	0.14

Each sample was prepared by mixing all components with water, homogenized and heated at temperature of 85 °C for about 7 minutes. After cooling and storage the systems were analyzed. The samples were divided into two. First parts of the samples were storage at 8±1 °C, and the others were frozen at -18±1 °C for four days following the method of Arocas et al., 2009. After frozen storage, the samples were thawed at room temperature and heated to 30 °C. The measurements were performed on the same day.

Measurement the value of the separated liquid (syneresis in %)

After storage the tempered samples were put in test tubes and centrifuged of 5000 rpm for 15 min (Sodhi and Singh, 2003). For analyze it was used a centrifuge Hettich Zentrifugen EBA 200 (Germany). The separated liquid was removed and weighed. Syneresis was expressed as weight percent of the decanted liquid phase.

$$\text{Syneresis} = (W_1 \ / \ W_0).100 \quad (1)$$

where: W_1 is The separated liquid, g; W_0 is the centrifuged sample, g.

Measurement of the structural-mechanical characteristics

The measurements were conducted at 30 °C with rotational viscometer "Reotest 2" (Germany) with shear rate in the range from 0.33 to 145.8 s^{-1}. The major rheological characteristics were determined - dynamic viscosity (η, Pa.s), yield stress (τ_0, Pa), consistency coefficient (k, Pa.s) and the flow behavior index (n). The dynamic viscosity (η) was calculated using the formula:

$$\eta = \tau / D \qquad (2)$$

where: τ is the shear stress, Pa; D is the shear rate, s^{-1}.

The thixotropic areas were also calculated. The Herschel–Bulkley equations (Rao, 1999) were fitted to obtained results.

Statistical analysis

All results were expressed as the mean ±standard deviation (SD). The experimental data were subjected to analysis of variance, at the confidence level of $p = 0.05$, using ANOVA. The test of Tukey was used for determination of the statistically significant differences between values of the samples storage at the same temperatures.

Results and Discussion

The value of the separated liquid (syneresis in %)

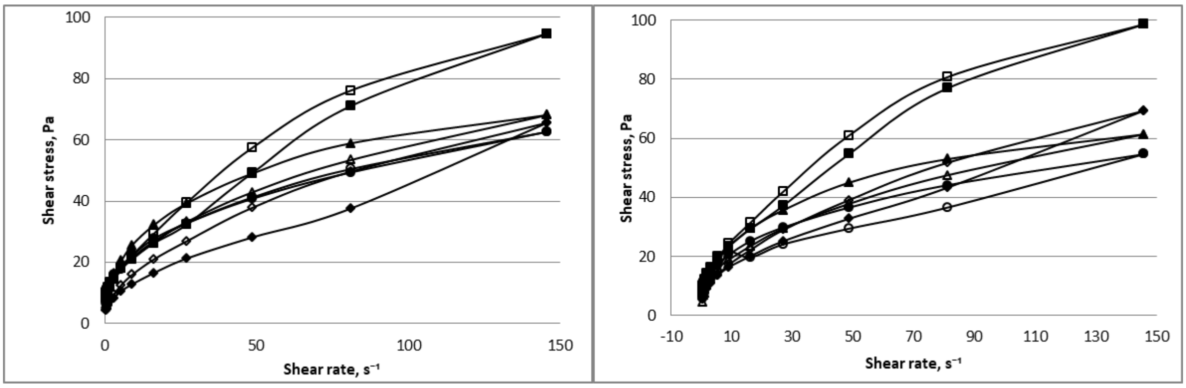
The measured value of the separated liquid is an indicator for the retrogradation (syneresis) properties of the used starches.

The results shown that only the sample №1 (only with starch) had a separated liquid in a quantity of: for the non-frozen sample: 8.721±0.16% released liquid and for the frozen sample: 9.000±0.08% released liquid. There were no significant differences in sample values stored in different conditions. The other samples had no separated liquid, which means that they are more stable than sample №1.

Structural-mechanical characteristics

The structural-mechanical properties are an important characteristic for all foods products, determine the quality, and it is essential information to the economic design of the most suitable food process equipment and operation that can be selected. Rheological properties of the samples were studied at 30°C.

The rheograms of the analyzed samples are shown in Figure 2. It is obvious that the samples represent Non-Newtonian fluids, which is evident from the shape of these flow curves.



(A) (B)

Figure 2. Rheograms of the systems, storage at 8±1°C (A) and freeze-thaw samples, storage at -18±1°C (B):
Sample 1 - □ (upward curve), ■ (downward curve); Sample 2 - Δ, ▲;
Sample 3 - ○, ●; Sample 4 - ◊, ♦;

Flow curves for all systems presented narrow hysteresis loops indicating rather changes in the structure of them on the shear applied.

The power law model parameters for the samples are given in Table 2, along with correlation coefficient (R^2). The multiple correlation coefficients, R^2, informed about, generally, very good fitting of the Herschel–Bulkley model and it`s obtained varied from 0.9620±0.048 to 0.9989±0.033, typical for the Herschel–Bulkley models.

$$\tau = \tau_0 + k.D^n \qquad (3)$$

where τ is the shear stress, Pa; D – is the shear rate, s^{-1}; τ_0 - is the yield stress, Pa ; k – is the consistency coefficient, Pa.s; n – is the flow behavior index.

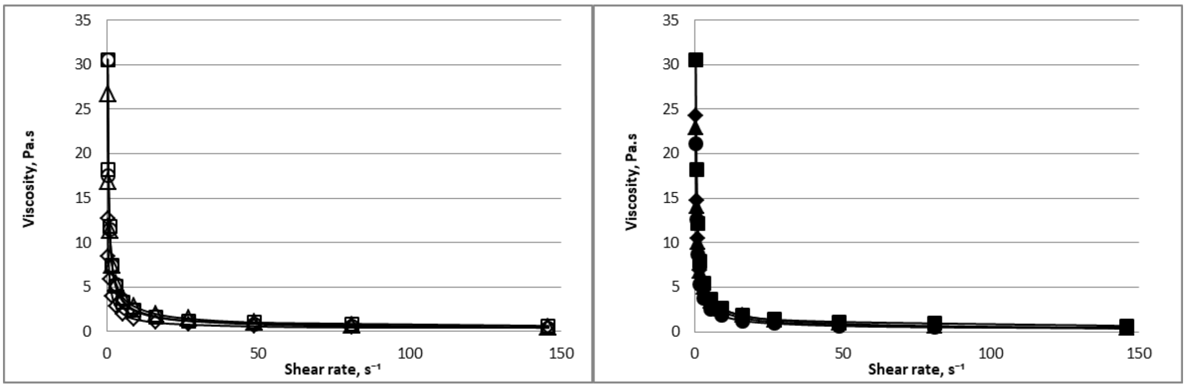
*Parameters in columns for different systems denoted which have the same letters do not differ statistically at the level of confidence p = 0,05. Comparison is made between the values of system storage at the same temperatures.

Yield stress is an important characteristic. The high values of yield stress, τ_0, from the Herschel–Bulkley model, pointed to a high stability of the structure of the. Sample №1 had the highest value of τ_0, followed by sample №3, and the lowest – Sample № 4. This dependence is valid for the two types of storage, so the high stability of structure have the samples №1 and №3. Viscosity functions data showed that the values for flow behaviour indices, n, were below 1, which was indicative of the pseudoplastic nature (Bayod et al., 2008). The smaller n values determine the greater departure from the Newtonian behavior (Sengül et al., 2005). That parameter usually decreased on storage (Sikora et al., 2007; Sharma et al., 2014), which is not observed to depend on the storage temperature. Consistency coefficient, K, from the Herschel–Bulkley model can also be used as a criterion of viscosity. In terms of that coefficient, all of the systems have closely viscosity except Sample №4 at 8±1°C, which was the least viscous. The data shown that the narrowest hysteresis loop area were found for the sample №3 storage at 8±1°C, followed by sample №1, storage at -18±1°C, so the structure of such sauces was the strongest and shear-resistant. Sample №4, storage at 8±1°C had the highest value of the hysteresis loop area which means the weakest and the lowest shear-resistant. This dependence was not observed at freeze-thaw samples. Moreover, the freeze-thaw storage of the samples influence on their stability. Only in the sample №2 there was no considered change in the stability. It was observed that freeze-thaw sample №4 changed its thixotropic properties, from thixotropic to anti-thixotropic. Anti-thixotropy, is also known as rheopexy was examine by Dewar and Joyce, 2006. It is just opposite to thixotropy of solutions or suspensions. Viscosity is also defined as the main rheological property of the different food systems. The viscosity values of the samples as a function of the shear rate (D) are shown in Figure 3.



(A) (B)

Figure 3. Changes in the apparent viscosity by shear rate, storage at 8±1°C (A) and freeze-thaw samples, storage at -18±1°C (B):
Sample 1 - □ (system A) , ■ (system B); Sample 2 - Δ,▲; Sample 3 - ○, ●; Sample 4 - ◊, ♦;

It was obvious that the shear rate increased and the viscosity decreased. These facts showed that all systems have closely viscosity variations. These samples have pseudoplastic properties because they flow with applying the external impact.

Conclusions

This study showed that the addition of a thickening agent reduced the amount of the used starch and increased the stability of the systems towards retrogradation as well as the structural-mechanical stability. Only the sample with starch had a separated liquid which was an indicator for reducing the retrograde properties of starch. This analyzes and results showed that the type of storage affects both the stability and the thixotropic behavior of the samples as the sample with guar gum had least dependence of the type of storage. The best result had the sample with xanthan gum and starch, and the worst - with pectin, storage at 8±1°C. A change in thixotropic properties was detected in a sample with pectin. As far as stability was concerned, the freeze-thaw treatment shown that the sample with pectin changed its thixotropic properties.

Abstract

Maize is one of the most susceptible crops to mycotoxins in the world. In relation to mycotoxins, the greatest attention has been paid to aflatoxins, because of their potential for carcinogenicity and other health issues in humans and animals. *Aspergillus flavus* and *A. parasiticus* produce aflatoxins in many economically significant crops in both, fields and storages. Since *A. parasiticus* isolates originating from Serbia caused significant direct losses as a result of maize grain infection and potential contamination with aflatoxins, it is necessary to establish their toxigenic potential. Aflatoxins were produced by almost all *A. parasiticus* strains. Obtained results indicate that there is a great diversity in the production of all individual aflatoxin. The concentrations of aflatoxin B1 were ranged from 33.05 to 7361.03 μg kg^{-1}, while the presence of aflatoxin G1 was in the range of 5.13-6666.12 μg kg^{-1}. The existence of atoxigenic isolates of this species can be significant for Serbia, as they have been increasingly applied as biocontrol agents for virulent strains of fungi. The use of these isolates as biological agent in plant protection should be estimated. Prevention is the most important and economically most beneficial practice in the decrease of fungal growth and mycotoxin production.

Key words: *A. parasiticus, toxigenic potential, aflatoxins, maize.*

Introduction

Maize is one of the most cultivated cereals worldwide ranking first in Serbia. The maize production satisfies national needs. At the same time it is a strategic product intended for export. The major aim of maize production is stable and high yields but also a high nutritional value of grain, which is at the same time health safe. *A. parasiticus* does not only degrade maize grain quality, but also synthesises toxic substance - aflatoxins, which are, from the aspect of human and animal health the key group of mycotoxins. At the same time, the study of the content of the most important individual and total aflatoxins synthesised by this species, emphasises an overall impact of *A. parasiticus* on yield components and maize health.

Aspergillus contamination has been occasional under agroecological conditions prevailing in cereal-growing regions of Serbia. However, frequent occurrence of high temperatures and prolonged droughts favour increased frequency of *Aspergillus* spp., therefore our assumption was that this pathogen might cause certain problems in Serbia. The species *A. parasiticus* was isolated from maize grain for the first time in Serbia in the 2012 growing season (Stanković *et al.*, 2015). Additionally, the isolates obtained from wheat grains were also identified as *A. parasiticus*, for the first time under climatic conditions of Serbia in 2017 (Nikolić *et al.*, 2018).

Maize is commonly known as a crop very susceptible to mycotoxins. Due to their capability to cause not only cancers but also durable complications in and animal health, aflatoxins, produced by *A. parasiticus*, represent a distinctive group of mycotoxins. *A. parasiticus* synthesises four aflatoxins (AFB1, AFB2, AFG1 and AFG2), but not CPA (Amaike and

Keller, 2011). Since mycotoxins cause enormous destructive effects their amounts are legally regulated in foodstuffs in Europe and our country (Kos, 2015).
The aim of this study was to establish aflatoxins accumulation from pathogenic and toxigenic *A. parasiticus* isolates originating from maize, because *A. parasiticus* causes damages on maize grain, which is also contaminated with aflatoxins.

Materials and methods

Ten *A. parasiticus* isolates were evaluated for levels of aflatoxin contamination.

Sample preparation for the mycotoxin assessment

The aflafoxin production was determined in isolates inoculated in the centre of the 9-cm Petri dish with a dense conidial suspension and grown on PDA as single colonies. The incubation of cultures was done at 28±1°C in the dark for 5 days (Abbas *et al*., 2004).

HPLC, extraction and quantitation of aflatoxins

According to Abbas *et al*. (2004), the contents of PDA dishes were put into a tube to collect fungal biomass, which was placed in glass vials of a known weight and weighed again. Fungal biomass was extracted with a solvent mixture acetonitrile-water (90:10, v/v) in the ratio of 100:1, v/m. A reciprocal shaker was used to shake vials for 30 min at high speed. A 1-mL aliquot of extract was removed and centrifuged at 12 000 g for 10 minutes. The HPLC-fluorescence detection method was used to confirm the presence of aflatoxins in the supernatant (AOAC Official Method 994.08). Data are reported as the mean value of three independent injections.

Results and Discussion

Toxicological characterisation

The quantitative and qualitative analysis of the production potential by the HPLC method has shown that there is a high variability in the concentration of individual aflatoxins (B1, B2, G1 and G2) among isolates.
Aflatoxin production capability of all *A. parasiticus* used in this experiment was analysed with chromatographic technique, HPLC-FLD. In our study, aflatoxins were produced by almost all *A. parasiticus* strains. The MRIZP isolates (MRI 2Ap, MRI 3Ap, MRI 5Ap, MRI 7Ap, MRI 8Ap) produced aflatoxins B1, B2, G1 and G2, except of the isolates MRI 6Ap and MRI 10Ap that did not produce aflatoxins B2 and G2, and MRI 1 that did not produce aflatoxins G2. Some isolates was unable to produce any aflatoxin (MRI 4Ap, MRI 9Ap). We pointed out the existence of isolates that synthesized aflatoxin G1 at higher concentrations, compared to aflatoxin B1 (MRI 2Ap, MRI 3Ap, MRI 5Ap) (Table 1).

The average synthesis of aflatoxin B1 was 3467.60 μg kg^{-1}, which ranks this species into strong AFB1 producers. The average synthesis of aflatoxin B2 was 257.69 μg kg^{-1}. The average synthesis of aflatoxin G1 was 2749.89 μg kg^{-1}, which classify this species into strong AFG1 producers, while the average synthesis of aflatoxin G2 was 59.31 μg kg^{-1}.

The highest concentrations of AFB1 were detected in MRI 1Ap isolates (7542.19 μg kg^{-1}), while at least concentrations were observed in MRI 10Ap (33.05 μg kg^{-1}) isolates. The highest concentrations of AFG1 were detected in MRI 5Ap (6666.12 μg kg^{-1}). The lowest concentrations of this mycotoxin were detected in the MRI 7Ap (5.13 μg kg^{-1}) isolates (Table 1). On the basis of the obtained results, there is a great diversity in the production of all individual aflatoxin.

Table 1. Different concentrations of *Aspergillus parasiticus* isolates

Isolates	B1	B2	G1	G2
	μg kg^{-1}	μg kg^{-1}	μg kg^{-1}	μg kg^{-1}
MRI 1Ap	7542.19	995.41	3205.56	nd
MRI 2Ap	4409.10	143.97	5357.14	68.92
MRI 3Ap	5708.12	150.01	6495.07	80.05

MRI 7Ap	5198.68	403.79	5.13	128.02
MRI 8Ap	5776.73	629.68	5746.97	217.83
MRI 9Ap	nd	nd	nd	nd
MRI 10Ap	33.05	nd	7.89	nd

nd – not detected

The results of the HPLC method indicated the existence of statistically very significant positive correlations between the production potential of AFB1 and AFG1 in isolate *A. parasiticus* (r = 0.74**), while the correlation between production potential AFB2 and AFG2 was significant (r = 0.37*) (Table 2).

Table 2. Correlation between the synthesis of aflatoxins B1, B2, G1, G2 in the *Aspergillus parasiticus* isolate obtained by the HPLC method

Mycotoxin	Correlation coefficient (r)	
	AFG1	AFG2
AFB1	0.74**	
AFB2		0.37*

** Statistically significant difference (p <0.01)
* Statistically significant difference (p <0.05)

A. parasiticus isolates showed high production potential of B and G type aflatoxins in studies performed by Vaamonde *et al*. (2003), Rodrigues *et al*. (2009) and Baquião *et al*. (2013).
Nikolic *et al.* (2017) analysed the concentrations of individual aflatoxins of the group G, established by the use of the HPLC-FLD method, varied from 8.03 to 7421.58 μg kg^{-1} for AFG1 and from 0 to 395.18 μg kg^{-1} for AFG2. Furthermore, Nikolic *et al.* (2018) studied the potential of the production of *A. parasiticus* isolates that originated from grain of wheat cultivated under different agro-climatic conditions in Serbia and found out that all isolates had the ability to synthesise AFB1, AFB2 and AFG1 in the concentration range of 4859.15-7361.03 μg kg^{-1}, 142.81-1543.8 μg kg^{-1} and 3085.11-7191.62 μg kg^{-1}, respectively. One isolate did not synthesise AFG2, while remaining ones synthesised this aflatoxin in the concentration ranging from 86.92 to 181.76 μg kg^{-1}. However, these authors established two isolates that synthesised AFG1 in greater concentrations than AFB1.
During testing of the production potential of the *A. parasiticus* isolates, Donner *et al.* (2009) recorded the average concentrations of AFB1 (90-2092 μg kg^{-1}) and AFG1 (99-3450 μg kg^{-1}). The range of concentrations of AFB1 and AFG1 synthesised in these tests amounted to 90-4957 μg kg^{-1}, and 0-6131 μg kg^{-1}, respectively.

On the occasion of studying the potential of the total aflatoxins of the *A. parasiticus* isolates originating from Nandi County in Kenya, Okoth *et al.* (2012) detected a significantly higher range of concentration variations (9982-13662 μg kg^{-1}). Concentrations of individual aflatoxins ranged from 603 to 11077 μg kg^{-1} (AFB1), 208 to 2876 μg kg^{-1} (AFB2), 24 to 5982 μg kg^{-1} (AFG1) and from 0 to 7798 μg kg^{-1} (AFG2). The production potential of isolates, originating from Makueni County, indicated significantly higher values of synthesised both total aflatoxins (22-55419 μg/kg) and individual aflatoxins: AFB1 (22-15139 μg kg^{-1}), AFB2 (0-3141 μg kg^{-1}), AFG1 (0-28728 μg kg^{-1}) and AFG2 (0-8411 μg kg^{-1}). These authors did not find out differences in increased synthesis of AFG1 in comparison to AFB1.

Okun *et al.* (2015) recorded significantly higher concentrations of the total aflatoxins (1742-1670000 μg kg^{-1}) synthesised by *A. parasiticus* isolates. Almost all isolates were capable to produce aflatoxins of the B and G group - there were just two isolates that synthesised aflatoxins only of group B.

Baquiao *et al.* (2013) established average concentrations of individual aflatoxins synthesised by this species in nutlets in Brazil: AFB1 - 6172 μg kg^{-1}, AFB2 - 184 μg kg^{-1}, AFG1 - 16.776 μgkg^{-1} and AFG2 - 313 μg kg^{-1}.

In Portugal, Rodrigues (2011) recorded that the majority of observed isolates (86%) showed a typical profile of the species *A. parasiticus*, meaning that they are strong producers of aflatoxins B1 and G1 and that they do not produce CPA. Nonetheless, studies showed that 8 isolates (4%) did not synthesise aflatoxins of the group G, as well as that 7% of isolates synthesised aflatoxin G1 in higher concentrations than aflatoxin B1.

Rodrigues (2011) recorded results obtained on the existence of isolates that did not synthesise aflatoxins. Horn *et al.* (1996), Vaamonde *et al.* (2003), Barros *et al.* (2006) pointed to *A. parasiticus* isolates that occurred naturally, but had no aflatoxin synthesis-ability, and ranged from 3 to 6%.

Studies carried out within the present paper indicated isolates that did not synthesise aflatoxins B1, B2, G1 and G2 or if they did the concentrations were very low and their values were impossible to determine. The existence of atoxigenic isolates of this species can be a significant gain for Serbia, since they are increasingly applied in the biological control of virulent fungal strains.

Conclusions

Gained results confirm the capability of this fungus to produce mycotoxins. Further studies are required to improve existing strategies for prevention and control of these economically important pathogens. Preventive actions and good practices at harvest can reduce the impact of *Aspergillus* ear rot on yield and grain quality. Certain isolates of *A. parasiticus* did not synthesize aflatoxins and their use as biological agents in plant protection should be estimated. If global climate changes persist to affect cereal-growing regions in Europe, this pathogen will further develop and the danger will be even greater. If climate changes could be precisely foreseen these changes and fungal infection and subsequent aflatoxin contamination could be accurately linked, then predicting and dealing with this emerging risk would be less difficult to quantify.

Abstract

In a top of the most devastating fungi all over the world the fourth and fifth positions are occupied by fungi from the Fusarium genus. They produce toxins which cause significant quantitative losses in many agricultural crops and introduce into the food chain some dangerous toxins which are a serious threatening to food safety. The main plants affected are cereals, which are actually the most important source of food for both humans and animals. Therefore the development of reliable, fast and cost effective methods for *Fusarium* strain identification based on gene/DNA fragments evaluation is of great importance. In our studies, after fungal isolation from wheat samples collected from different locations, the DNA was extracted and purified, followed by specific amplification (PCR) or sequencing. First, the primers which amplify specific genes for *F. graminearum, F..culmorum, F..proliferatum and F. verticilloides* were used in a qualitative PCR. Following amplification of DNA from 58 single spore colonies with the *F. graminearum* species-specific primer, 39 positive and 19 negative results were obtained. The amplifications with the other specific primers were not successfully. Therefore another identification method was necessary. According to the literature data for the unknown samples the elongation 1 factor (TEF) genes were amplified, sequenced and compared with the databases *Fusarium*-ID. Therefore the precise identification was possible. It has been shown that some negative samples for the *F. graminearum* - specific primers are still part of this specie, indicating the possibility of genetic polymorphisms that degrade the binding sites of some primers. For a safe and accurate identification the sequencing for specific genes is recommended.

Keywords: *Fusarium, strain identification, molecular methods, DNA sequencing*

Introduction

In a top of the most devastating fungi all over the world the fourth and fifth positions are occupied by fungi from the *Fusarium* genus, namely *Fusarium graminearum* and *Fusarium oxysporum* (Dean *et al*., 2012). Also, of the 101 plant species of economic importance (www.apsnet.org/online/common/search.asp), at least 81 are associated with a disease caused by *Fusarium* sp. The climate change in recent years has had a strong impact on *Fusarium* species. Increasingly unpredictable oscillations of rainfall, humidity and temperature levels have led to an increase in plant vulnerability, an increase in pathogenicity, aggression, and toxicity of these fungi. All these changes have caused significant quantitative losses in agricultural crops, but also the introduction of strong toxins into the food chain, which is a serious threat to food safety. The main plants affected are cereals, which are actually the most important source of food for both humans and animals.

Mycotoxins produced by *Fusarium* sp., including deoxynivalenol, zearalenone and fumonisins, are considered dangerous food contaminant with hepatotoxic, nephrotoxic and neurotoxic effect. Acute toxicity results in the rapid installation of immediately visible and sometimes fatal manifestations, while chronic effects are more misleading and difficult to classify, resulting in serious economic losses caused by declining domestic livestock productivity.

Identification based on morphological traits is difficult, time-consuming and requires experienced specialists. For this reason, different methods of molecular analysis have been developed, which are fast with high accuracy (O'Donnell *et al.,* 2000, Aoki and O'Donnell, 1999; O'Donnell, 2004, Geiser *et al*., 2001, Ward *et al*., 2002).

The most common molecular technique is based on polymerase chain reaction (PCR), which is very useful in identifying and analyzing a particular region of the genome (Seifert, 2009). In contrast to traditional methods, this is very specific and allows identification of the pathogen even from impure crops. The selection of the region to be amplified is determined by three factors: DNA sequences should include a region highly conserved to allow the design of specific PCR primers; the same sequences have to show some differences in order to distinguish one species from another, and in the specialized databases should be sufficient information about the sequences (Geiser *et al*., 2004; Sampietro *et. al.,* 2010**;** Ioja-Boldura *et. al.,* 2012). Once the target region is selected, the samples can be amplified with species-specific primers - a positive amplification result means confirmation of the specie for which the primers were designed or in the direction of identifying the toxicogenic strains, the so-called chemotype can be determined.

Another method for molecular identification of Fusarium species is based on the DNA sequencing technique. This assumes the selection of a specific locus, considered as a marker in these identifications, which could be subjected to the sequencing (Geiser et al., 2004). Repeated attempts to find the most convenient marker allowed the discovery of the gene encoding the elongation factor EF-1 alpha which contains the information of an essential part of the protein biosynthesis translation mechanism. This turned out to be an excellent tool for identifying *Fusarium* species, and since September 2003 a database has been created containing TEF sequences of thousands of *Fusarium* strains. This information has been made available to researchers around the world through the Fusarium-ID site that currently contains 77 species, 1844 strains, 5558 sequences (http://isolate.fusariumdb.org/guide.php).

The aim of this paper was the development of reliable, fast and cost effective methods for Fusarium strain identification based on gene/DNA fragments evaluation.

Material and Methods

As biological materials 58 samples of wheat grains collected from different granaries were analyzed, collected in 2017 from different farms from the West part of Romania..

The grains, sterilized for 1 min with NaClO 3% and washed twice with sterile distillated water were transferred on PDA (Potato Dextrose Agar) medium and maintained at 25°C, with a photoperiod of 12/12 light/dark. After 10 days the growth mycelium have been used for development of a single-spore culture. For this purpose the serial dilution method described by Hansen & Smith (1932) was applied. A small amount of mycelium was introduced into sterile water and diluted until reaching the concentration of 10^2 cells/ml, or 4-5 macroconidia in a water drop, determined with the Burker counting chamber. The solution was transferred on PDA (Potato Dextrose Agar) medium and single spore were further on isolated and analyzed (Leslie *et al*., 2006). The mycelium required for DNA extraction was harvested after 5 days from the single-spore culture initiation. 100 mg of each sample was used for DNA extraction, using the Plant/Fungi DNA extraction kit (Norgen). The quality and concentration of DNA samples were evaluated by spectofotometric method (Nanodrop 8000) and standardized at 20 ng /µl.

Next, genes specific to each species of Fusarium were identified by amplification with specific primers (Table 1),

Table 1. The primer sequences and amplification conditions for *Fusarium* specie identification (Sampietro *et. al.*, 2010**)**

Fungal specie	Primer sequences 5'…3'	Primers annealing conditions (temp/time)	number of cycles	Amplicon size
F. graminearum	GTTGATGGGTAAAAGTGTG CTCTCATATACCCTCCG	53ºC/ 30sec	25	230
F. culmorum	ATGGTGAACTCGTCGTGGC CCCTTCTTACGCCAATCTCG	65°C/ 30sec	25	450
F. proliferatum	CGGCCACCAGAGGATGTG CAACACGAATCGCTTCCTGAC	65°C/ 30sec	25	500
F.verticillioides	CGCACGTATAGATGGACAAG CACCCGCAGAATCCATCCATCA	65°C/ 30sec	25	700

In all cases, the reaction volume was 25 µl containing 50 ng of DNA. The reaction mixture was made according to the manufacturer's instructions with the KAPA2G RobustHotStart ReadyMix kit (KAPA BIOSYSTEMS, Boston, USA) and amplified with Mastercycler ProS (Eppendorf), The resulting PCR products were separated in 1.5% agarose gel at room temperature, with a voltage of 90 volts. After about 30 minutes the products were visualized and photographed in UV light (UVP, England).
In the second step of molecular analysis the gene sequencing was followed up. The primers used for the amplification of the TEF (elongation factor EF-1 alpha) gene were first developed by O'Donnell et al. in 1998, known as ef1 ($^{5'}$ATGGGTAAGGAGGACAAGAC $^{3'}$), and ef2 ($^{5'}$GGAAGTACCAGTGATCATGTT$^{3'}$). These primers amplify a gene region of approximately 700 bp, marking three introns that occupy about half of the TEF gene (Geiser et al., 2004). The composition of the amplification mixture was similar to that described above and the specific primers annealing temperature was 53ºC.
The amplification products were separated by 1.5% agarose gel electrophoresis, with a voltage of 100. The gel fragments containing the fragments of interest with the expected size of 700 bp were excised under UV light and purified using the PureLink kit, Quick Gel Extraction & PCR Purification Combo Kit (ThermoFisher Scientific). The concentration of purified DNA samples was determined by the spectrophotometric method (Nanodrop 8000, Thermo Scientific). The purified DNA was sequenced by Macrogen Company, Holand. Once the nucleotide sequences were established, it was inserted into the Fusarium-ID database as well as the NCBI Genbank for Fusarium specie identification.

Results and Discussion

The 58 *Fusarium* samples, originated from the single-spore culture colonies isolated and morphologically identified (Bozac *et. al.*, 2014), have been evaluated with the PCR technique, namely the extracted and purified DNA was amplified with the primers specific for different *Fusarium* species.
The isolated DNAs were subjected to amplification with the primers for *F. proliferatum*, *F. verticilloides* and *F.culmorum*, without positive results. Lack of amplification may indicate that the strains do not belong to the mentioned species or the chosen primers were not suitable for the studied material. Following amplification of the 58 DNA samples with the *F. graminearum* species-specific primers, 39 positive and 19 negative results were pointed out (Fig. 1).

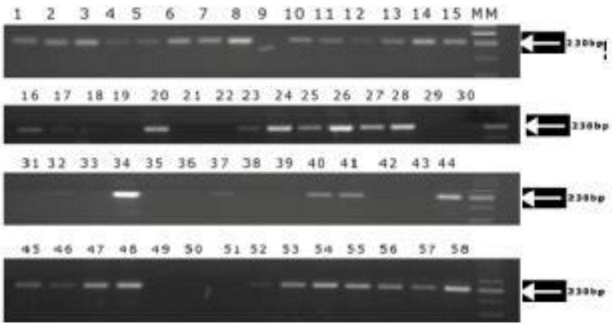

Fig. 1. The agarose gel (1.5%) electrophoresis for the *Fusarium* DNA samples amplified with *Fusarium graminearum* (Fg) specific primers

All the positive samples with the Fg primers which were previous identified as *Fusarium graminearum* based on morphological analysis have not been further analyzed. The 19 negative samples (9, 17, 18, 19, 21, 22, 29, 30, 31, 33, 35, 36, 38, 39, 42, 43, 49, 50, 51) were further evaluated along with 2 positive samples (37, 47) used as control.
The obtained results were compared with the previous morphological evaluations. Therefore, in the case of 14 samples from the negative ones, the morphological identification of the *Fusarium* species was not possible. Two of the samples (19 and 36) were identified as *Fusarium gramineraum* following morphological analyzes, with macroconidia with 5-6 septa with a tipical basal cell without microconidia, with pink/orange colour, even they were not amplified with the Fg primers. Other two samples (38, 42) were identified as *Fusarium equisety* with long, thin macroconidia, with a very long apical cell, dirty yellow colour and one strain was identified as *Fusarium avenaceum* (22), with long, slights curved, thin macroconidia, with orange colour.
For all of the 19 negative samples with the Fg primers together with the two samples considered as control the DNA was amplified with the primers specific for the TEF gene (ef1/ef2) (Fig. 2).

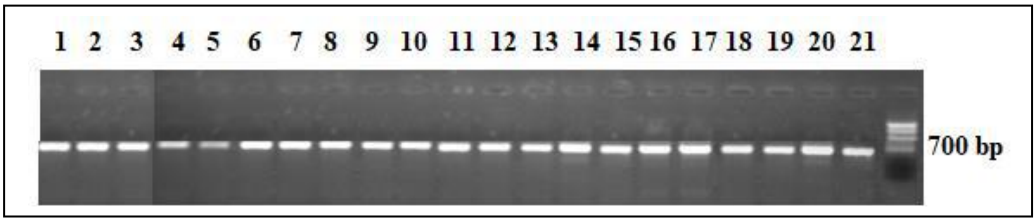

Fig. 2. The fragments amplified by the ef1/efr primers, seoarated by 1.5 agarose gel electrophoresis

Legend. 1- 9, 2- 17, 3- 18, 4- 19, 5- 21, 6- 22, 7- 29, 8- 30, 9- 31, 10- 33, 11- 35, 12- 36, 13- 38, 14- 39, 15- 42, 16- 43, 17- 49, 18- 50, 19- 51, 20- control 37, 21- control 47

All the fragments were excised from the gel, the DNA was purified and sent for sequencing to Macrogen company (Holand). All the sequences were compared with Fusarium Id and NCBI databases. The results, jointly with the morphological ones were presented further on (Table 2).
It was pointed that of the 14 samples for which the morphological identification of species were not possible, 6 belong to the F. *graminearum* species, even if amplification with Fg-specific primers did not occur. In addition, it was determined that 5 samples (9, 17, 39, 50 and 51) belong to the species *F. proliferatum*, one sample is *F. verticilodes* (49), one *F. subglutinas* (29) and one *F. andyiaze* (43). For two samples, morphological identified as *F.*

graminearum (19, 36) the specie was confirmed by sequencing, even if the amplification with Fg primers failed. For the samples which were morphological identified as *F. avenaceum* (22) and *F. equisety* (38 and 42) the results were correlated with the sequences evaluation.
For the samples used as control (37 and 47) all the evaluations methods had the same result - *F. graminearum.*

Table 2. Correlation of results obtained through morphological, PCR and sequencing evaluations

21.	**47**	+	*F. graminearum*	*F. graminearum*	99	99

Conclusions

Our results pointed out that if in the first stage the results of the morphological analysis are confirmed by amplification with specific primers, species identification can be considered accurate. When morphological analysis did not have precise results, it is recommended to evaluate the sequences specific to the TEF gene. It is possible to get negative results for the amplification with species-specific primers because of polymorphism that can distort primers binding sites.
Therefore, molecular analysis could be considered to be an important tool in identifying *Fusarium* species, and sequencing the TEF gene and comparing results with international databases as a sensitive, specific, accurate and fast method.

EVALUATION OF SPRAY QUALITY USING WATER SENSITIVE PAPERS AND SIMULATED TREE CANOPY

Reza TABATABAEEKOLOOR*, Behrooz MOKHTARPOUR, Yahya ABTALI

Department of Biosystem Engineering, Sari Agricultural Sciences and Natural Resources University, Iran
*Corresponding author: r.tabatabaei@sanru.ac.ir

Abstract

There are many problems due to remaining of excessive pesticide residues on agricultural products and risk of environmental pollution. Therefore, it is necessary to use new methods to enhance the spraying technique and quality. In this research, the number of droplet and volume of consumed chemical were evaluated for two sprayers (turbine and lance-nozzle) and two sizes of peach tree (small and large) using water sensitive papers and simulated tree canopy. Droplet diameters was considered in four categories as 0-150, 150-300, 300-450 and >450 micro meter. Data were analyzed based on randomized completely design by factorial test at five replications. Results showed that type of sprayer, droplets diameter and their interactions have significant effect on canopy size but volume of chemical used in large tree canopy was 16.5% more than small tree canopy. Also, in air blast sprayer the volume of chemical was about 101% and the droplet number was 17% more than lance-nozzle sprayer. Mean comparison of data showed that there is a significant difference between number of droplets and volume of chemicals at different particle size, as the maximum number and the minimum volume was obtained at 0-150 micro meter. Mean of total droplet number with turbine sprayer at range of 150-450 micro meters was 42.2% that considers about 84.7% of chemical volume. For lance-nozzle sprayer, mean value of droplet number at the same range of diameter was about 49.9% as it considers 46% of chemical volume. In general when we use turbine sprayer, the consumption is about 50% less than lance-nozzle sprayer.

Keywords: *Spraying, water sensitive paper, air blast sprayer, spray droplet diameter.*

Introduction

The most important component of food security in the community is healthy food. At present, in Iran, about 25 to 27 thousand tons of different types of pesticides are used annually at a level of about 16 million hectares (taking into account the number of application per unit area) (Plant Protection Organization, 2018). Spraying is effective in protecting the product, but the quality depends on the correct choice of sprayer type and how it works (Derksen *et al.*, 2010).
Use of water-sensitive paper cards to indicate or quantize the distribution of poison is one of the most commonly used methods in agriculture to measure the diameter and density of particles per unit area. These cards, which have a yellowish surface, become blue spots as a result of the collision of droplets of venom (Khot *et al.*, 2011). The color changed cards can be evaluated by image analysis (Cunha *et al.*, 2012; Zhu *et al.*, 2011a). Water-sensitive cards to determine the appropriate volume of poisons (Zhu *et al.*, 2011c), evaluation of intraocular canine venom concentration for the development of variable rate sprayers (Jeon *et al.*, 2011), spray output control for proper pest control (Zhu *et al.*, 2011a) or determining the pattern of poison distribution in aerosol sprayers (Fritz *et al.*, 2006). In a research, using the water-sensitive paper, the amount and distribution of solution droplets, the volume of spray solution, surface area, diameter of droplets and number of droplets on citrus trees were evaluated (Salyani *et al.*, 2013). Peyman *et al.* (2011) determined the number and diameter of pesticide particles by scanning water-sensitive cards using the artificial neural network. In a study, water sensitive card was used at three altitudes of the ground and four depths of tree canopy (Sanchez *et al.*, 2012). Zhu *et al* (2011b) evaluated portable scanners, surface coverage and

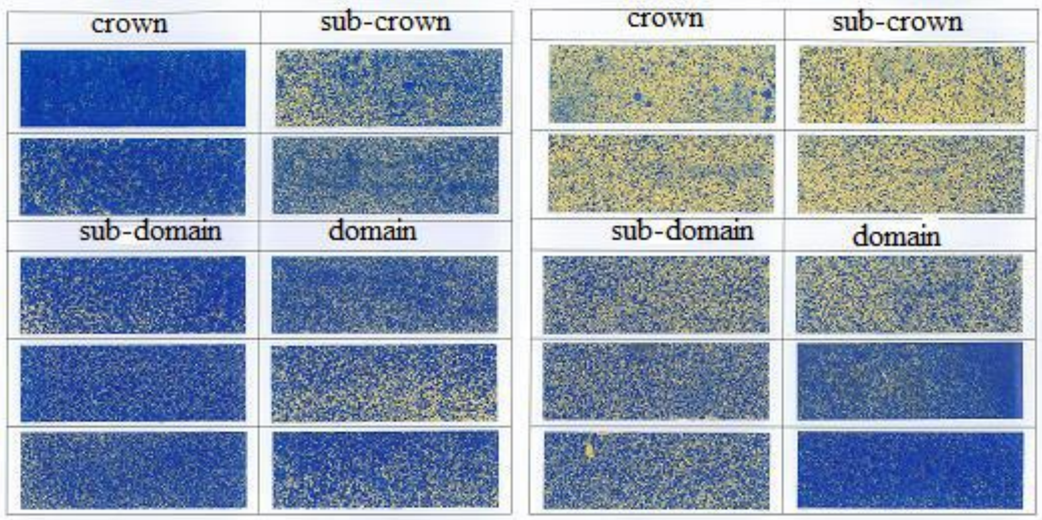
distribution patterns on water-sensitive paper. Fuentes *et al.* (2015) tested a blown air sprayer in a densely packed olive garden and found that the parameters of poison coating, the amount and distribution of poison droplets in different areas of the tree umbrella were affected by the volume of spraying and the intensity of the poison flow. Therefore, the aim of this study was to determine the volume, diameter and number of soluble particles per unit area using water sensitive papers and simulated tree canopy.

Material and Methods

Figure 1 shows spraying on the simulated tree canopy using lance-nozzle and turbine sprayers. The tractor was first placed in the right direction and about five meters before the tree plant. The engine speed was set at 2250 rpm and the pump pressure was 25 bars. The angle and amount of spray nozzles were regulated and controlled in the same way as spraying. Spraying five meters before the start of the tree and five meters later it was cut off. After the spraying was completed as a first repetition, after about 15 minutes, the cards were collected from the tree canopy and sorted.

Fig. 1. Spraying on the simulated tree canopy using two methods

All collected cards were individually scanned each time with a 1200 dpi professional scanner (CanoScanLide, Canon, Japan), and each group was stored in a special file. Due to the fact that the diameter and number of particles are different, four ranges of 0-150, 150-300, 450-300 and more than 450 microns for particles were defined. The scanned cards were separated by 5 x 5 mm (5000×5000 micron) using Photoshop image processing software environment and then magnified 10 times. After the segmentation, the number of particles was counted according to the defined range. Finally, the particles of the same domain were numbered in a special layer with a certain color and the information was recorded in the relevant tables. An example of collecting and sorting cards is shown in Fig. 2.



Lance sprayer Turbine sprayer

Fig. 2. Typical particle distribution on water sensitive paper for two methods of spraying

Results and Discussion

The particle number and volume per unit area

The number and volume of solution consumption per unit area, according to the type of tree and type of sprayer, are shown in Fig. 3. The comparison of averages indicates that the number of particles for tree type is not significant, but spraying method has a significant effect on the number of particles sprayed per unit area, so that the number of particles in turbine sprayer was found to be about 17% more than the lance type. This indicates that the number of particles in the surface area of water-sensitive cards is independent of tree canopy, but the turbine spray disperses more particles per unit area of tree than the lance sprayer. The number of particles in different diameters has a significant difference, so that about 83% of the number of particles in the range of 0-150 microns was observed and the lowest number was in the range of more than 450 micron.Due to the fact that in the turbine spray the intensity of the blown air for powdering and spreading the solution is used, therefore, most of the particles are found to have fewer diameters due to the air flow and collisions, resulting in a more uniform distribution of the solution per unit area.

There is a significant difference between the two types of sprayers in the large tree, with the highest number of particles per unit area when using a turbine sprayer and the smallest number of particles associated with the use of lance sprayer. The highest amount of soluble consumption for large tree and lance sprayer and the lowest for small tree with turbine spray were obtained. Since the turbine spray can withstand the turbine wind through a wide range of canopy trees, the size of the tree has no effect on the number of particles sprayed and the amount of solution consumption.

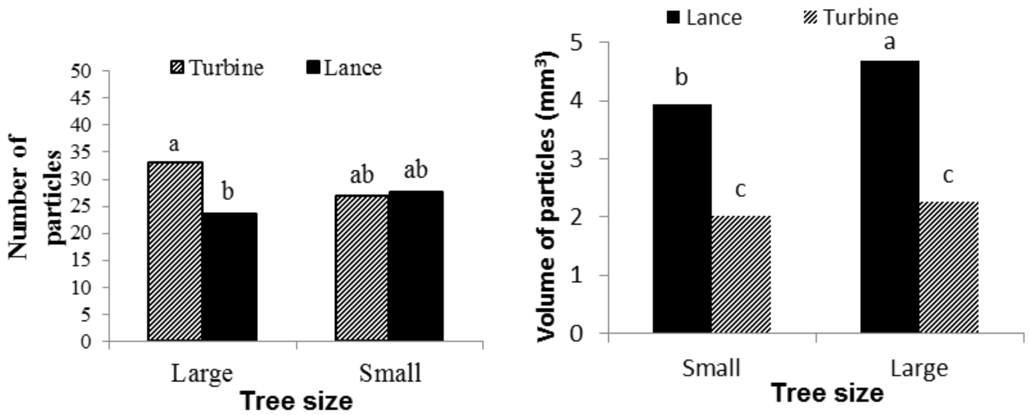


Fig. 3. Interaction of number and volume of particles on two size of tree and two types of sprayer

The highest and lowest amount of the consumed solution volume was for large trees and particle diameter greater than 450 microns and 0-150 microns, respectively (Fig. 4). The same result was obtained for lance sprayer (Fig. 5). About 1.4 to 2% of particles in a turbine sprayer have a diameter of more than 450 microns, which is not suitable for spraying. This value for lance sprayer in small trees is 11.4% and in large trees is 17.6%. The maximum and minimum number of solution particles was obtained for a turbine spray with a range of 0 to 150 microns and >450 microns, respectively (Fig. 5). One of the indicators of effective spraying is the finer content of sprayed particles, resulting in more toxins in the leaf area of the trees. Therefore, turbine sprayers are preferred over lance type. The difference of about 97% between these two particle sizes in the lance sprayer shows that most of the particles sprayed with these type of sprayers, are coarse and for this reason, when using them, the uniformity of particle spraying and their coating surface relative to the turbine type is much less. Hermosilla et al. (2012) reported that the use of turbine sprayers reduced solution consumption about 54% and subsidence into the canopy was about 40% more than lance sprayers. Fuentes et al. (2015) showed that in air blown sprayers spraying efficiency, the penetration into the canopy of the tree and the uniformity of spraying on the leaves are significantly higher than that of non-air assistant sprayers.

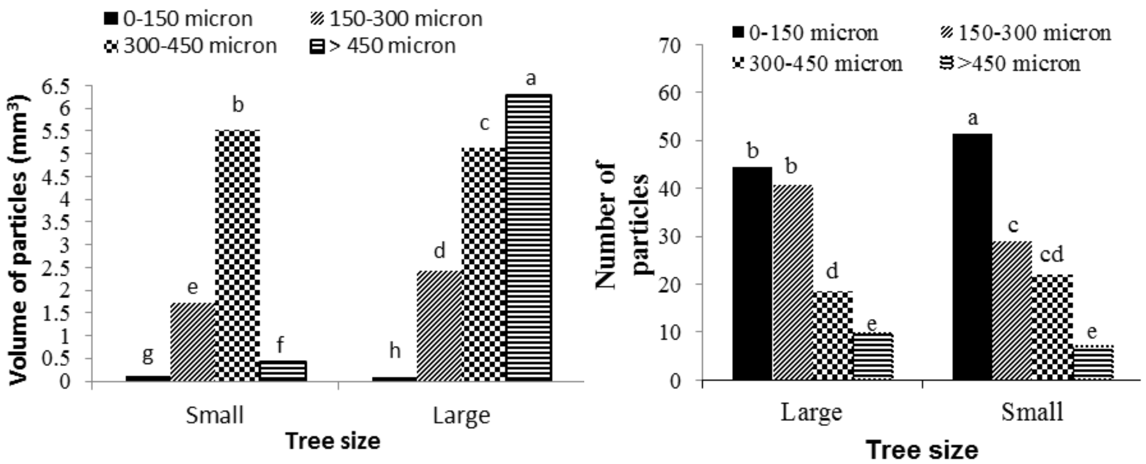

Fig. 4. Interactions of tree and sprayer type on the number and volume of particle on unit area

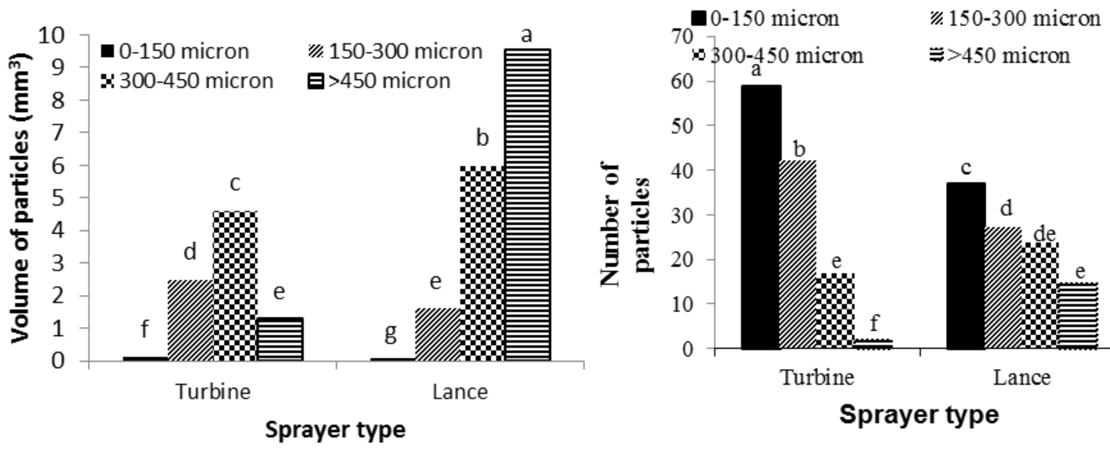

Fig. 5. Effect of sprayer type and particle size on volume and number of particles

Analyzing the effective range of particle diameter and volume

As we know, the most types of pesticides are mostly effective in the range of 150-450 micron diameter. By analyzing the diameter and particle size data, the cumulative percentage of each domain and the separation of the range of 150-450 microns with a range of less than 150 and more than 450 microns can be calculated and compared with the solution volume in these two domains (Fig. 6). Regarding the total number of particles on water-sensitive cards, it was determined that the total number of particles on the cards in small and large trees was 46.1% and 52%, respectively, with turbine spray in the range of 150-450 microns and this number was about 89.6% and 79.8% of the amount of solution consumed, respectively.

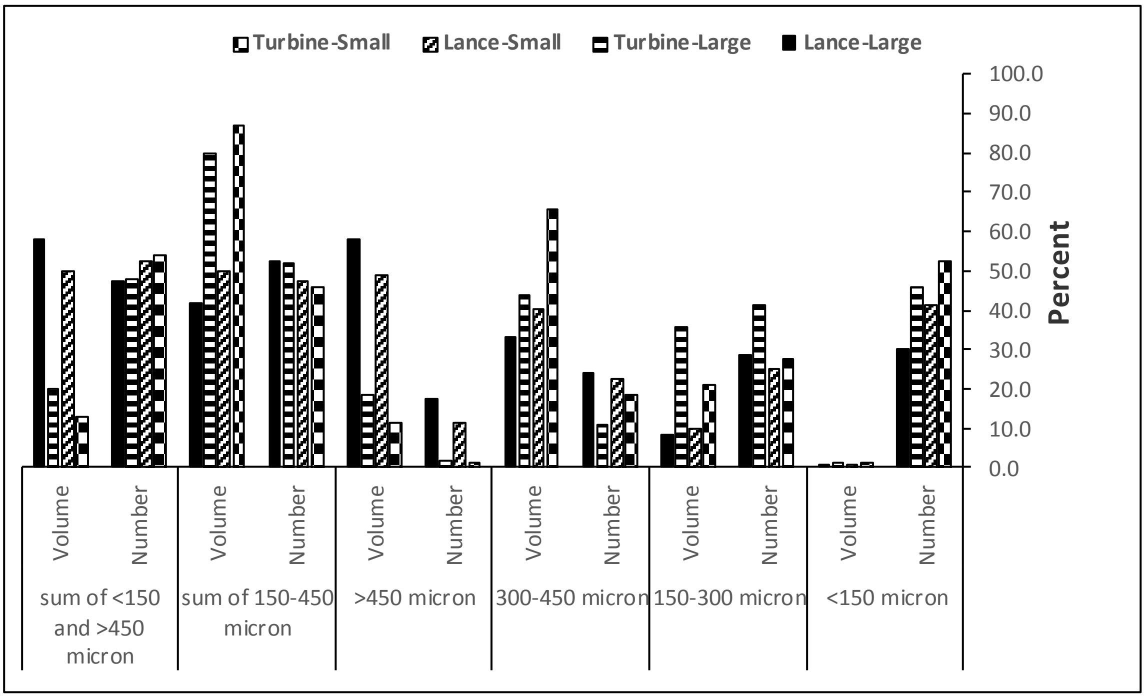

Fig. 6. Comparison of cumulative percentage of particle diameter

Conclusions

The type of sprayer and size of tree have significant effect on volume of chemical used in spraying. In turbine sprayer the number and volume of chemical droplet was more than lance-nozzle sprayer. More than 80% of chemical volume was at the range of 150-450 micro meters. For lance-nozzle sprayer, mean value of droplet number at the same range of diameter was about 49.9% as it considers 46% of chemical volume. In general when we use turbine sprayer, the solution consumption is about 50% less than lance-nozzle sprayer.

Abstract

Since their discovery in the twentieth century synthetic antibacterial drugs, penicillin, streptomycin and, other antibiotics have significantly influenced the reduction of the risk of contagious diseases. On the other hand, bacterial infections (respiratory and urinary tract infections, meningitis, sexually transmitted infections) are increasingly frequent in recent years, mainly due to the resistance of bacteria to synthetic antimicrobial drugs. In recent decades, there is an increasing need for natural and non-toxic antimicrobial substances, which is conditioned by the more frequent development of microorganisms resistance to synthetic antimicrobial drugs.

Natural preparations made from fresh plant material and biologically active compounds isolated from various plant species that have been used in folk medicine for centuries can represent valuable resources for the production of new natural remedies.

The aim of this paper is to test the antibacterial activity of *Sempervivum tectorum* on the tested bacterial isolates : pure *Sempervivum tectorum* juice, then in combination with honey and the action of the honey itself and to determine the type of action. The results of the work have confirmed the antibacterial activity of *Sempervivum tectorum* on seven clinical isolates, with a growth inhibition zone from 9.00 mm to 24.33 mm. Also, the obtained results show that *Sempervivum tectorum* represents a potential source of new compounds with antibacterial activity.

Key words: *Sempervivum tectorum, antibacterial, natural preparations*

Introduction

The use of plants in medicine and pharmacy instead of synthetic drugs has significantly increased in recent years. Phytotherapy is today most prevalent in underdeveloped countries, so it is estimated that between 60% and 80% of the world's total population relies on the use of herbs (Tucakov 2010). Medicinal herbs represent a significant source of medicines and medicinal raw materials (Harvey, 2000). Nowadays, thanks to modern methods and contemporary laboratory techniques, medicinal, aromatic and other useful plants, are being studied in more detail from all aspects in the search for new and better medicines and medicinal products. There are still completely or insufficiently unexplored plant species which leads to inexhaustible possibilities of modifying natural substances with polysynthesis in order to obtain compounds of better physiological and pharmacological properties. (Savikin *et al*., 2013,, Nanjan, 2010). The chemical constituents present in medicines of plant origin or plants themselves are part of the physiological functions of the plants and therefore they are believed to have better compatibility with the human body. Natural products from plants are rich sources of medicinal substances used for centuries to treat various diseases. It is well known that the use of synthetic drugs, in addition to their primary function, also has a secondary effect that may be even more dangerous than the disease which is treated. Herbal remedies contain natural substances that can promote health and alleviate the disease, have better patient tolerance and are relatively cheaper (Savikin *et al*., 2013, Sen *et al*., 2009;

Ramchoun *et al.,* 2009; Kamboj, 2000). Chronic administration of nonsteroidal anti-inflammatory drugs used to treat pain, high temperatures, inflammation, rheumatic and cardiovascular diseases can lead to gastric or duodenal damage and severe complications such as gastrointestinal bleeding and perforation (Kamboj, 2000). *Sempervivum tectorum* is a plant commonly known as houseleek, ayegreen, ayron, bullock's eye, hens and chickens, jupiter's beard, liveforever, sengreen and thunder plant. It is mainly grown as a decorative plant with medicinal properties. The name *Sempervivum* originates from the Latin word semper- to live, because the plant lives on the ground where most plants do not survive, it is very resistant to drought and high temperatures. (Muselin *et al*., 2014, Alberti *et al*., 2012, RHS 2008). It originates from Mexico, but it has been grown in our area for 9 centuries. It has been known since ancient times and is mentioned in the documents of Charles the Great (742-814) as "a plant that everyone grows on roofs of houses". It was believed to protect a house from fires and lightning struck. Because of this myth (lat. Tectorum- on the roof) it got this Latin name (Baum et al. 2005). Our people also believe that houseleek protects the house and household members from evil spirits so there is a saying that '' it's better to have a houseleek on the house than two watchdogs in front of it'' (Perić S. 2008). It is a succulent perennial terrestrial plant from the *Crassulaceae* family with a diameter of 10-20 cm and a strong root system. It has pinkish white flowers. Its leaves are fleshy, juicy and elliptical with a pointed tip. (Harvey, 2000, Muselin *et al*., 2014). Houseleek is widespread throughout southern Europe, especially in Peloponnese, Alps and the Dinaric Alps. In folk medicine, whole-fruit juice (*Sempervivum tectori succus*) or only leaf (*Sempervivum tectori folium*) is used against burns, herpes and ulcers. The leaves have an astringent and sour taste without odor. Houseleek in the form of a tincture is used as a homeopathic remedy against throat inflammation (Milovanović, 1975, Alberti *et al*., 2012). *S. tectorum* is a plant that is mainly used in folk medicine and its medicinal properties have not yet been fully explored. Its medicinal substances contain malic and formic acid, AHA acids, tannins, calcium malate, polysaccharides, flavonoids, alkaloids, as well as a smaller amount of resin, and there are some substances that are still unexplored (Karabegović *et al*., 2017., Blažević *et al*., 1992 a,b,c, Blažević *et al*. 1994.,Sentjurc *et al*., 2003). These ingredients have medical properties and houseleek is commonly used in the treatment of various conditions such as cysts, hemorrhoids, ear infections, diarrhea and urinary tract infections, ulcers (Rashid *et al*., 2014, Alberti *et al*., 2012., Bremness, 1996, Tierney *et al*., 2005). It is used in the form of juice, lining, ointment, tincture or tea. Due to its antibacterial, anti-inflammatory and antiseptic properties it is a great first aid to burns, insect's stings and bites, ulcers, and pain because it provides rapid relief and sedation. It is also used for removing warts and foot corns (Grieve 1994). *S. tectorum* is rich in flavonoids, which are responsible for its healing and beneficial effect in various inflammatory processes. Polyphenols isolated from the leaves of *S. tectorum* are the main agents responsible for antibacterial effects (Abram, 1999). Alkaloids act regenerative, palliative and as an anti-inflammatory, while tannins exhibit an adrenergic, antimicrobial, antipruritic, anti-inflammatory, antioxidant, and uv-protective property (Rovčanin *et al*., 2015, Khlifi *et al*.,2011., Šentjurc *et al* 2003., Abram and Donko, 1999.) Today, this plant is mostly used in the cosmetics industry for the preparation of sunscreen and after shave preparations, as well as in baths and shampoos. It is found in all anti-age and sunscreens preparations because it is rich in AHA acids. Houseleek has a long history of human use and there are no side effects (except it can be an emetic in high doses) or drug interactions and it is good against swallowing and water retention. The famous English herbalist Culpepper pointed out that *S. tectorum* is good for all internal and external inflammations, because its juice cools and reduces thirst and it is especially good in severe inflammation (eg erisipelas) and greatly relieves pain and gout. (Duke, 2002). In traditional medicine, *S. tectorum* is mostly used in otitis and ulcers, and therefore we have tested *S.tectorum* antibacterial activity on bacterial cultures isolated from the clinical material of humans and animals. *S. pseudintermedius* is the dominant type of coagulase-positive staphylococci on the skin and the main cause of pyoderma and otitis externa in dogs. Dermatoses represent a large percentage of dog diseases in veterinary practice. Uropathogenic *Escherichia coli* is the primary cause of urinary tract infections, while *S. aureus* is one of the main causes of inflammation of the throat, nose and ear. The aim of the study is to examine the antibacterial activity of *Sempervum tectorum* against clinical isolates of certain bacterial cultures. and to determine the type of action.

Material and Method

Sempervivum tectorum juice, domestic acacia honey and mixture of honey and *Sempervivum tectorum* juice were used as materials. *Sempervivum tectorum* juice is obtained by extracting juice from leaves that are very juicy in the summer. The mixture of houseleek and honey is made using the traditional recipe; 300g of leaves are chopped and mixed with 300g of honey. The mixture was left in a cold place for seven days with occasional stirring.

Test microorganisms

For antibacterial activity of *S. tectorum* the following seven bacterial cultures isolated from the clinical material (human isolates) were used to test antibacterial activity of *S. tectorum* : ß hemolytic *E. coli* (urine), coagulase positive staphylococci (throat), *E. coli* (urine) and *S. aureus*$_s$ (nasal blisters) *S. pseudintermedius*$_n$ (swab of a dog's ear), *S. pseudintermedius* (ureter swab) and one *Staphilococcus* spp. (swab from a dog's skin). Cultures were inoculated in a nutrient medium and incubated at 37^0C for 18h. Petri plates with the appropriate substrate (Müeller - Hinton agar) were inoculated with 0.1 ml of a bacterial suspension with a concentration of 10^5cfu / ml.

Test method

An agar diffusion method was used (Bauer 1966) by placing a metal cylinder of 9 mm in diameter on a solid sterile substrate (Müeller-Hinton agar-MHA). 100 μL of plant and honey mixture, 100 μL of *S.tectorum* juice, and 100 μL of honey were dropped on the disks by micropipet. A disc with 100 μL of 96% ethanol was used as a control. The ability of a strain to grow and multiply depends on its susceptibility to the tested substances, and if the effect is present there is a clear translucent zone formed around the disk in which there is no growth of microorganisms. Petri plates were incubated for 24h at a temperature of 37 ° C. Three repetitions were performed and results were obtained after 18-24h incubation by determining the inhibition zone diameter and the mean value was calculated.

Type of action

The type of action was also determined. To see if *S. tectorum* has bacteriostatic or bactericidal properties, a small amount of the agar was added from the zone of inhibition and added to the nutrient broth. Incubation was carried out at 37ºC for 24h. if after incubation the broth is clouded, the effect is bacteriostatic, that is, if the broth remains clear, the effect is bactericidal.

Results and Discussion

In the paper, the antibacterial activity of *S.tectorum* is examined in the form of mixture of plants and honey, honey itself, and pure plant juice.The results of the work are shown in Chart 1.

The results of this study showed that *S. tectorum* possesses a specific antibacterial activity against tested clinical isolates. Growth inhibition zone ranged from 9.00 mm to 24.33 mm. The mixture of *S.tectorum* and honey was antibacterial with an inhibition zone of 12.33 mm to 24.33 mm. The honey had antibacterial activity against tested bacterial isolates with inhibition zones of 10.00 mm to 23.33 mm.

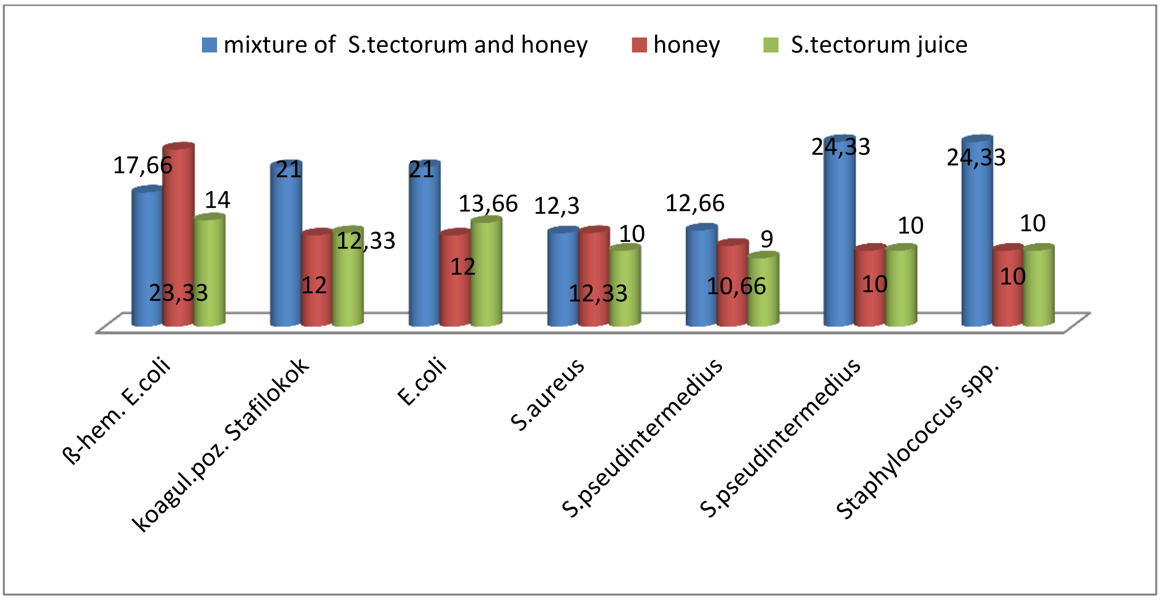

Chart 1. Antibacterial activity of Sempervivum tectorum to clinical isolates

It is evident that only ß-hemolytic *E. coli* honey showed stronger antibacterial activity with a 23.33 mm inhibition zone. The antibacterial activity of pure juice *S. tectorum* was quite uniform for *S. aureus*, *S. pseudintermedius*$_s$, *S.pseudintermedius*$_n$ and *Staphilococcus* sp. with an inhibition zone of 9.00 mm to 10.00 mm, while somewhat more pronounced antibacterial activity was observed in ß-hemolytic *E. coli*, *E. coli*, and coagulase-positive *Staphylococcus* with an inhibition zone of 12.33 mm to 14.00 mm. The results of the work are in accordance with the work of other researchers (Rovčanin et al., 2015, Gao et al., 2012, Abram et al 1999, Stojkovic et al., 2015) that examined the chemical composition and antibacterial activity of *S. tectorum*.

The results of the study justified the use of this traditional herbal remedy itself or in combination with honey for certain (otitis, gastritis, ulcer, dermatitis and the like) bacterial diseases.

Antibacterial activity of *S. tectorum* may vary from partial to full inhibition of bacterial growth, so it exhibits bacteriostatic or bactericidal activity. *S. tectorum* exhibited stronger bactericidal activity against tested clinical isolates, while the honey was more bacteriostatic, as shown in Chart 2

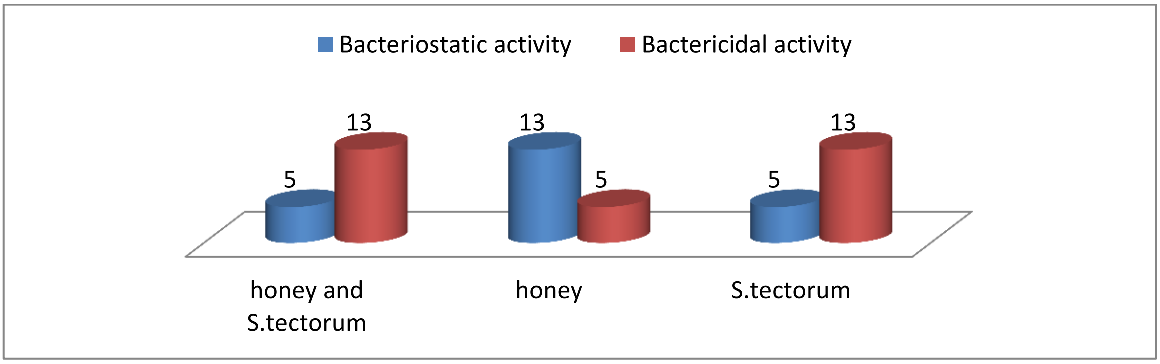

Chart 2. Bactericidal and bacteriostatic activity S.tectorum

Conclusion

The obtained results show that *Sempervivum tectorum* is a potential source of new compounds with antibacterial activity. Continued use of antimicrobial drugs has led to many bacteria becoming resistant and modern lifestyle has led to the emergence of a large number of stress-induced illnesses, which imposes the need for isolation and identification of antimicrobial compounds from plant sources that are pharmacologically powerful and have a low or no side effect of use in both medicine and the food industry. Increasing knowledge about phyto-constituents as biologically active substances and their inclusion in everyday use and nutrition can provide sufficient support to the human and animal body in combating many diseases. The present research is the basis for further testing of the biological activity of plants from the *Crassulaceae* family.

Abstract

Recently, the number of greenhouse plants (cucumbers, strawberries, tomatoes) has grown. Pathogens become the main enemy in this system of cultivation. The main pests of tomato plants include insects. These pests cause fading of leaves and necrosis. Leaves become yellow, lose turgor and finally degraded. Moreover, some insects produce honeydew, which allows the development of fungal diseases. In view of the EU's rejection of the introduction of new genetic methods (CRISPR), it is necessary to look for new ways how to protect plants from pests and the associated sustainability, which is most important for agricultural production. The main objective of this work was to test nanocomposite materials and their toxicity for individual pathogens and the plant itself. In this work, we tested metal nanoparticles on the growth of Solanum lycopersicum L. and viability of model pathogen Tenebrio molitor. Basic biochemical analysis of stress markers was performed as part of NPs plant toxicity analysis. Mainly, the total content of carotenoids, polyphenols, flavonoids, chlorophylls, antioxidants was associated with abiotic stress. Samples were analyzed using ambient and chromatographic techniques with a mass detector, spectrophotometer with 96-well plate reader. During the experiment, we used a different concentration of Zinc oxide nanoparticles (ZnO NPs). Larvae T. molitor was sprayed with nanoparticles 3 times a week, and the greatest effect had the highest concentrations of ZnO NPs, where the mortality was 80 %.

Keywords: *Tomato, Zinc-oxide, nanoparticles, Tenebrio molitor.*

Introduction

Nanotechnology is one of the potentially effective options for significantly strengthening the global agricultural production needed to meet the future demands of a growing population. Nanoparticles, materials usually 1-100 nm in size, have a number of specific properties, based on their size, shape and structure (Jeevanandam, Barhoum et al. 2018). Zinc is one of the essential elements playing an important role in many plant pathways. Its deficiency in plants results in persistence of growth, sterility and susceptibility to phytopathogens (Duffy and Défago 1997, Helfenstein, Pawlowski et al. 2015).

Zinc oxide nanoparticles (ZnO NPs) belong to the most used nanostructures of metal oxide in practice and research (Mishra, Mishra et al. 2017). Due to their small size, ZnO NPs are better absorbed by the plants and depending on the used concentration ZnO nanoparticles can have both, positive or negative effects (Lin, Xing et al. 2008, Doolette, Read et al. 2018, Akanbi-Gada, Ogunkunle et al. 2019). Zinc oxide nanoparticles are widely used in many application in the agricultural industry (McClements and Xiao 2017) and can be used as potential pesticides in protecting plants from various pathogens, as well as fertilizers in foliar treatment of plants.

Tomato (*Solanum lycopersicum* L.) is the most widely vegetable in the global production system (Testa, Trapani et al. 2014). Belongs to the order of *Solanales* and family *Solanaceae*. Botanically, tomato is not a vegetable but is a fruit berry (Bergougnoux 2014). After potato, consumption of tomato surpasses all other vegetables, making it one of the most popular garden crops. During the last 10 years, area and production of tomato cultivation are continuously increasing. Major problems in tomato production are pathogens (insects, bacterias, viruses, fungi). *S. lycopersicum* L. contains primary metabolites (protein, sugar, lipids) and the number of secondary metabolites (vitamin A, ascorbic acid, antioxidants, alkaloids and polyphenols) which are considered to reduce the risk against cancer and cardiovascular diseases (Rao and Agarwal 2000).
The aim of the experiment was to test zinc oxide nanoparticles on larvae *T. molitor*, as potential insecticides, as well as testing phytotoxicity of ZnO NPs on tomato plants. Although *T. molitor* is not a primary tomato pest, it will be used as a model for our research.

Material and Methods

Preparation of Zinc oxide nanoparticle (ZnO NPs) solution:
Solutions of ZnO NPs were prepared by mixing distilled water and stock solution of the commercial ZnO NPs (Houston, USA) at five different concentrations (285 mg/L, 95 mg/L, 40,71 mg/L, 850 mg/L and 2 g/L). The size of the nanoparticles was 20-30 nm. Solutions were sonicated for 10 minutes before use.
Cultivation of tomato (*Solanum lycopersicum* L.) and larvae *Tenebrio molitor*:
Larvae and plants were cultivated separately. Larvae *Tenebrio molitor* were bought in an animal shop and were cultured under laboratory conditions in Petri dishes.
Tomato seeds were sown in Grodan® cubes size 2,5 x 2,5 x 4 cm. After two weeks plants were transferred to flowerpots with soil. Tomato was cultivated in cultivation boxes with the optimal condition. During the experiments, plants and larvae were sprayed three times per week with the aforementioned concentration of nanoparticles.
Preparation of plant samples for analysis:
After lyophilization, 5 mg of each sample was homogenized by homogenizer in 1 mL of 80% methanol. In the case of chlorophylls and carotenoids determination instead of methanol, 96% ethanol was used. Incubation was followed for 1 hour at 55 °C. Each sample was analyzed three times.
Determination of flavonoids:
The total flavonoids were determined by a colourimetric method (Zhishen, Mengcheng et al. 1999). Rutin (RE) was used as the standard. The result was expressed as an equivalent in mg rutin on 1 g of dry weight (DW).
Determination of polyphenols:
The phenolic content was detected by Folin-Ciocalteu assay, based on the reduction of a phosphowolframate – phosphomolybdate complex by phenolic compounds to form blue-coloured products (Koşar, Dorman et al. 2005). Gallic acid (GAE) was used as the standard. The result was expressed as an equivalent in mg/GAE/g DW.
Estimation of total antioxidant capacity (TAC):
The total antioxidant capacity of extracts was investigated by phosphomolybdenum assay, according to the methods published before (Alam, Bristi et al. 2013). Like a standard sample, Trolox was used.
Determination of chlorophylls (a and b) and total carotenoids:
Chlorophylls (a and b) and total carotenoids were measured spectrophotometrically at 470, 649, 665 nm. The extract of each sample (200 μL) was pipetted into the holes of the spectrophotometric plate. Chlorophylls a (C_A) and b (C_B) and carotenoids (C_Z) were calculated as (Hynstova, Sterbova et al. 2018):

C_A – *chlorophyl a* = (13,95 x absorbance 665 nm) – (6,88 x absorbance 649 nm)
C_B – *chlorophyll b* = (24,96 x absorbance 649 nm) - (7,32 x absorbance 665 nm)

$$C_Z - carotenoids = \frac{(\mathbf{1000\ x\ absorbance\ 470\ nm}) - (\mathbf{2{,}05\ x\ CA}) - (\mathbf{114{,}8\ x\ CB})}{\mathbf{245}}$$

Mortality of larvae *Tenebrio molitor*:
Mortality was measured by Henderson-Tilton's formula (Henderson and Tilton 1955).
Statistical analysis:
Each sample had 3 biological repetitions. All data were expressed as a mean of standard deviation. The data were determined by one-way ANOVA variance test followed by T-test at $p < 0.05$.

Results and Discussion

The effects of various ZnO NPs concentrations were monitored in this study. Differences in the synthesis of secondary metabolites in *S. lycopersicum* L. plants were observed by biochemical analyses, but larval mortality was observed with the naked eye. The plants were grown for 5 weeks. Application of ZnO NPs, took place a week with a subsequent one-day pause. Plants treated with the highest concentration of ZnO NPs 2g/L were the highest and had the largest leaves in comparison with other plants treated with smaller concentrations.
Effects of ZnO NPs on chlorophylls and carotenoids content:
ZnO NP showed a slight effect on the overall content of plant pigments in the treated variant compared to the control. Figure 1 (A) shows that the difference between the control sample and the sample treated with 95 mg/L ZnO is statistically significant ($p < 0{,}05$) with estimated concentration for chlorophyll a of 51.45 ± 3.91 and 66.62 ± 2.28, respectively. Other samples did not show a significant difference from control.
Figure 1 (B) shows the overall amount of chlorophyll b. The chlorophyll b concentration increased in the sample treated with 95 mg/L ZnO (27.58 ± 0.97) versus the control sample (20.27 ± 1.54) with a statistic difference ($p < 0{,}01$).
Singh, Singh et al. (2016) observed the effect of Zinc sulphate and ZnO nanoparticle to *Elaeagnus angustifolia*. They concluded that at lower concentrations ZnO NPs had a positive effect on the plant pigments production but the highest concentration resulted in a decrease. Statistically non-significant differences in carotenoid content were observed in all samples, as shown in Figure 1 (C). Similarly, the highest concentration of carotenoid shows a sample of 95 mg/L ZnO NPs compared to the control. Liu, Zabaras et al. (2009) monitored the carotenoid content of tomatoes under the influence of UV-C and found out that the carotenoid content was increased by the ageing of tomatoes and UV radiation. Faizan, Faraz et al. (2018) observed the effect of ZnO on photosynthetic activity, and results show that a concentration of 8 mg/L maximizes photosynthetic activity.

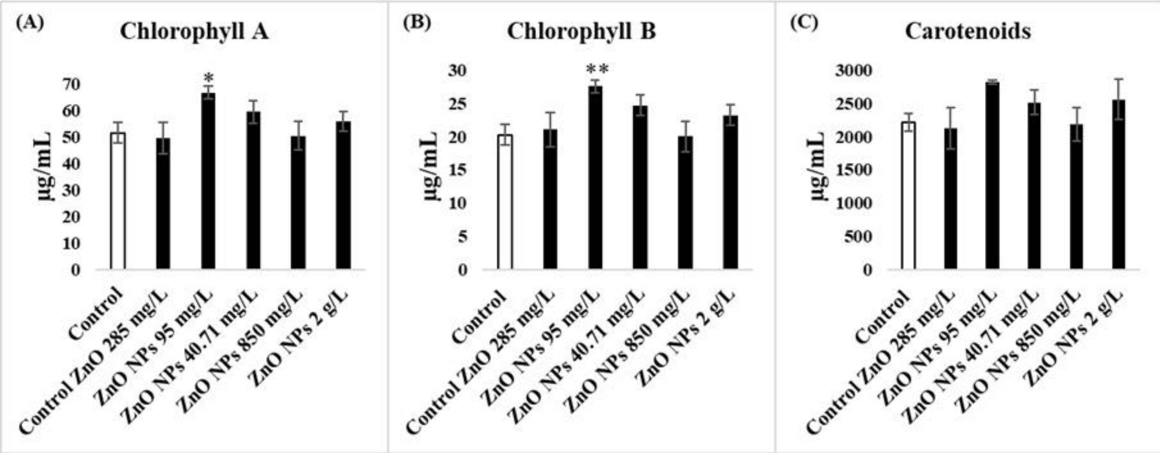

Figure 1 *Plant pigments treated by different concentration of ZnO nanoparticle A) Total chlorophyll a, B) Total chlorophyll b, C) Total carotenoids*

Effects of ZnO NPs on secondary metabolites (flavonoids, polyphenols and total antioxidant capacity):

The total amount of flavonoids, polyphenols and total antioxidant capacity was determined spectrophotometrically. The statistical analysis revealed a decrease in flavonoid content compared to control (Figure 2 (A)).

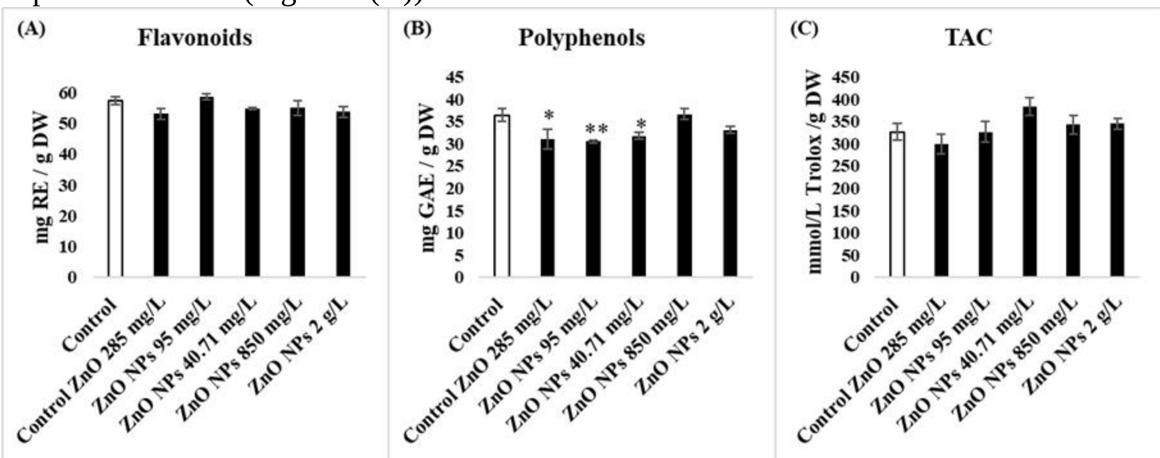

Figure 2 *Plant secondary metabolites by different concentration of ZnO nanoparticle A) Contain flavonoids expressed as mg RE g DW, B) Contain polyphenols expressed as mg GAE g DW, C) Total antioxidant capacity expressed as mmol/L Trolox g DW*

In the case of polyphenols content Figure 2 (B), statistical differences ($p < 0,05$) in polyphenols decreasing were found in the samples 285 mg/L (31.10 ± 2.24) and 40.71 mg/L (31.82 ± 0.80). The decrease was also in the sample of 95 mg/L (30.53 ± 0.41) with statistical differences ($p < 0,01$). Results of total antioxidant capacity were standardized on Trolox and expressed per mmol/L Trolox / g DW. Figure 2 (C) shows the TAC and here is seen that the nanoparticles do not lead to ROS (Reactive oxygen species) formation. Most of the samples had the same values as the control (327.16 ± 19.10). Pinheiro, Alegria et al. (2015) observed the effect of stress factors on the production of phenolic compounds and found out that greater stress leads to the production of secondary metabolites. Stress induces the formation of ROS in plants, which leads to an increase in antioxidant production (Ma, Wallis et al. 2014). Plants synthesize secondary metabolites that function to protect cells from oxidative stress.

Mortality of larvae *Tenebrio molitor*:

Nanoparticles have been successfully tested against a wide range of pathogens such as insects, bacteria and fungi (Benelli 2016). *T.molitor* larvae were used for the experiment because of their easy availability in the shops. They were cultured in laboratory conditions during 120h. During the experiment, larvae were sprayed three times a week with different concentrations of ZnO NPs and then mortality was monitored. During the first 48 hours of ZnO nanoparticles, they did not have any effect on the larvae. This can be explained, that the nanoparticles ZnO are slowly getting to the inside of larvae. The first effect of mortality occurred after 72 h from the first spraying. Total mortality during 120h is shown in Figure 3.

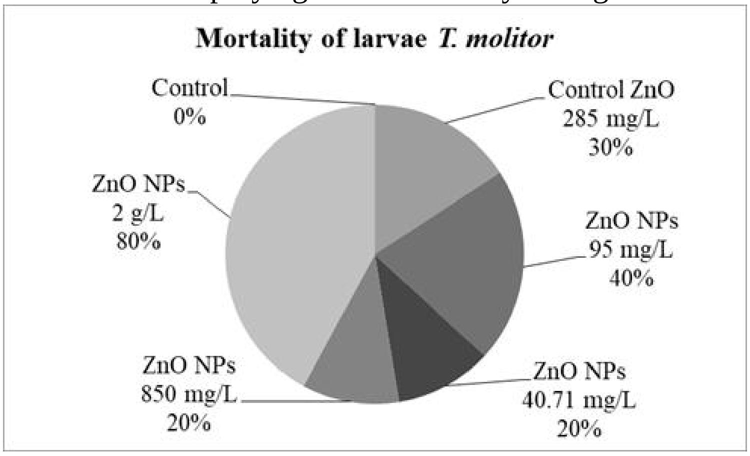

Figure 3 *Mortality of larvae Tenebrio molitor during 120h*

Mortality of the control sample, sprayed with water, during 120 h was 0%. Water was found to have no effect on the larvae, which was expected. The most significant effect had the sample treated by 2 g/L of ZnO NPs, where 80% of larvae died within 120h. Dead larvae had very dry skin, probably because of dehydration caused by the treatment with nanoparticles. Chakravarthy, Kandakoor et al. (2012) reported the inorganic silver nanoparticles and TiO_2 against *Spodoptera litura* Fab. under laboratory conditions had an insecticidal effect. Silica nanoparticles are equally effective and exhibit dose-dependent insecticidal activity. Insect dead bodies have been found to be extremely dehydrated and killed all *S. litura* larvae (Debnath, Mitra et al. 2012).

Conclusion

Nanotechnology is the emerging technology which found its wide application in the field of agriculture. ZnO NPs are gaining attention as pesticides and fertilizers because they are able to supply needed nutrients for the plant and also to protect the plant from the harmful pests. Further experiments, based on the use of nanoparticles will be performed and their efficiency toward different tomato pests will be explored.

Abstract

The main aim of this paper is to start the discussion about the potential antioxidant activities of oil extracts and oils from various vegetable raw materials. Many publications reported that the seed oils and essential oils possess the high antioxidant activities. In our opinion it is not so. We want to share the results of own investigations and our view at this topic. We tested: a) oils extracts from seeds of apricot, grape, peach, pumpkin, fenugreek, white bryony, sea buckthorn and rosehip; b) walnut oils (eight samples of oil); c) essential oils from needles of juniper and pine. Antioxidant activities of oils and oil extracts were appreciated by two spectrophotometric methods: method based on model oxidation reaction of N,-diphenyl-n-phenylenediamine by azo-bis-(isobutyronitrile) as the initiator of free radicals; and procedure of DPPH free radicals scavenging. Trolox was used as standard antioxidant. Tested oil extracts from seeds did not show antioxidant capacities; on the contrary, they took part in reaction enhancing of free radical oxidation. Walnut oils demonstrated a neutral effect against free radicals. They did not enhance and did not reduce oxidative processes. Thus, the antioxidant capacities of walnut oils also were not identified. Freshly obtained essential oils from needles of juniper and pine possessed the antioxidant activity, which decreased by 2-8 times during one mount of storage. The oil extracts, vegetable and essential oils have others nutritional values and should not be considered as antioxidant. Moreover, to extend shelf-life they need to be fortified by antioxidants.

Keywords: *oil extract, vegetable, essential oil, antioxidant activity*

Introduction

Vegetable oils are valuable sources of high-calorie fats and essential fatty acids, phospholipids, carotenoids and other physiologically active components. Many publications reported that the seed oils and essential oils possess the high antioxidant activities (Poiana et al., 2009; Xie et al., 2015; Jorge et al., 2016; Akbari et al., 2018; Shinagawa et al., 2018). Taking into account the beneficial effects of antioxidants on human health, many researchers and manufacturers endeavour to find the high antioxidant activity of vegetable oils. In this regard, in 2007, the Armenian company Hagenas LLC asked us to study the antioxidant properties of oil extracts from various seeds, which were intended for sport nutrition. The results of these investigations were not so positive as to be shared in a wide public publications or commercial promotion. That is why we can write about it just now. Subsequent testing of other vegetable oils allowed us to confirm that the quality of the vegetable oils should not be focused on its antioxidant activity. Some authors, describing the qualitative parameters of cold-pressed oils from vegetable seeds, studied the antioxidant activity of methanolic extracts from the corresponding seeds, but no these oils (Kulaitiene et al., 2018), which is not the same thing. The purpose of this paper is to start the discussion about the potential antioxidant activities of oil extracts and oils from various vegetable raw materials based on our comparative researches.

Materials and methods

The oil extracts from seeds of apricot, grape, peach, pumpkin, fenugreek, white bryony, sea buckthorn and rosehip were produced by HAGENAS LLC (Yerevan, Armenia); and were stored during one year at 20±2ºC. In plus the samples of grape seed oils and beta-carotene oil solution were purchased from Moldovan markets.

The walnut oil samples were obtained by cold pressing using an electrical press (Model PSU-125) in laboratory of the Technical University of Moldova. Tatarov & Popovici (2014) described the general scheme of procedure for walnut oil extraction. The eight samples of walnut oil obtained in different times were tested.

The essential oils from needles of *Juniperus sabina* (juniper), *Pinus sylvestris* (scots pine) and *Pinus nigra* (black pine) were extracted by hidrodistillation using Ginsberg method. (Rassem et al., 2016) in laboratory of Institute of Genetics. Physiology and Plant Protection.

The chemicals: ethanol, N,-diphenyl-n-phenylenediamine, azo-bis-(isobutyronitrile), 2,2-diphenyl-1-picrylhydrazyl, trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) of HPLC, spectrophotometric or analytical grade were supplied by Sigma-Aldrich.

Spectrophotometric methods for antioxidant activity determination of oils and oil extracts were used. One of them, the method that was proposed for standardization of individual and complex herbal remedies, including hydrophobic ones (Dadali &Dadali, 2015). The essence of the method consists in applying a model oxidation reaction of N,-diphenyl-n-phenylenediamine (DPPD) dissolved in dimethylformamide (DFA). Azo-bis (isobutyronitrile) was used as the initiator of free radical oxidation of DPPD. The result of the oxidation reaction is the formation of N, N-diphenyl-n-benzoquinone-diimine (DPBQD), which has a stable chemical structure and could be quantified at 450 nm. The reaction was carried out at a temperature of 60°C for 4-5 hours. Other method was widely reported procedure that based on scavenging of 2,2-diphenyl-1-picrylhydrazyl (DPPH) free radicals (Clarke et al., 2013) with absorption at 515 nm. Trolox was used as standard antioxidant substance and antioxidant activity was expressed in trolox equivalent (TE).

***The statistical analysis** of the results was carried out by EXCEL software. All assays were performed at least by triplicate.*

Results and discussion

During 4-5 hours of the reaction for oxidation of DPPD free radicals, the DPBQD formation and accumulation had the greatest approximation according the Beer-Lambert's law (R^2=0.951-0.998). The linear dependence of DPBQD absorbance on time, that very evident is shown in fig.1, allowed us to recalculate its content. The amount of accumulated DPBQD in reaction with tested samples was compared with amount of DPBQD accumulated in reaction without antioxidants (control). Thus, using the curves of absorbance the antioxidant activity of standard substance - trolox (fig.1a) and beta-carotene (fig. 1b) was calculated. The freshly prepared solution of trolox in concentration of 0.39 mg/ml inhibited 75–80% of free radicals, while the oil solution of beta-carotene in concentration of 0.01% scavenged only 5-10% of free radicals.

As shown in fig.1 the accumulation of DPBQD in reaction with Armenian oil extracts from grape (fig.1a) and fenugreek (fig.1b) seeds was proceeded at an increased rate. The tested oil extracts contributed to a greater accumulation of DPBQD or, in other words, they increased the number of free radicals involved in the reaction as an initiator of free radical oxidation. According our results, the oil extracts of fenugreek and grape seed enhanced of the reaction of free radical oxidation of DPPD to DPBQD by 3.6 and 2.4 times, respectively. Akbari with coauthors (2018) reported that the fenugreek seed oil possesses the high antioxidant activity. Index of antioxidant activity IC_{50} (concentration that inhibit 50% of free radicals) determined by DPPH radical scavenging procedure was equal to 172.6±3.1 μg/ml (Akbari et al., 2018).

This fact can be explained by excellent prevention of powdered seeds and extracted oil from air and light oxidation before determination of antioxidant activity. Moreover, the oil extraction was performed so that the polyphenolic content of oil (38.97±0.34 mgGAE/g) was analogic to water-ethanolic extracts of fenugreek seed (Melikyan et al., 2008). It is known (Kulaitiene et al., 2018) that antioxidant activity directly depends on the content of polyphenols in vegetable extracts, but it is necessary to indicate that these substances are soluble in water (no fat soluble).
Many authors (Shi et al., 2003; Ivanova & Casian, 2008; Ross et al., 2011) described the rich content of polyphenols in grape seeds. However, the property of grape seed oils to exhibit the antioxidant activity (from 53.41 to 205.52µM TE/100g) was saved through maintaining the samples at temperature -20°C into amber glass bottles and under nitrogen gas (Shinagawa et al., 2018). The highest values of antioxidant activity and polyphenols amount were obtained foe the fresh unrefined grape seed oil (Poiana et al., 2009). The pumpkin seed and orange seed oils after extraction were also stored under nitrogen gas at -18°C and oils with liquid nitrogen were analyzed (Jorge et al., 2016; Kulaitiene et al., 2018), which is not quite suitable for public markets.

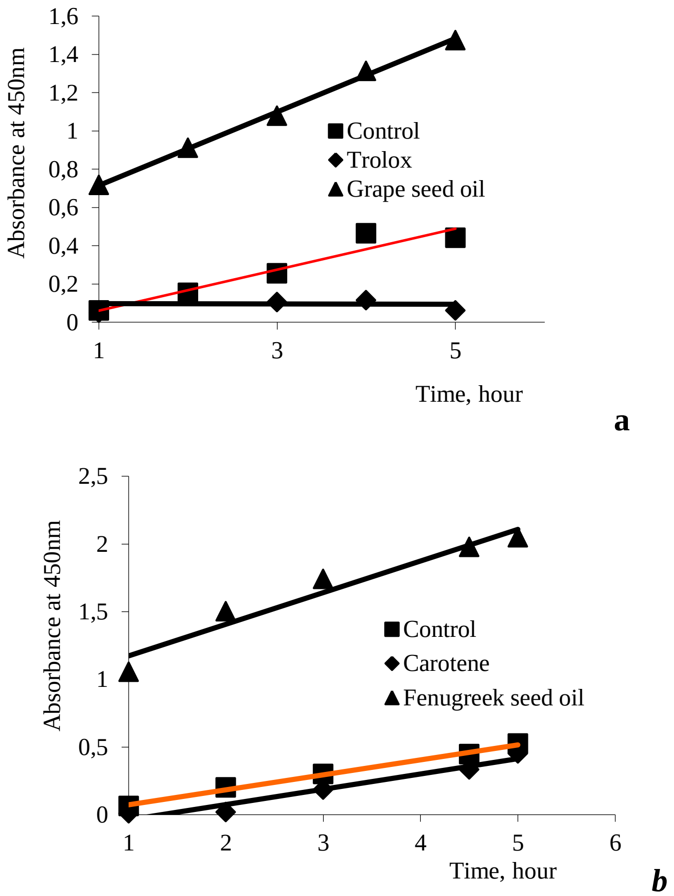

Figure 1. Dependences of DPBQD absorbance on time in reactions without antioxidant (control), with antioxidant trolox (a) and in presence of oil extracts: carotene (b), Armenian grape (a) and fenugreek seeds (b).

The other tested by us oil extracts from seeds also exhibited no antioxidant properties. Taking into account their capacities to increase the reaction of free radical oxidation (an increase by calculated % compared to control) the oil extracts from seeds can be represented by the following sequence: fenugreek (363%) > grape (Armenia) (238%) > white bryony (229%) >

sea buckthorn (138%) > rosehip (136%) > pumpkin (97%) > peach (65%) > grape (Moldova) (39%) > apricot (25%). Thus, the studied oil extracts from various seeds took part in the reaction and contributed to the enhancement of free radical oxidation of the reaction components.
The presence of walnut oils (it were tested eight samples of oil) in the reaction mixture did not significantly increase or decrease the oxidation processes (fig.2). Three samples showed the radical scavenging activity equal to 7.14-13.39%, two samples increased the content of oxidation products by 14.29-16.07%, and three samples practically did not differ from the control (0.89-1.79%). This fact indicated that the presence of walnut oil does not interfere with the normal course of the reaction. Since the values of radical scavenging activities, constituting less than 20% in this method are not statistically significant, it can be argued that walnut oils do not exhibit antioxidant activity. Therefore, it was showed, that these oils were unstable during the storage (Tatarov et al., 2017), and to increase their shelf life they needed to be fortified with some antioxidant ingredients.

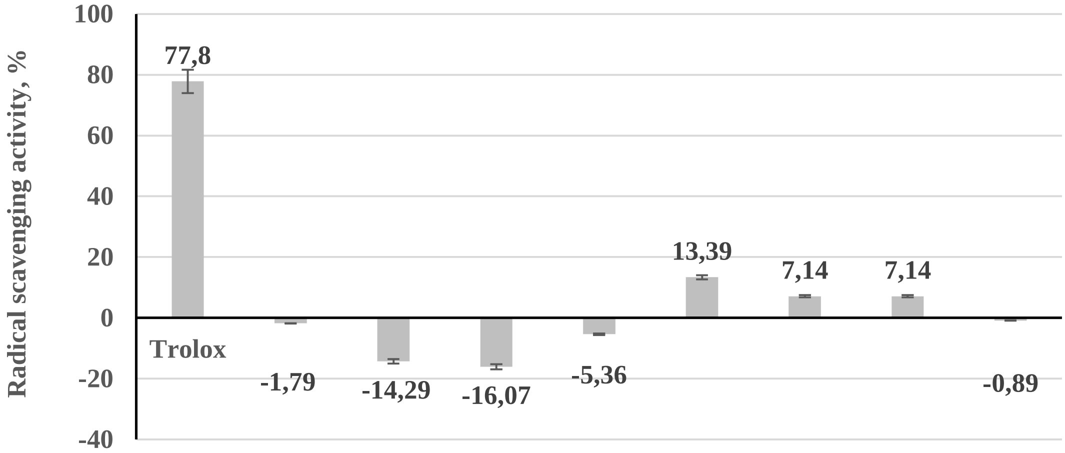

Figure 2. Radical scavenging activity (%) of trolox and various samples of walnut oil (total 8) determined by DPBQD method

It necessary to mention, that the main components of chemical composition of vegetable oils are saturated and unsaturated fatty acids, which easily are exposed to oxygen oxidation and according their chemical structures could not act as antioxidant. Protection against oxidation of oils is achieved by the action of antioxidants both natural (γ-tocopherol, β-carotene, lycopene) and synthetic (butylated hydroxytoluene), which are soluble in lipids. Influences of γ-tocopherol content on resistance during storage of vegetable oils were reported (Guseva et al., 2010; Radvzievska & Melnik, 2016). Moreover, the dependences of antioxidant activity values on total content of antioxidants (γ-tocopherol and carotenoids) are the extreme character and can be described by the function of the standard normal distribution. Because of that, the maximal antioxidant activity demonstrates only in certain concentration intervals of antioxidant substances contained in vegetable oils (Lobaeva et al., 2004).
Index of antioxidant activity IC_{50} for trolox determined by DPPH method was equal 140.02±0.24μg/ml. The essential oils from needles of juniper, scots and black pine collected in different areas of Slovak Republic (SR) and Republic of Moldova (RM) possessed the antioxidant activity. The antioxidant activities of tested essential oils expressed in trolox equivalent (mgTE/g) were equal to: 1.79±0.08 for *Juniperus sabina* (SR), 1.57±0.07 for *Juniperus sabina* (RM), 1.20±0.03 for *Pinus sylvestris* (RM); 1.63±0.02 for *Pinus nigra* (RM).

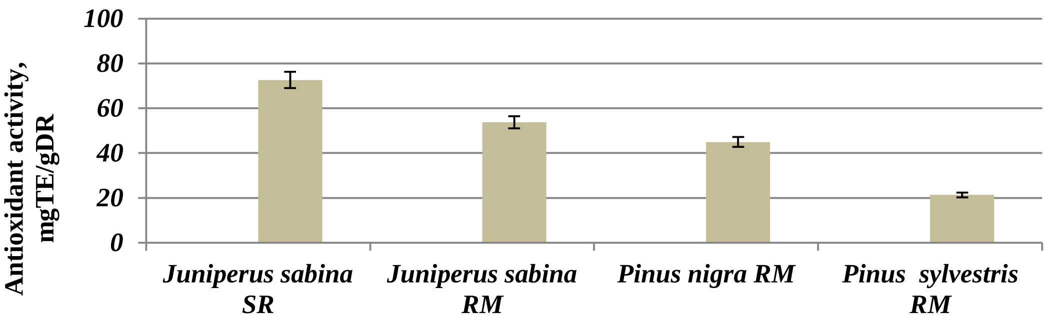

Figure 3. Antioxidant activity in trolox equivalent of water-ethanolic extracts from needles of juniper and pine determined by DPPH method

The essential oils from needles of six China endemic Pinus taxa exhibited antioxidant activity, which authors name as “acceptable” (Xie et al., 2015). However, they reported that antioxidant activities of pine oils were lower than some popular plant species such as Camellia sinensis and Oenocarpus bacaba. Low antioxidant activity of essential oils from different parts of Juniperus spp. was been explicated by specific constituents of the oil, which can be inactive in DPPH test, and the trace amounts of compounds that act as antioxidants (Emami et al., 2010). Samusenko A.L. (2011) concluded that the antioxidant activity of essential oils in a complex way depends on oils constituents, concentration and ratio between the most active components.

In our experiments, the trolox equivalents of essential oils were 17-40 times less than analogical indexes of water-ethanolic extracts from the same vegetal materials (fig. 3). It should be to mention that the storage of essential oils during one mount led to decreasing 2-8 times of their antioxidant activity. Due to the high content of no antioxidant biologically active constituents (for example α－pinene), the juniper essential oil, as natural product, has a perspective in ecological agriculture as insecticide against harmful insect species ((Elisovetcaia & Brindza, 2018) in medicine as a potential anti-tumor drug, in food and cosmetic industries as donor of aroma and odour (Salamon & Petruska, 2017).

Conclusion

The high nutritional and biological value of vegetable oil extracts and essential oils is due to the content of biologically active components, such as polyunsaturated essential fatty acids, terpenes etc., which do not act as antioxidants. Some vegetable oil extracts contain fat-soluble antioxidant compounds (tocopherols, carotenoids) which are useful and at the same time consumed to prevent oils from oxidation. Because of this, many long-stored vegetable oils lose or do not possess antioxidant capacity. To extend the shelf life of vegetable oils, they must be enriched with fat-soluble antioxidants in concentrations and ratio determined for the predicted shelf life

HAZARDS RELATED TO FOOD SAFETY

Yasin AKKEMİK*

Department of Food Processing, Karapınar Aydoğanlar Vocational School, Selçuk University, Konya, Turkey
*Corresponding author: yasinakkemik@selcuk.edu.tr

Abstract

Today, it is clear that the concept of food production and food safety must be dealt with together. It is not possible to talk about a commercial success when food safety is not applied. Reliable food cannot be obtained at all stages of production unless necessary control measures are taken. In this case, public health hazards can enter the food chain from many different points and may adversely affect production. Therefore, the entry point or points of each hazard should be determined and necessary precautions should be taken at these points. Contagion occurring at one point in the food chain also affects the next stage of production. Thus, even if the other steps of the food chain are successful, the result is negative. What is the concept of food chain, which has an important place in food safety? 'Farm to table' 'or' 'from field to fork' expressed in the food chain until it covers all the processes available to consumers, starting from primary production. Chemical contaminants (industrial residues, remnants of pesticides, remnants of veterinary drugs), biological agents (bacteria, viruses, parasites) and physical contaminants (nails, glass pieces, stones, bristles, etc.) effect chain process negatively. It impairs food safety and endangers public health. In this review article, it is aimed to give information about the physical, chemical and biological hazards that threaten food safety.

Keywords: *Food Safety, Public Health, Physical Hazards, Chemical Hazards, Biological Hazards.*

İntroduction

Food safety hazards are a preventable public health problem that cause foodborne diseases. Because of these hazards, diseases and deaths occur every year around the world. Food safety hazards are classified as chemical, biological and physical hazards. Food-borne diseases occur as a result of consuming foods that contain these hazards. In excess of 250 distinct kinds of infections, microbes, parasites, poisons, metals and prions are related with foodborne diseases in people. In spite of the fact that infections are in charge of over half of foodborne maladies, hospitalizations and passings are normally brought about by bacterial specialists. Indications shift from gentle gastroenteritis to perilous neurological, hepatic and renal disorders (Nyenje & Ndip, 2013). Albeit a large portion of the foodborne diseases cases are mellow and constrained in zones, genuine cases can result in high mortality and morbidity in unsafe gatherings. High hazard bunches for foodborne ailments incorporate babies, youngsters, the old and immunosuppressed people. The battle against sanitation risks is tested by the globalization of the nourishment advertise, environmental change, and the adjustment in human utilization, for example, the decision of new and negligibly prepared sustenances (Schelin *et al*., 2011). Food safety hazards negatively affect general wellbeing and the national economy. Food safety hazards and associated outbreaks can lead to the closure of food outlets or the food industry, resulting in job loss for employees. Thus, individuals and communities can be adversely affected. Local foodborne diseases episodes can turn into a worldwide danger. Foodborne diseases flare-ups are as often as possible revealed at national and universal level, underlining the significance of sanitation (WHO, 2011). The most evident food safety hazards are protozoa, viruses and bacteria. Other food safety hazards incorporate compound chemical residues and physical contaminants. Elements that assume a job in the study of disease transmission of rising foodborne issues incorporate changes in pathogens, advancement, urbanization and new ways of life, issues in wellbeing frameworks, existing learning, convictions and practices, statistic structure, travel and movement, sustenance and creature exchange, neediness and contamination (Magkos *et al*., 2006). Foodborne problems are likely to become even more important in the coming years.

Biological Contaminantions

Bacteria

Numerous normal instances of the runs are brought about by bacterial diseases brought about by ingestion of contaminated food. Aversion of these illnesses should concentrate on great individual cleanliness by all food processors (food chain), including the sustenance buyer. Some bacterial illnesses, for example, Bacillus anthracis, bovine tuberculosis and brucellosis, are especially identified with animal foods. (Bari & Yeasmin, 2018). Some bacterial agents related to food safety hazards are described below.

Escherichia coli O157 is a pathogenic microorganism called enterohemorrhagic *E. coli* (EHEC). This microorganism produces toxins known as verotoxins. Dairy cattle are the principal reservoir. Contamination to humans occurs with consumption of crude or half-cooked meat items and contaminated foods such as raw milk. Freshly squeezed apple juice, yogurt, cheese, salad and cooked corn are shown as a wellspring of contamination. Fecal contamination of water and food, cross-contamination during food processing, person-to-person contact can lead to infections. Symptoms include bloody and non-bloody diarrhea. It additionally causes chronic difficulties, for example, hemolytic uremic syndrome (Ferens & Hovde, 2011).

Listeria monocytogenes have been isolated from a variety of environments such as rotting vegetation, soil, animal feed, sewage and water. Impervious to various ecological conditions. It can develop at low temperatures up to 3 ° C. Milk and cheese can be found in a wide assortment of crude and handled foods such as meat (including poultry) and meat products, seafood and fish products. Even in storage conditions, it can survive and survive (Ajayeoba *et al*., 2016). L. monocytogenes is in charge of contaminations of immunocompromised individuals, including pregnant ladies, babies and the older. Initially, it causes meningitis, encephalitis or septicemia. At the point when pregnant ladies are tainted, they can cause premature birth, stillbirth or preterm labor (Bari & Yeasmin, 2018).

Most sporadic diseases with *Campylobacter jejuni* are related with the utilization of defiled poultry. Some *C. jejuni* episodes are related with crude milk or chlorine-free water utilization. Campylobacteriosis can prompt Guillain-Barré disorder, a reason for pendulous loss of motion (McCarthy & Giesecke, 2001). Poultry, cattle, pigs, sheep, rodents and birds are reservoirs of *C. Jejuni* (Whiley *et al*., 2013).

Viruses

Fecal-oral diseases can sully people from tainted foods. Foodborne viral contaminations for the most part have a brooding time of 1 to 3 days. They cause self-restricting sicknesses in people (that is, they recuperate normally), yet extreme diseases and even passings can once in a while happen. Rotavirus is a typical reason for spewing and watery looseness of the bowels in the gathering of viral diseases that reason viral gastroenteritis (VGE). Lack of hydration is a conceivable result except if proper rehydration treatment is utilized (Bari & Yeasmin, 2018). Some viral agents related to food safety hazards are described below.

Viral hepatitis brought about by hepatitis A and E infections is transmitted by the fecal-oral course. Hepatitis A differs from other viral agents due to its long-term incubation period (2-6 weeks), its capacity to spread to the liver outside the stomach and digestive organs. It usually causes jaundice. It can sometimes cause chronic liver dysfunction. Hepatitis E infection

(HEV) more often than not enters the body with crude shellfish polluted with water or foods, particularly waste water (van der Venter, 2000).
Noroviruses are a gathering of infections that reason "stomach influenza" or gastroenteritis in people. Most foodborne norovirus infections have been related with direct pollution of food by a sustenance processor just before utilization (Achson *et al*., 2002). Noroviruses are found in feces or vomits of infected persons. It is transmitted to people when expending foodpolluted with norovirus, contacting surfaces or items tainted with norovirus, and after that carrying the hands to the mouth, direct contact with someone else who is contaminated and symptomatic. Noroviruses can make due on practically any surface, including entryway handles, sinks, handrails and dishes. It is progressively regular in winter and influences all age gatherings (Bari & Yeasmin, 2018).
Rotavirus is a noteworthy reason for extreme looseness of the bowels (gastroenteritis) in youngsters, particularly in creating nations. Approximately 95% of children develop infection until the age of 5 (Festini *et al*., 2010). It is estimated that around 600,000 children die annually worldwide due to rotavirus infection. Mortality rates are high in India, Nigeria, China, Pakistan, Congo, Ethiopia and Bangladesh (Bernstein, 2009). Rotavirus infection is clinically more important in children, usually between the ages of 3-35 months, and the first infection is the most severe. Rotaviruses are exceedingly infectious and are frequently transmitted by the fecal-oral course. Since the infection is steady in the earth, disease may happen by individual to-individual contact or by contact with food, water and sullied surfaces. Rotavirus disease is believed to be restricted to the gastrointestinal tract. However, rotavirus has also been reported in nasopharyngeal secretions (Azevedo *et al*., 2005).

Parasites

There are three primary classes of parasites that can cause infection in people. These include protozoa, helminths and ectoparasites (Bari & Yeasmin, 2018). Some parasitic agents related to food safety hazards are described below.
Toxoplasma gondii is delegated protozoa and its essential hosts are felines. Human infection occurs in contact with cat feces. What's more, rodents can be delivered by crude or half-cooked meat from meat from middle has, for example, pigs, dairy cattle, goats, chickens and feathered creatures. Toxoplasmosis in people for the most part creates mononucleosis-type manifestations, yet buttran-splacental disease can cause fetal passing on the off chance that it happens from the get-go in pregnancy. In immunocompromised people, contamination may cause pneumonia, myocarditis, meningoencephalitis, hepatitis, chorioretinitis, or mixes thereof. Cerebral toxoplasmosis is every now and again found in AIDS patients (van der Venter, 2000).
Taenia Saginata (Bovine tapeworm) is a helminth that is a causative agent of tapeworm disease (Gebrie & Engdaw, 2015). Youthful types of tapeworm are found on infected herbs. When these herbs are consumed by the animals, the eggs contaminate the animals and tapeworms develop in the muscles of the animals. People become contaminated when they eat crude or half-cooked meat. Grown-up tapeworms create in the small digestive system of humans, and parts of tapeworms containing eggs are transmitted to the environment by human feces. The cycle continues in this way (Qekwana *et al*., 2016).

Chemical Contaminantions

Chemical contaminants can be found in buildups of pesticides and veterinary drugs, defilement from natural sources (water, air or soil contamination), cross sullying or pollution during food handling, relocation from bundling material to food and/or utilization of unapproved food additiv (Bari & Yeasmin, 2018).

Pesticide Residues

The utilization of pesticides, for example, bug sprays, fungicides and herbicides has turned into an essential piece of present day horticulture to improve harvest yield and quality by controlling different vermin, infections and weeds (Maksymiv, 2015). The enlistment of new pesticides is a carefully controlled procedure that evaluates their poisonous quality and ecological effect and decides the most extreme remaining points of confinement (resiliences) in crude and/or prepared items (Damalas & Eleftherohorinos, 2011). There are more than 1400 pesticides known. Some of them should not be used because they threaten public health. Some should be used within certain limits. Older pesticides should be reassessed based on available scientific data (Bari & Yeasmin, 2018).

Veterinary Drug Residues

Veterinary drugs are synthetic substances that have experienced an extensive enrollment procedure bringing about the change of greatest buildup limits/resiliences in sustenance of creature root. Significant classes of veterinary medications incorporate anti-infection agents, anthelmintics, coccidiostats, nonsteroidal calming drugs, tranquilizers, corticosteroids, beta-agonists and anabolic hormones. These medications directed to live creatures may stay as buildups in creature tissues (Bari & Yeasmin, 2018). Liver and kidney natural capacities are touchy to the remaining parts. A few anti-infection agents, for example, penicillin, can cause serious unfavorably susceptible responses in delicate people. This is a significant explanation behind deciding buildup restricts in creature determined food. Another significant purpose behind constraining the utilization of anti-infection agents in creatures utilized in food generation is to decrease the danger of pathogenic microorganisms being impervious to anti-microbials. Most veterinary prescriptions don't have intense toxicological concerns, yet a few substances, for example, nitrofurans, chloramphenicol, clenbuterol and diethylstilbestrol are restricted in numerous nations since they are cancer-causing (Mohsina, 2011).

Environmental Residues

Synthetic substances, for example, dioxins, chlorinated biphenyls, furans and overwhelming metals can contaminate the earth because of modern exercises (Kataria *et al.*, 2015). From nature, these synthetic substances can enter the evolved way of life through plants or creatures and cause different medical issues. These are viewed as issues that emerge in nations that are in the beginning times of industrialization. Instances of natural contaminants entering the evolved way of life incorporate overwhelming metals, polychlorinated biphenyls (PCBs), "dioxins" (polychlorinated-dibenzo-dioxins and dibenzofurans), tireless chlorinated pesticides (eg, DDT, aldrin, dieldrin, heptalor, mirex, chlorine).), brominated fire retardants (particularly poly-brominated-diphenyl ethers), polyfluorinated mixes, polycyclic fragrant hydrocarbons (PAHs), perchlorate, pharmaceutical and individual consideration items or haloacetic acids (Bari & Yeasmin, 2018).

Physical Contamination

Physical hazards are defined as all kinds of foreign substances that are undesirable in food (glass pieces, plastic, bone, paper, stone, soil, wood, metal pieces, hair, nails, cigarette ash, flies, insects, radioactivity and visible dirt). Physical hazards arise from faulty and incomplete applications applied at many points of the food chain during production, consumption. In addition, these dangers bring microbiological risks in some cases, give an idea that food is not produced under hygienic conditions, affect consumer choice and may cause public health problems (Aydınol *et al.*, 2015).

Conclusions

Sanitation risks may cause maladies that reason indications, for example, sickness, spewing and diarrhea. Be that as it may, it can likewise cause infections, for example, malignancy, renal or hepatic inadequacy, cerebrum and nerve issue. These ailments might be increasingly genuine in youngsters, pregnant women, the old and those with feeble invulnerable frameworks. Be that as it may, expanding foodborne episodes represent a worldwide risk to power and raise the requirement for further work to avert foodborne illnesses.

As sanitation is a typical duty of all partners all through the evolved way of life, there is a significant requirement for instruction and preparing in the aversion of foodborne illnesses among sustenance producers, providers, chiefs and general society. What's more, all through the natural way of life, all partners need to work intimately with governments to help distinguish and actualize sanitation procedures and strategies that will give safe sustenance to the total populace.

Abstract

In our intestines, only digestion and absorption is not realized. Furthermore, the microbial activity required for a healthy life is carried out by microorganisms in our gut. There are 10^{14} microorganisms of more than 500 different species in the gastrointestinal tract. In determining the composition of these microorganisms, the place of probiotics is very important. Microorganisms used as probiotics; *Lactobasillus* species, *Bifidobacterium* species, *Bacillus* species, *Pediococcus* species, *Streptococcus* species, *Bacteriodes* species, *Propionibacterium* species, *Leuconostoc* species, some molds and yeasts. The most commonly used microorganisms among these microorganisms are *Lactobasillus* species and *Bifidobacterium* species. These microorganisms were selected and characteristics such as being reliable, stable, colonizing the intestines, competing with carcinogenic and pathogenic bacteria, producing antimicrobial bacteria, being able to produce resistance to diseases, being resistant to antibiotics, staying alive and stable in storage conditions for a long time heve been studied. This review article aims to give information about the positive effects of probiotics on public health.

Keywords: *Probiotics, Public Health, Microorganisms*

İntroduction

Useful microorganisms in the body play an important role in adapting to human life and environment. The relationships between body cells and microorganisms have made human beings dependent on a wide variety of microorganisms. Factors that disrupt this relationship can damage the human body and cause various disorders. With modern life, the relationship between mammalian cells and microorganisms has weakened, and less common diseases have become more common in the past. Probiotics contribute to the prevention of diseases by strengthening this weakened relationship. Probiotics are useful microorganisms that, when taken orally, in sufficient amounts reach the digestive system and affect one's health in a positive way. These microorganisms affect the health of the person by regulating the balance in the intestinal flora. The word "probiotic" is derived from the Greek word için for life. Foods that contain enough live probiotic microorganisms (108cfu / g) until the end of their shelf life are called probiotic foods. In line with these expressions, a significant number of microorganisms were isolated and classified as probiotic. Some of these probiotics have been tested in humans and animals for the purpose of treating or preventing various diseases, disorders and syndromes. There are various strains of microscopic organisms that have probiotic properties in all microorganisms named probiotics. For instance, 23 unique strains in *Lactobacillus* are in the probiotic class, while in *Bifidobacterium* this number is 5, in *E. coli* 2, *Bacillus*, *Streptococcus*, *Enterococcus* and *Lactococcus* this number is one. Moreover, there is *Saccharomyces boulardii* yeast with probiotic properties (Goldin, 2011).

Probiotics and Public Health

Lactose Intolerance

The sickness happens because of the abatement in the movement of the lactase compound in the intestinal mucosa. This diminishing in movement results in a decrease in lactose ingestion. This is brought about by inadequate assimilation, gas, swelling, stomach spasms and moderate or serious loose bowels. The ailment is increasingly regular in the old. The utilization of dairy items, particularly milk, by wiped out individuals is confined. A few examinations have demonstrated that the lactase chemical delivered during yogurt creation is powerful in the intestinal tract alongside yogurt utilization (de Vrese *et al*., 2001; Kim & Gilliland, 1983; Kolars *et al*., 1984; Savaiano *et al*., 1984). Living beings utilized for the generation of yogurt *Lactobacillus delbrueckii* subsp. bulgaricus and *Streptococcus thermophilus*. A portion of the patients with lactose narrow mindedness were nourished with yogurt and some of them were given milk. There was a critical decline in hydrogen levels in the breath of yogurt-encouraged patients. The degree of hydrogen in breath mirrors the intestinal microflora digestion of non-absorbable lactose in the small digestive system and is along these lines found in the colon where the microflora is available in high fixations (Kim & Gilliland, 1983). In another investigation, it was accounted for that individuals taking 18 g of lactose in yogurt had 67% less hydrogen in their breath contrasted with a similar portion of lactose given in milk (Kolars *et al*., 1984). An examination of intestinal duodenal desires from yogurt-expending subjects demonstrated huge degrees of lactase in the duodenum. In 2005, it was presumed that probiotics were not successful in the treatment of lactose prejudice (Levri *et al*., 2005). Notwithstanding, a few scientists have contended this might be because of the sort or nature of probiotics utilized in treatment. For instance, lactobacilli with low lactase levels can be possibly jumbling. The strains chose for the creation of yogurt must have the elevated amounts of lactase required for the proficient arrangement of yoğurt (Goldin, 2011).

Inflammatory Bowel Disease

Inflammatory Bowel Disease (IBD) is an articulation utilized for intestinal irritation. This classification incorporates Crohn's illness, ulcerative colitis and peevish inside disorder. Probiotics have noteworthy potential in IBD treatment and avoidance of repeats. There are a set number of concentrates on the advantageous impacts of probiotics in the treatment or easing of IBD side effects. Probiotics have been accounted for to help alleviate manifestations in Crohnis sickness from E. Coli (Malchow, 1997). The expansion of Lactobacillus salivarius to drain and organization to interleukin (IL) - 10 knockout mice fundamentally decreased aggravation in the secum and colon contrasted with milk nourished knockout mice (O'Mahony *et al*., 2001). It is a calming cytokine that causes colonic irritation when IL-10 level is practically zero. This investigation showed that probiotics can influence the colonic invulnerable framework and forestall low IL-10 levels. In another investigation, L. salivarius and Bifidobacterium longum subsp. IL-10 knockout mice treated with the mix of infantis have been accounted for to cause an abatement in sickness seriousness. The seriousness of the illness was surveyed over a 6-week time frame with weight reduction, colon pathology, and outward presentation (McCarthy *et al*., 2003).

Cholesterol Lowering Effect

A few examinations have announced that probiotics lessen complete serum cholesterol and/or low thickness lipoprotein (LDL) cholesterol. The outcomes are dubious and frequently conflicting. Bringing down LDL cholesterol will effectsly affect diminishing the danger of coronary artery infection and lethal myocardial dead tissue. Because of human investigations which affect plasma cholesterol levels in fermenteddairy items, it has been accounted for that absolute cholesterol diminished between 5.4-23.2% and LDL diminished between 9-9.8% (Anderson & Gilliland, 1999). Yogurt with typical and L. acidophilus and B. animalis subsp lactis was tried to analyze serum total cholesterol in a randomized hybrid gathering of 14 individuals, including a 6-week nourishing period and a 4-week washout period. There was a huge lessening in total cholesterol levels in yogurt with L. acidophilus and B. animalis subsp lactis (Ataie-Jafari *et al*., 2009). Scarcely any subjects took an interest in cholesterol contemplates and the term was commonly constrained to about a month and a half. In view of in vitro and creature thinks about, a few systems have been proposed to decrease serum cholesterol by probiotics. These are the ingestion or absorption of cholesterol by probiotics (Walker & Gilliland, 1993).

Treatment of Urogenital Infections

Vaginal contaminations are brought about by operators, for example, *Candida*, *Trichomonas*, or microorganisms, for example, *Gardnerella vaginalis* and *Mycoplasma hominis*. Urinary tract contaminations are increasingly regular in ladies. These diseases are generally brought about by *E. coli*, *Chlamydia* and *Candida*. Ordinary sound ladies have around 50 unique sorts of microorganisms in the vaginal verdure. In an investigation of 10 pre-menopausal ladies, intravaginal lactobacilli were regulated to ladies and a lessening in urinary tract contaminations was accounted for (Goldin, 2011). Yogurt containing *L. acidophilus* has been accounted for to diminish *Candida*-inferred vaginitis triple (Hilton *et al*., 1992). Concentrates on the treatment and/or counteractive action of urogenital diseases with probiotics are exceptionally restricted. In any case, there are specialists attempting to plan explicit probiotics to be managed orally to anticipate or decrease the rate of urogenital contaminations.

Cancer Treatment and Prevention with Probiotics

Because of their metabolic movement, probiotics may impact the etiology of colon malignant growth and tumors in different areas. Probiotics have been accounted for to diminish intestinal bacterial proteins engaged with enactment of procarcinogens (Hosoda *et al*., 1996). Probiotics can likewise deliver short-chain unsaturated fats that can be defensive in the colon. Mouse studies have demonstrated that probiotics hinder the arrangement of anomalous tomb foci in the colon. The mix of inulin in addition to B. longum has been accounted for to decrease synthetically incited strange grave foci by 74% (Rowland *et al*., 1998). Inulin alone diminished anomalous sepulchers by 21%. Mice encouraged with a blend of oligofructose, inulin, LGG, and B. animalis subsp lactis were altogether less helpless to azoximetane-incited colon tumors (Marotta *et al*., 2003).

Conclusion

When utilizing or endorsing probiotics, consideration must be paid to the probiotic definition, including live, dead, joined arrangements or items thereof, the successful portion to be utilized, and the sort of infection focused on. It is unimaginable to expect to gauge the particular impacts and/or dosages of a specific probiotic and sum up these properties to different portions and/or strains of probiotic microorganisms. The Food and Drug Administration of the United States as of now does not direct probiotic items and does not give any administration oversight to quality control. In this manner, the genuine number of living creatures in business items might be very not quite the same as that promoted. In synopsis, future enormous scale clinical preliminaries that control dosing, suitability and other basic factors will be urgent to give the logical proof important to decide the viability of expanding probiotic use.

Abstract

The codling moth (*Cydia pomonella* L.) is the most economically significant pest found in apples, pears, quinces, peaches and walnuts in southern Serbia. The research was carried out with the aim to determine the presence of this species in the monocultural apple plantations, apple plantations with mixed varieties of apple trees, abandoned apple plantations and on apple trees that were part of the spontaneous flora. The monitoring was also carried out on the individual apple trees grown on infields, whereby some of them were chemically protected and others were not. The standard entomological methodology used for the research was divided into the field observation (pheromone traps, trunk bands made of corrugated cardboard, visual examination, the branch beating method, entomological isolators) and the laboratory growth (the growth of interwoven larvae, the growth of the collected plant organs with eggs hatched on them, taxidermy, labelling, determination and collecting of the material gathered in the field). The results of the research showed that the variability of abiotic factors affected the length of the codling moth's developmental phases. It also affected the numerousness of codling moths. These are the identified natural enemies of the codling moth: parasite species of codling moth from the Hymenoptera order (Ichneumonidae, Braconidae), species known as moth (Tortricidae) parasites from Hymenoptera and Diptera orders, predator species from the following orders: Dermaptera (Forficulidae), Neuroptera (Chrysopidae), Coleoptera (Coccinellidae) and Heteroptera (Miridae).

Key words: *Cydia pomonella L., abiotic factors, natural enemies, southern Serbia.*

Introduction

Serbia has favorable agroecological conditions for the growth of continental fruit species (Mišić, 2005). Apple is the most significant fruit that is of big economic importance because of its capability to adapt to natural conditions and high quality of its yield (Blagojević, 2000). Weather change can affect the development of apple production in a specific way. In order to overpower the adverse impact of drought and fruit stress caused by extreme meteorological changes, it is necessary to use high-level agro-pomotechnical measures.

Modern strategy of fruit production for control of harmful organisms requires producer's expertise in terms of knowing agrobiocenosis, biology and ecology of each individual species as well as their interaction (Nikolić *et al.*, 2018). Thus the development of harmful organisms is enabled while the possibility of increasing of many helpful organisms is improved. This also enables the production of unpolluted, health-wise safe yields (Milić *et al.*, 2011).

Apple is being attacked by many pests, such as insect species from the Tortricidae family. The most represented pest is codling moth (*Cydia pomonella* L.), one of the most economically harmful insect species in fruit growing. Fighting for its survival, codling moth feeds on the yields the man is also interested in (Almaši *et al.*, 2004).

Its appearance is recorded in monocultural orchards, mixed orchards, neglected trees or trees that can be found next to planted apple orchards and are not treated, and wild fruits. In southern Serbia, it can also be found on pear, quince, peach and walnut yields (Nikolić, 2015).

The goal of the research was to determinate the influence of variable abiotic factors over the length of developmental phases of codling moth (hatching of the first eggs and drilling of infant larvae into the fruits, as one of the most important stages of the development cycle of codling moth). The goal was to determinate the presence of the natural enemies of codling moth in orchards with different protection systems and in variable localities.

Material and Methods

The research was carried out in fruit plantations in the territory of southern Serbia in 8 localities (with different altitude) in the following districts:

1. Jablanica District: Beli Potok (272 m), Donje Stopanje (253 m), Leskovac (230 m) and Strojkovce (266 m);
2. Nišava District: Niš (237 m);
3. Toplica District: Prokuplje (285 m);
4. Pčinja District: Vladičin Han (389 m) and Prekodolce (299 m).

In all orchards except in locality of Strojkovce, chemical protection has been performed. The number of pests approximately close to the main plantations in neglected untreated orchards, on trees of houses in the surrounding or on wild trees, was also recorded for the comparison of the presence of codling moth and its natural enemies.

During the research period (2006-2008), the weather (air temperature and rainfall) was being analysed in the weather stations in: Leskovac (for Jablanica District), Niš (for Nišava and Toplica District), Vranje (for Pčinja District).

The standard entomological methodology (Group of authors, 1983) was used for the research necessary for the field observations (visual examination, pheromone traps, trunk bands made of corrugated cardboard, the branch bearing method, entomological isolators) and the laboratory processing of material gathered on the field (the growth, taxidermy, labelling, determination and collecting) (Nikolić, 2015).

Results and Discussion

The codling moth was registered in all localities of the three yeard research in the territory of southern Serbia. Except on apple fruits, its damage was determined on peat, quince, peach, and walnut. Its presence with a different intensity in plantations of apples, but also pear, quince, peach, walnut and sweet cherry, is confirmed in researches of other authors (Tadić, 1957; Ciglar, 1989; Stamenković *et al.*, 2006, Kutinkova, 2010).

The codling moth is a thermophilic species, to which growth periods with high temperatures and a lack of rainfall are suitable. With the appealing conditions for its development, it has multiple generations and causes bigger economic damages. The characteristics of weather conditions in southern Serbia in the period of the research are the following:

- the year 2006 was a pretty warm year with a quantity of rain in a normal state;
- the year 2007 was one of the hottest years recorded in Serbia, with heatwaves and unevenly rainfalls during the year;
- the year 2008 was extremely hot and quite dry, with fewer exceptions than 2007.

The activity and the length of the developmental phases of *C. pomonella* are in direct correlation with weather changes, distribution and quantity of the rainfall in vegetation period. The average monthly temperature between April and October had the highest variable recorded in the year 2007, and the lowest in 2006 in three weather stations (Figure 1a). The sum of rainfall in the period between April and October was the highest in the year 2006 in three weather stations, and lowest in 2007 in Vranje, as well as in 2008 in Leskovac and Niš (Figure 1b). During the research weather conditions with stimulating characteristics for the codling moth were also registered, such as mechanical damage of the fruit from hail and drying of the fruit due to the high temperature, periodical rotting and decreasing of fruits.

Damaged and softer fruits are an easier target to attack by caterpillars of codling moth and the damage itself is doubled.

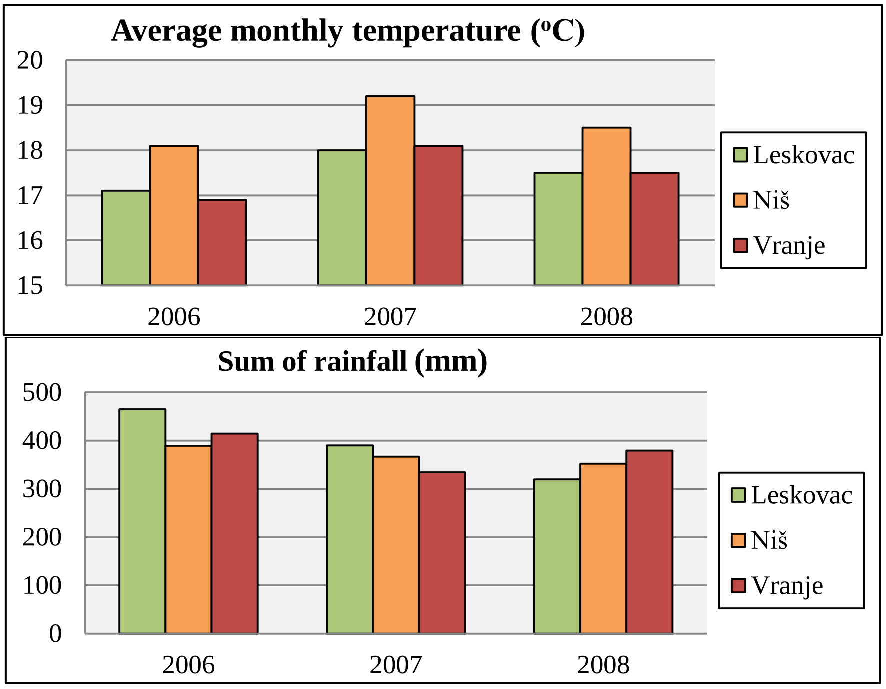

Figure 1. Weather conditions in southern Serbia in the period between April and October in years 2006 to 2008: a) Average monthly temperature (ºC), b) Sum of rainfall (mm)

Weather conditions were extremely in favor of the development of this species. Two generations per year in each locality were determined, while in some localities of Jablanica district it was recorded prolonging of the flight and extension of the development of the second generation of codling moth: in year 2006 in localities Donje Stopanje T (treated orchards) and UT (untreated orchards), Leskovac T, Strojkovce UT, in year 2007 in localities Beli Potok UT, Donje Stopanje T and UT, and in year 2008 in locality Donje Stopanje T and UT (Nikolić, 2015).

Multiple authors in Serbia and neighbor countries indicate an easy adaptation of codling moth on weather conditions and its big potential of reproduction (Tadić, 1957; Maceljski, 1973; Thalji, 2002; Lazarevska *et al.*, 2005; Pajač – Živković, 2012; Nikolić, 2015).

The variability of abiotic factors affected the length of the developmental phases of the codling moth and its number. Laying and hatching of the first eggs and drilling of infant larvae into the fruits is of big importance for the representation of the complete development cycle of the codling moth, as well as for overlapping of developmental phases from different generations (Table 1). The first appearance of the eggs and hatched larvae happened a few days earlier in the localities that were chemically treated in comparison to the chemically untreated localities (Nikolić, 2015).

First hatched eggs in the period of examination were determined on April 29th, 2006 in locality Beli Potok, on April 30th, 2007 in Donje Stopanje and on April 24th, 2008 in Donje Stopanje. First drilling of larvae in the fruits was registered in the locality of Beli Potok (May 14th, 2006, May 21st, 2007, and May 16th, 2008).

Examinations of autochthonous useful entomophauna of *C. pomonella* are in the interest of every fruit production area. Determination of differences of the faunistic composition of natural enemies of codling moth, depending on the locality and implemented protection system, give a different mark to a specific area and to apple production in general. The role of every determined natural enemy cognates in the possibility that they are used as a factor for regulation of the number of the pest. Reduction of its population is possible, keeping in mind that the codling moth can be exposed to the attack of the entomophagous parasites and predators in every developmental phases (Lazarevska *et al.*, 2005).

(T – treated orchards; UT – untreated orchards)

The registered natural enemies of the codling moth in the conducted researches can be clustered in the following groups:

➢ Parasite species *C. pomonella* from Hymenoptera order (Ichneumonidae: *Pristomerus vulnerator* Panc. and *Trichomma enecator* Rossi. and Braconidae: *Ascogaster quadridentata* Wels. and *Chelonus annulipes* Wesm.);

➢ Parasite species Tortricidae from Hymenoptera order (Ichneumonidae: *Itoplectus maculator* F., *Itoplectus alternans* Grav., *Phaeogenes invisor* Thumb., Braconidae: *Agathus laticorpa* Telenga and *Apanteles* sp.) and from Diptera order (*Actia pilipennis* Fall.);

➢ Predator specias from the followig orders:

- Dermaptera (Forficulidae: *Forficula auricularia* L. and *Forficula smyrnensis* Audinet-Serville);
- Neuroptera (Chrysopidae: *Chrysopa carnea* Steph., *Chrysopa perla* L. and *Dichochrysa ventralis* Curtis);
- Coleoptera (Coccinelidae: *Coccinella septempunctata* L., *Coccinella quatuordecimpustulata* L., *Adalia bipunctata f. Tybica* L., *Adalia bipunctata f. Sexpustulata* L., *Adalia decempunctata* L., *Chilocorus renipustulatus* Scriba, *Hippodamia variegate* Goeze, *Oenopia conglobate* L., *Platunaspis luteorubra* Goeze, *Propylea quatourdecimpunctata* L., *Psyllobora vigintiduopunctata* L. and *Scumnus frontalis* Fabr.);
- Heteroptera **(**Miridae: *Deraecoris ruber* L.).

The presence of the natural enemies of codling moth is encountered in the researches of multiple authors (Lacey, Unruh, 2005; Lazarevska *et al.*, 2005; Andreev *et al.*, 2006; Nikolić, 2015). The codling moth eggs parasitised by the Trichogramma species were identified on both chemically treated and chemically untreated fruits in Prokuplje and Vladičin Han during all three years of the research. These parasits were indicated by Tadic (1957) in his researches.

C. pomonella falls under the species with a lesser number of generations, smaller reproductive capability and species with specific parasites and predators that regulate its number (Krnjajić, Injac, 2000; Almaši *et al.*, 2004; Lazarevska *et al.*, 2005).

Conclusions

The codling moth was present in all examined localities in the territory of southern Serbia with a different intensity. Economically, it is the most significant pest of apple, but also of pear, quince, peach and walnut.

The variability of abiotic factors during the vegetation affected the length of the codling moth's developmental phases and its number. The activity and the length of the developmental phases of *C. pomonella* are in direct correlation with weather changes, distribution and quantity of the rainfall in vegetation period. The mechanically damaged fruits from hail and drying of the fruit due to the high temperature are an easier target to attack by caterpillars of codling moth and the damage itself is greater.

In the conducted researches the following were registered as the natural enemies of the codling moth:

- Parasite species *C. pomonella* from Hymenoptera order (Ichneumonidae and Braconidae),
- Parasite species Tortricidae from Hymenoptera and Diptera orders,
- Predator species form following orders: Dermaptera (Forficulidae), Neuroptera (Chrysopidae), Coleoptera (Coccinellidae) and Heteroptera **(**Miridae).

The role of every determined natural enemy cognates in the possibility that they are used as a factor for regulating the population of the codling moth.

Abstract

The increased need for fresh vegetables has led to the application of new technologies for the preservation of quality during storage. Lettuce is a type of vegetable that is consumed often and in relatively large quantities**.** The objective of this study was to determine the effect of storing and keeping sensory properties of lettuce using packaging in normal atmosphere and modified atmosphere (MA). The research was done with one control group and two experimental groups. The control group consisted of lettuce stored in normal atmosphere in the refrigerator and the experimental group included lettuce stored in MA, (98% nitrogen and 2% oxygen). During 25-day storage period, the sensory properties and colour were evaluated using a spectrophotometer (CM-5, Konica Minolta). Colour was measured on the outer, middle and inner leaves of the lettuce and ribs, under storage conditions of relative humidity of 95% and temperature 4°C. The colour parameter L* in the control group, changed from 61.92 at the beginning to 68.59 at the end of the experimental period. An increase in L* value in lettuce is a sign of decreased intensity of the green color due to the appearance of yellow pigments. Sensory evaluation determined that there was significant difference ($p = 0.05$) in the overall impression in the MAP, normal atmosphere and control samples.
MAP enables the preservation of quality and sensory properties for a longer period of time (5 days).

Key words: *Green lettuce, MAP, normal atmosphere, color change, sensory rating.*

Introduction

Lettuce is one of the most popular types of vegetables available almost all year round. It is a rich source of bioactive substances important for human health, which serve to prevent many diseases. The most important bioactive substances contained in lettuce include chlorophyll, poly-phenols and flavonoids, carotenoids, vitamins (tocopherol, ascorbic and folic acid) and minerals, especially magnesium (Nicolle et al., 2005; Hamu ł ka, et al., 2005; Kenny and O'Beirne, 2009; Murillo et al., 2010; Perucka et al., 2011). Today, there is a growing demand for fresh, naturally preserved and high quality food products that are treated as physically and chemically as possible during production. The life of the product is influenced by physical, chemical and biological factors (Lee et al., 1997; Mattheis and Fellman, 2000).

The shelf life and maintenance of freshness is determined by monitoring the parameters of the chemical composition, physical, sensory and microbiological properties during the time when the lettuce maintains the properties appropriate for its consumption. Apart from the storage conditions of the product, choosing the right packaging material is just as important as choosing the right gas mixture inside the package (Ballantyne et al., 1988; Kader, 2002).

In cases where the lettuce is exposed to uncontrolled conditions of relative humidity and temperature, the main reason of lettuce deterioration is water loss, which causes degradation of cell walls and affects quality properties such as texture, discoloration, enzymatic darkening after picking (Alzamora et al., 2000; Rodrigues et al., 2013). In a sensory evaluation of lettuce, the external appearance has a great influence on the choice of the product. According to Almeida (1995) and Gonzales et al. (1999), instrumental color determination can be used to establish quality standards in fresh or processed products. Colour can also be used as a factor to determine the shelf life of a product when studying color variations during storage (Lee et al., 1996). Chlorophyll is responsible for the green color of the plants. Because their chemical structure is unstable, they are easily degraded, resulting in degradation products that alter the perception and quality of food (Lopez-Galvez et al., 1997; Schoefs, 2002). This aspect is entirely related to the purchase of these products by consumers; a reduction in chlorophyll content leads to market losses, thereby doing research is an attempt to find methods for better preservation .

Material and Methods

The tested lettuce samples, *Iceberg*, were stored at 4℃ and 95% relative humidity. The chamber temperature and relative humidity were measured using a digital thermometer with a „Tesko AG 922" thermocouple. Samples were stored in MRC LTD, PGI-550V 0 to +70℃. The samples were tested for color on 1, 4, 7, 10, 12, 14, 16, 18, 20, 23, 25 days, while sensory tests were performed for 1, 10, 20 and 25 days.

Method of growing lettuce

Production of seedlings was carried out in early August, and planting in early September in an open field in Gornja Bioča, in the production area of the company "BH food". About 5000 *Iceberg* lettuce seedlings are planted at 2000 m^2, with an average daily temperature of 25℃ to 30 ℃.

The harvest was done on the 65^{th} day after planting. Immediately after sowing, the seedlings were treated with *Previcur* for protection. Savings were made three times during production with different NPK ratios and irrigation every 3 days at 0.4 l per seedling.

Lettuce packing method

The lettuce was packaged at „BH Food" in MAP and in a normal atmosphere with „Multivac" packer. When packing in MAP, a gas mixture (O_2: N_2: CO_2) (2: 98: 0) was used by the manufacturer's Messer, which was pressed into polyethylene bags (0.07 mm - throughput level), dimension 240 x 340. The packaging program was set to 50 MB per pack. When packing in a normal atmosphere, the same bags as the modified atmosphere were used.

Determination of color

CM-5 (Konica Minolt) spectrophotometer was used to determine the color. The changes inthe color of lettuce was evaluated using the CIELAB system at light source D65. Observation of color change was done on ribs and leaves, with three repetitions, on the outer, middle and inner part of the lettuce head. Mean values were taken to determine the color coordinates of L* (brightness), a* (redness) and b* (yellow).

Determination of sensory properties

Sensory evaluation of lettuce was performed by ten trained evaluators, in the laboratory for heat treatment. Samples of lettuce heads were encrypted and prepared on white plastic plates. The method of sensory evaluation of lettuce is described, where the sensory properties of the product are evaluated on the basis of the proposed quality criteria, (from 5 for the intrinsic quality to 1 unacceptable). Color, odor, taste, texture and appearance were evaluated.

Statistical processing
Experimental data were analyzed with a statistical package (SAS Ver. 9.0). One-way analysis of variance (ANOVA) was performed for each type of package to obtain a statistical estimate of the evolution of parameters during storage at a confidence level of p = 0.05. For sensory processing, the Mann-Whitney U nonparametric test was used to evaluate significant differences in the dependent variable.

Results and Discussion

The loss of quality due to the appearance of yellow, rusty brown, head damage and fading were slightly higher in the lettuce control samples and the ones packed in a normal atmosphere than in MAP. The color parameters L*, a* and b* of lettuce samples, as well as the values of total color change measured during storage in the refrigerator for 25 days at a relative humidity of 95%, represent the mean of three measurements from three parts of the lettuce head (outer, middle and of the inner part). The values of the lettuce color parameters are shown in Figure 1.

*Source: Author's elaboration based on lab measurements

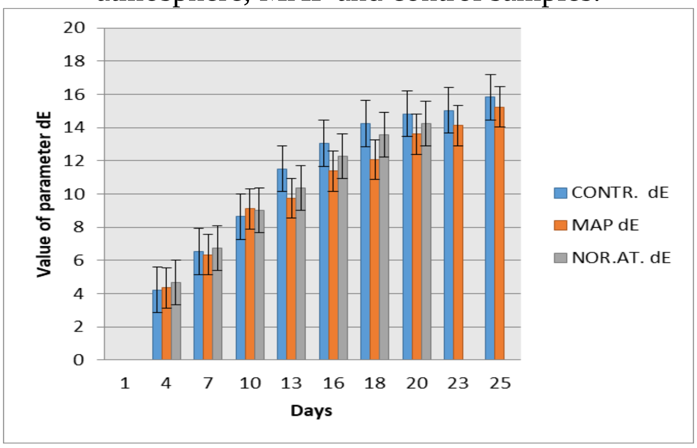
Figure 1 shows the changes in the color parameters L*, a* and b* during the storage at different packing conditions (MAP, normal atmosphere and control sample) at 4℃ and 95% air humidity. Treatments of packing had a very little effect on the color of lettuce, measured by L*, a*, b*, which is not statistically significant with a 95% probability. These results confirm the stability of chlorophyll content during cold storage and agree with those reported by Lopez et al., (1997) and Managa (2018). Individual analysis of color parameters reveals which parameter influenced the most the overall change in the color of lettuce and under which treatment is the highest change. The largest changes were measured in keeping the lettuce in the refrigerator without packaging, that is, in the control sample, whereas by the sensory evaluation the sample was stored in a normal atmosphere after 20 days, judged to be unacceptable for consumption due to the unbearable smell of fermentation and taste changes, which were evaluated by the lowest grade. The largest changes in the L* parameter occurred from 16 days, when a change of more than 1.5 was observed in the control sample and normal atmosphere, while the changes in the MAP were more uniform. The difference between the first and the last day in the MAP was 4.52, while in the control it was 6.67 and in the normal 5.43. An increase in the value of the parameter L* indicates an increase in the luminance (brightness) of the sample. Changes in the color of lettuce are not defined by the standard. Although there is no scale to determine the quality of lettuce on the basis of color, it can be concluded whether the measured changes are significant or not. Sharma (2003), state that changes in color parameters greater than 3 are significant. In all three samples, an increase in the + b* parameter indicating yellow was measured during the storage process. Major changes were measured in the storage of control samples 3.54, while in the normal atmosphere they were 2.85 and in MAP 2.65. An increase in the value of the + b* parameter occurs continuously over 25 days of storage. Changes in the -a* parameter on all three samples were small and did not affect the color change much. The value of a* of first, to day 25 for the control sample changed by 2.13 and for MAP by 1.47.

The quality lettuce packed in MAP, normal atmosphere and control sample prepared from whole *Iceberg* heads up to 13 days at 5 °C was similar. Afther 13 days of storage lettuce in normal atmosphere, CO_2 injury resulted in severe discoloration and tissue softening. The use of MAP delayed the development of a change lettuce color, for several days (Brecht et al. 2003; Singh 2010).

Changes in the value of the total color

The occurrence of discolouration in fresh leafy vegetables has been reported as a severe problem for the food industry as a whole (Chiesa, 2003). Losses due specifically to cut-surface discolouration are hard to quantify although anecdotal evidence suggests that this can account for substantial customer (Hunter et al., 2017). The analysis of variance did not confirm the influence of the experimental factors on the change in brightness of lettuce samples, as well as the parameters a* and b* on the change in the values of these parameters. The results of the total color change, which contains all three parameters, which is why this size and the best indicator of color change are also included in the analysis. The results of the analysis are shown in Figure 2. Major changes in ΔE during storage were measured in control samples, which is a consequence of water loss of transpiration and drying of the outer leaves (Kader, 2002).

Figure 2. Values of ΔE with error bars for lettuce leaves during storage under normal atmosphere, MAP and control samples.



*Source: Author's elaboration based on the lab measurement

Sensory evaluation was performed to compare the main visual-qualitative attributes with the measured physicochemical parameters over the life of the lettuce. Ratings during storage showed good correlations with changes in the color parameters tested. Error bars are used that express a potential error, relative to the point or marker for the given data set. Average mean scores of the ten assessors are given in Table 1.

Table 1. Sensory evaluation of lettuce

SAMPLES	CONTROL				MAP				NORMAL AT.		
	DAYS										
CARACTERISTICS	1	10	20	25	1	10	20	25	1	10	20

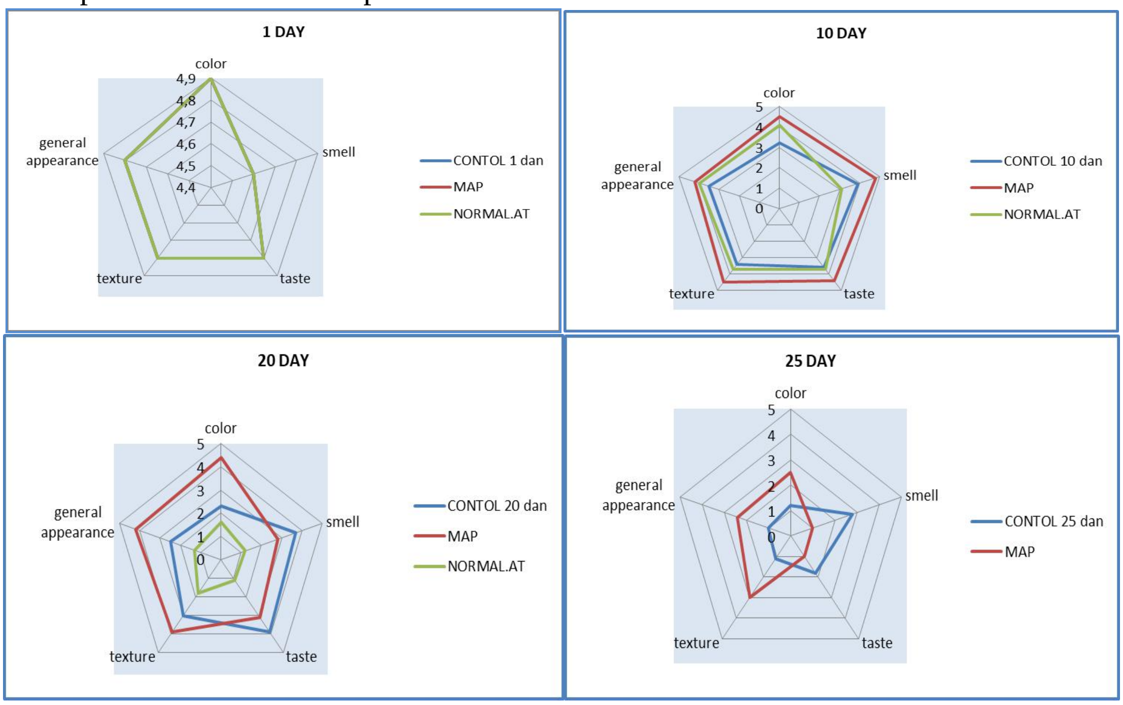
Average	4,78	3,52	3,08	1,58	4,78	4,48	3,68	1,98	4,78	3,72	1,4

*Source: Author's elaboration based on the questionnaire survey results.

Specifically, lettuce packed in a normal atmosphere were rated as unacceptable after 20 days, while packed in MAP had the highest ratings up to 25 days when the evaluators stated that the smell and taste were not specific to the product, which was the case with the products in the normal atmosphere of the 20th day.
Overall visual quality scores were generally at or above the minimum acceptable value for salability at the ''Best if Used by Date'' (12—16 days after processing) (Lopez-Galvez; 1997). Another problem that arose during storage was the appearance of browning, which was expressed in packs of normal atmosphere. The problem with the control sample was drying the outer leaves and leaving a poor visual impression.

Figure 3. Demonstration of sensory evaluation by day for lettuce stored in MAP, normal atmosphere and control sample.



*Source: Author's elaboration based on the questionnaire survey results.

According to Chitarra and Chitarra (2005), aging is considered to be a period of the life cycle of a plant when catabolic processes (degradation), which are responsible for tissue death, prevail, as the ability of plant synthesis is very limited in the final stages of life. Analyzing the results, the most sustained mixture of gases into which lettuce was packaged showed a modified atmosphere (Figure 3). Regarding the general appearance parameter at storage day 25, lettuce in MAP represented a mean of 2.4; while the continuity of the sample was graded 1. The smell and taste of the sweet packed in MAP for 25 days were graded 1. Texture and color are the parameters that the graders rated higher, (3 textures and 2.5 colors). An overall acceptability score of three was considered an acceptable limit for sales or consumption (Zhan et al., 2012; Rodrigues et al., 2013). Analysis of variance revealed that there was a statistically significant difference between samples packed with MAP and control ($p = 0.05$) in overall impression as well as in color and texture based on the sensory evaluation of the evaluator. For the other parameters tested, odor and taste, no statistically significant difference was found between the samples.

Conclusion

Lettuce stored in different packages (normal and modified atmosphere and control sample), had a very little effect on the color, measured by L*, a*, b*, which is not statistically significant with a 95% probability. Sensory evaluation provided a comprehensive picture confirming that the most durable lettuce was packaged in a modified atmosphere. The sensory quality of lettuce was reduced from day 1 to day 10 of storage, in control samples, while a sudden decrease in quality was observed in the normal atmosphere on day 20th, when lettuce was considered unsuitable for consumption, due to its extremely unpleasant odor and taste. MAP enables the preservation of quality and sensory properties for a longer period of time (5 days), as confirmed Brecht et al., 2003; Singh, 2010; Hunter, 2017.

Abstract

Seed quality is an indication of thesuitability for sowing. The species composition of the seed mycophlora is an important factor for seed sowing qualities. This study aimed to determine the species composition of the epiphytic mycophlora developing on the seeds of different genotypes of sorghum and their influence on the sowing qualities of the seeds, in 2018. Seeds of 5 plants of each sorghum genotype were collected to determine the species composition of pathogens growing on their surface. The collected seeds were transported to the phytopathological laboratory of Shumen University and analyzed for the presence of epiphytic microflora on them, and to study their seed qualities - germination and germination energy. The seeds germination and the germination energy is determined in line with the standard methods. All genotypes under laboratory conditions showed germination above 85%. The identification of phytopathogens is performed by the wet chamber method, by microscopic diagnosis and using different methods of isolation. It was found that *Alternaria alternate* (Fr.) Keissl. Was the most common fungus growing on the surface of the seed among all 7 isolated species, referring to 6 genus: *Alternaria alternate; Alternaria solani*, *Fusarium moniliformae*, *Helminthosporium turcicum*, *Peronospora sorghu*, as well as the causative agents of the *Aspergillus* and *Mucor* species.This pathogen is capable of damaging seeds and sprouts, thereby aggravating the sowing properties of sorghum seeds. When introducing new species of agricultural cultures in specific region information on seeds germination, seed-borne diseases eventual manifestation and development is explicitly important. In this connection, the present research is directed towards the germination and germination energy of the seeds, as well as the mycoflora of different sorghum genotypes, cultivated in Shumen region.

Key words:*Sorghum, Epiphytic micophflora, Qualities of seeds, Alternaria alternate.*

Introduction

The composition of the seeds' mycoflora is determined as an aggregate of all types of microorganisms, colonizing the sheath and the internal parts of the seeds, such as viruses, bacteria and microfungi. Part of those microorganisms are pathogenic and they are referred as pathogenic microflora in literature (Stancheva, 2010). In accordance with researchers on seeds pathology (Bakan, 2002; Dawar, 1991; Thakur et al., 2007; Little, et al., 2012) the microorganisms, colonizing the seeds endosperm, infect the seeds systematically and other microorganisms occupy the surface of the seeds and infect the healthy plants under suitable conditions. The results from tests, made by the above-cited authors, show that this is a variety of pathogenic microorganisms, adherent to different groups. According to (Stancheva, 2010) the surfaces of the agricultural seeds may be colonized also by microorganisms, which do not cause any visible pathological changes in the seeds, they do not participate in diseases transmission and they are determined as non-pathogenic microflora. The microorganisms colonizing the seeds as pathogenic or non-pathogenic microflora are predominantly representatives of different types of bacteria and fungi (Sharma et al., 2015).

All transmitted sorghum seed-borne diseases affect the growth and the productivity of the crop. (Stancheva, 2010). The infected seeds are characterized with reduced germination and rotting; local and systematic infections are observed in later stages of the plantation development. (Isakeit and Jaster, 2005; Ramathani, 2010; Kikindonov et al. 2013). The only way to reduce to minimum the risk of transmission of seed-borne diseases and the introduction of new types or strains is the good knowledge of the pathogens biology and the modes of transmission from vegetation to vegetation (Degefu,1990). Some fungi, infecting the sorghum and corn seeds – representatives of *Fusarium*, *Aspergillus*, *Rhizoctonia*, *Penicillium*, *Helminthosporium*, attack and destroy the seeds' endosperm by eating the starch inside, leading to reduced germination and incapacity to develop normal sprouts (Stancheva, 2010; Cook, 1980; Domsch, Degefu,1990) Representatives of *Pythium* and *Peronospora* species, attack the young seedlings and lead to rotting of the roots and the bases of the plants at the initial phases of their development, which leads to reduction of the crop (Isakeit and Jaster, 2005). Examinations on the seeds' microflora of the cereal grain crops show that the colonization of the seeds by representatives of the following species: *Fusarium* and *Alternaria* decrease the production efficiency (Stancheva, 2010; Bakan, et al., 2002). The authors consider that those pathogens, under certain conditions, may associate in pathogenic complexes causing withering, root and stem rotting for the whole vegetation. The *Fusarium* and *Alternaria* produce mycotoxins, deteriorating the quality of the seeds and make it unusable as fodder. Stancheva (2010) describes *Fusarium* (*Fusarium moniliforme* J. Sheld; *Fusarium graminearum*) and *Alternaria*, (mainly *Alternaria alternate)* species as the causative agents of a complex pathological syndrome, showing pathologic symptoms on the seeds, the vegetative organs and the roots: stem rotting – manifestation through the phases of milk and dough-ripe maturity, head rotting. **Figure 1** shows pictures of the causative agents of those symptoms. The manifestations starts after the milk-dough-ripe maturity and the symptoms continue to develop during the storage phase as well, such as rotting.

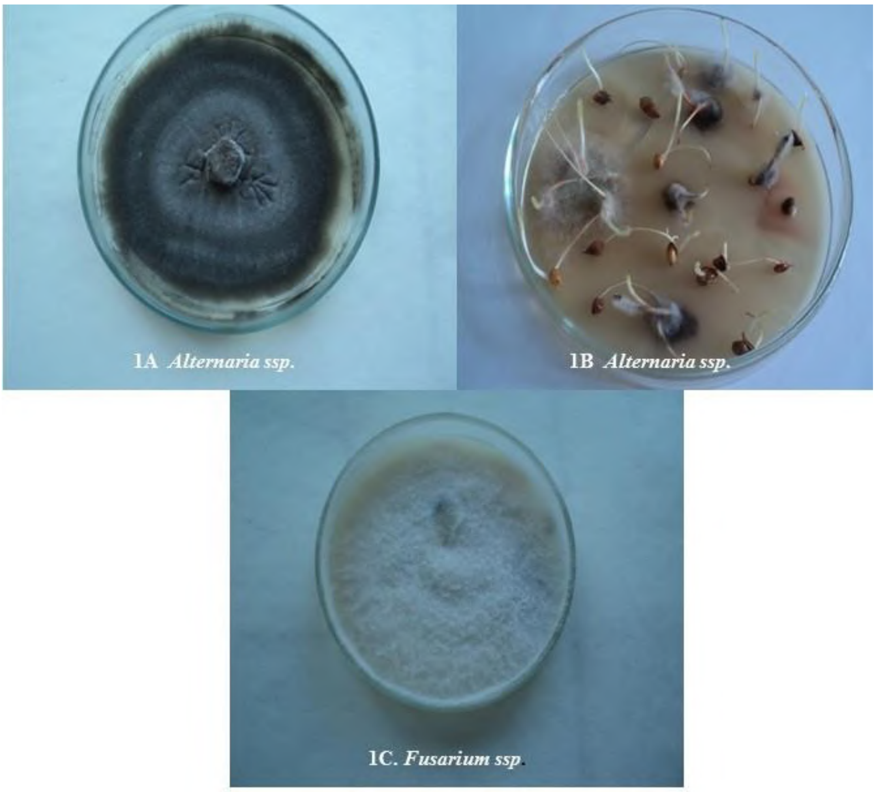

Figure1. Pathogens that cause diseases in sorghum.
(Image by Krasimira Tanova)

The pathogenic fungi - *Fusarium moniliforme*J. Sheld**,** *Fusarium culmorum*, *Penicillium* ssp.are the causative agents of those pathologies (Stancheva, 1996; Stancheva, 2009; Andreeva and Tanova, 2011).
When introducing new species of agricultural cultures in specific region information on seeds germination, seed-borne diseases eventual manifestation and development is explicitly important. In this connection, the present research is directed towards the germination and germination energy of the seeds, as well as the mycoflora of different sorghum genotypes, cultivated in Shumen region.

Materials and methods

In January and February 2019 an examination on germination and epiphytic microflora constitution is conducted in the phytopathology laboratory of the Natural Science Faculty of the University in Shumen, Bulgaria. The subject of the examination are 7 sorghum varieties, 6 of them were by RAGT, seeds producer: DODGGE, FLAGG, GGUSTAV, ANGGY, ISEBERGG, GOLDEN and one of them, Maxired, is from the selection program of Shumen Agricultural Institute, serving as standard. The varieties were included in a demonstration, which took place in 2019 on the territory of the Shumen Agricultural Institute (Kikindonov et al. 2013). Seeds from 5 plants from each variety are provided on random basis, for the purposes of determination of the germination and the analysis of the present epiphytic microflora.
Standard phytopathology methods are used for the determination of the sub epidermal mycoflora pathogens, therefore each version includes 3 repetitions with 100 pcs. seeds (Popkova, 1989, Popkova et al., 2005). The surface of the seeds is sterilized with 0.01 % Hg CI_2 in advance. On the 7^{th} day after the incubation the quality and quantitative composition of the seeds mycoflora is measured (Stancheva, 2010).
The seeds germination and the germination energy is determined in line with the standard methods of the Executive Agency in Species Testing, Approbation and Seed Control of the Bulgarian Ministry of Agriculture. Binocular microscope Optika-B150 is used for the microscopic examinations.
The accuracy of the difference between the compared estimates of each version of measurements is valued through the means of the so called marginal difference. The number of the seeds, contaminated with different species fungi is reported in %. The results of the laboratory analysis are statistically processed through the means of a variation analysis of the qualitative signs (Zapryanov, 1983).

Results and Discussions

Figure 2 presents the results from the genotypes sowing qualities. Visible from the results presented, the germination energy is highest with the seeds from the DODGGE and GGOLDEN materials, respectively 86.50 % and 87.85 % and they show higher values than the seeds of the controlled variety – Maxired.
The lowest index is with the seeds of GGUSTAV, ANGGY, FLAGG ANGGY и ISEBERG varieties, showing lower germination energy in comparison with the control version of the seeds. The seeds germination under laboratory conditions shows differences as per the tested genetic origin, as the seeds from the analyzed genetic origins show higher values than the control version. The maximum reported value is for the FLAGG seeds, respectfully 96.25 % and the lowest one with the ANGGY-86-75%.

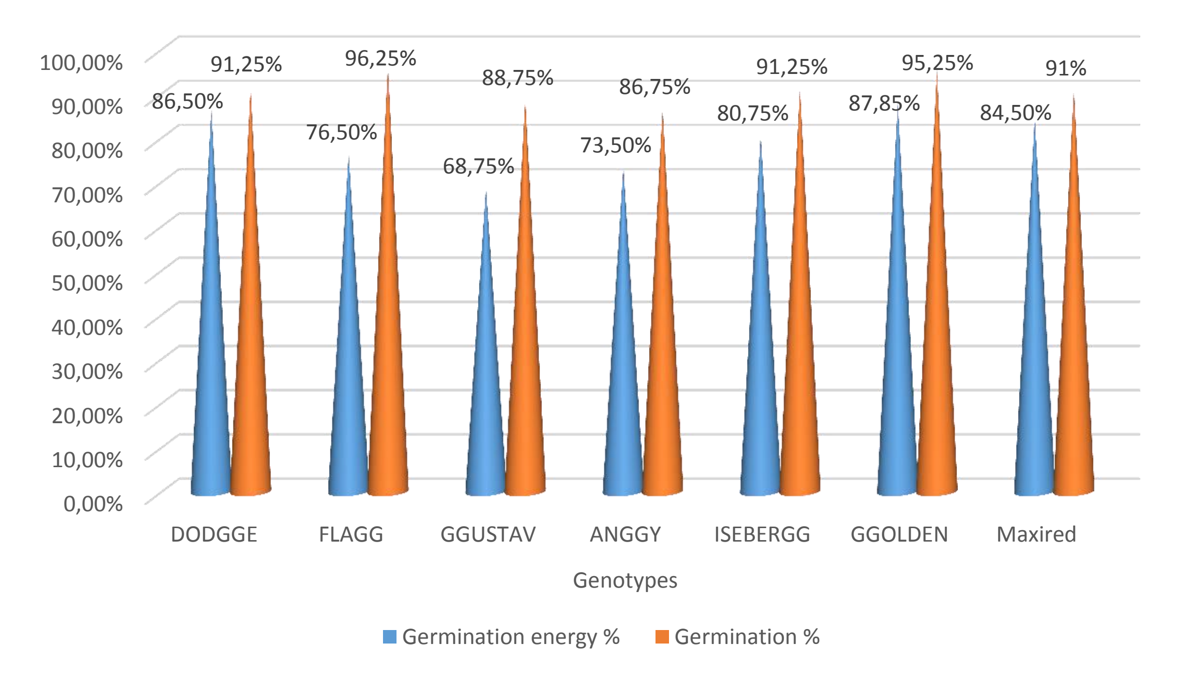

Figure. 2 Germination and germination energy of various genotypes sorghum

Table 1. Reliability of differences between genotypes studied and control

Germination energy						
Genotypes	DODGGE	FLAGG	GGUSTAV	ANGGY	ISEBERGG	GGOLDEN
Maxired	**t>2,58**	**t>3,29**	**t>3,29**	**t>3,29**	**t>3,29**	**t>3,29**
Germination						
Genotypes	DODGGE	FLAGG	GGUSTAV	ANGGY	ISEBERGG	GGOLDEN
Maxsired	**t<1,96**	**t>3,29**	**t>3,29**	**t>3,29**	**t>3,29**	**t>3,29**

t<1,96	not credibility
t>1,96	P = 5%
t>2,58	P = 1%
t>3,29	P = 0,1%

High values of this index, above the control seeds values, we encounter with the following varieties: DODGGE and GGOLDEN, which show a value higher than the control one and they are showing to be the seeds with best germination under laboratory conditions. **Table 1.** show the differences between the Maxired control variety and the remaining varieties in terms of germination energy. The germination index shows unreliable difference with the first variety, DODGGE.

Seven fungi species are determined by the surface and sub epidermal mycoflora, referring to 6 genus. They have different frequencies of presence, depending of the seeds origin. Two of them are causing the alternariosis disease (*Alternaria alternate; Alternaria solani*), fusariosis (*Fusarium moniliformae)*, septoriosis (*Helminthosporium turcicum*), dawny mildew - *Peronosclerospora sorghu*, as well as the causative agents of the *Aspergillus* and *Mucor* species. The research data is presented in **table 2**. Most frequently present istheAlternaria *alternate*, available in the mycoflora of all origins.

Table 2. Frequency of isolated seminal mycophlora in%

Genotype	Pathogens							Root tip necrosis
	Alternaria alternate	*Alternaria solani*	*Aspergillus ssp.*	*Mucor ssp.*	*Helmintosporium turcicum*	*Fusarium monilifor*	*Peronosclespora sorghum*

DODGGE	21	0	9	0	0	0	0	18
FLAGG	30	0	8	0	5	10	0	18
GGUSTAV	29	0	10	0	12	17	0	19
ANGGY	32	0	1	4	7	0	14	4
ISEBERG	47	42	0	0	13	0	13	0
GGOLDEN	74	10	0	6	6	0	0	0
Maxired	47	26	0	0	30	0	15	0

P = 5%; P = 1%; P = 0,1%

Most frequent presence of this pathogen is ascertained for the GGOLDEN, ISEBERGG and MAXIRED varieties -47-74%. Lowest frequency of presence is ascertained for DODGGE-21%. Contamination with the other causative agent of the alternaosis- *Alternaria solani* is ascertained only in the mycoflora of GGOLDEN, ISEBERGG and MAXIRED in moderate degree – 10 – 24 %.

The causative agent of the fusariosis -*Fusarium moniliformae*is found in two origins - GGUSTAV, frequency of presence- 17 % and *Helminthosporium turcicum*– ascertained in all origins, besides DODGGE, as the frequency in the mycoflora composition is within the limits from 5 to 30%. The causative agent of the downy mildew for the FLAGG is with encounter frequency of 10% and the one for the septoriosis - *Peronospora sorghum*is present in the mycoflora composition of 3 varieties and ecounter frequency between 10-15%. The share of the varieties of genus *Aspergillus ssp.* and *Mucor ssp.*is comparatively lower. In four of them a sprout necrosis is encountered, due to the unfavorable combination of pathogenic species, as it is best displayed with the GGUSTAV. It is noticed that the control Maxired does not show sprout necrosis, which would be due to the genotype sustainability.

Conclusions

The results gained provide grounds for the following conclusions:

- All tested seeds show better laboratory germination than the MAXIRED variety.
- The mycoflora of the sorghum seeds analyzed consists of 7 types of pathogenic fungi, referred to 6 genus. Key importance is given to the causative agent of the alternariosis, fusariosis, septoriosis.

The combination of pathogens in the seeds damages the germs and the deterioration of seed qualities.

Abstract

Knowledge of the mobility of heavy metals and radionuclides, such as Pb, Cd, Zn and U, represents one of the goals of protection, regulation, rational use and irrigation of agricultural soils from the aspect of safe food production. The aim of this work was investigation of efficiency of natural mineral materials based on zeolite and apatite from domestic deposits in the mobility of heavy metals and radionuclides in the waters and soils of the different physico-chemical characteristics (pseudogley and chernozem). The affinity, efficiency, zeolite adsorption mechanisms and apatite adsorption precipitation were determined in a constant-pressure column system at 300 mg l^{-1} for different pH values (5.00 and 7.00) of the basic contaminated solution (Pb, Cd, Zn, U) at time intervals of 30, 60, 90, 120, 180 minutes. In all experiments, significant changes in the pH of the filtrate occurred. The most significant changes in the pH of the filtrate, minimal fluctuations in the time interval, at pH = 5.00, recorded the basic solutions of Pb (7.69-7.87) and U (7.77-7.93) during leakage through the column with apatite, while slightly lower changes for Cd and Zn were observed. Changes also occurred in the column with the zeolite, but with a much lower intensity compared to the column of apatite, and with the trend of changes U> Pb> Cd> Zn. The trend of changes between apatite and zeolite also occurred in the basic contaminated solution with initial pH=7.00. Zeolite and apatite adsorption/precipitation processes successfully immobilized Pb at both tested pH values of stock solution. Our investigation showed that in colonies, apatite better immobilized U, zeolite is better for immobilization of the Cd, while for the Zn both materials showed a very similar affinity. Zeolite and apatite were added in amount of 20 gkg^{-1} soil to reduce the content of water-soluble and easily accessible forms of Pb, Cd and Zn in uncontaminated and contaminated soil.

Keywords: *soils, water for irrigation, zeolite, apatite, heavy metals*

Introduction

The partial damage and destruction of land and water are a major problem for many countries in the world today, especially in food production. Land and water are the main natural resource not only in food production but as an environment with which human are in constant contact. According to that, it is a very serious problem for both: professional and socio-political organizations how to protect these irreplaceable natural resources. Increasingly stringent conditions and rules to produce health food are provided from "HACCP" and "GAP" concepts. It is predicted that Serbia will not be able to export any agricultural product without a certificate of land quality as a "critical place" in primary agricultural production after 2020 (Grubišić, 2017). Usage of nonmetallic mineral materials is important "in-situ" technology for remediation of toxic metals and radionuclides. The materials used for this purpose must be efficient, inexpensive, available in tonnes, and applicable in different mediums (water, soil).
The most commonly used materials are iron oxides, zeolites, apatites, MgO, carbonates, compost, peat, cottonseed flour and lime (Conca, 1997, Brown *et al.*, 1996).

"In situ" technology is a successful and efficient passive method for the sanitation of contaminated groundwater and surface water as well as soil. It involves in some way control-management combining chemical, biological and physical remediation processes. The use of "in situ" technology has advantages in comparison to the conventional technologies for remediation due to it requires no maintenance and minimal operation (Knox *et al.,* 2000, NATO/CCMS U.S. EPA, 2002).
It is known that zeolites (from the clinoptilolite group) can be successfully used for immobilization of Cs, Sr, Cu, Cd, Pb, and Zn in soil and water (Alther, 2005, Ming & Mumpton, 1989). Ma *et al.*, 1993 showed that metal stabilization is efficient in combination with apatite especially for Pb, Zn, Cu, Cd, Ni, U, Ba, Cs, Sr, Pt, Th and other elements.
The usage of minerals for adsorption and precipitation processes in soils and waters is highly dependent on the pH of the medium, the presence of carbonate, organic matter, Fe-Mn oxides as well as the mechanical composition and type of soil mineral clay (Mission *et al.*, 2009). Prior to the in-situ remediation procedure and the use of mineral raw materials, it is necessary to carry out the procedure under laboratory conditions in order to determine the fillers (adsorbents, precipitators), the amount of material, the shelf life, the methods efficiency, etc. Based on experimental results and equations it can be calculated efficiency (K) and capability (Cap) of the various additives for immobilization and outdoor application in field conditions (Jang *et al.*, 1998).
The aim of the study is to investigate the efficiency and possibility for application of zeolites and apatites for remediation of contaminated groundwater, irrigation water and soil.

Material and Methods

Efficiency of mineral raw materials (zeolites and apatites) in a mobility of toxic metals and radionuclides are investigated in Institute for Technology of Nuclear and other Mineral Raw Materials. Experiment was carried out in glass columns (diameter 4 cm), with controlled constant flow. The mass of the clinoptilolite zeolite in the column was 30 g, granulation of 0.8-2.0 mm. The weight of the second mineral supplement-apatite was 30 g, granulation <100 microns. Due to the low filtration coefficient of micronized material, the apatite was mixed with 300 g of purified and calcined quartz sand (ratio 1:10). In this way, a complete control of the constant-pressure filtration coefficient of 200 ml/h for both mineral adsorbents was performed (Figure 1a).

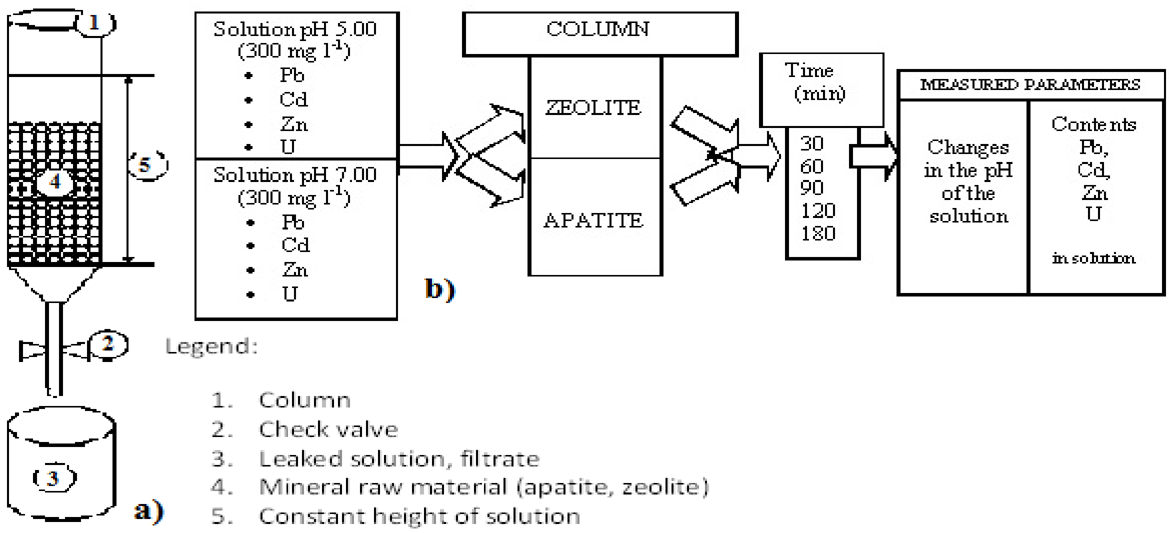

Figure 1 – Schematic veiw of: column a), column experiment b)

The concentration of toxic metals (Pb, Cd, Zn) and radionuclides (U) used for column experiments was 300 mg/l. Toxic metals solutions were prepared from acetates and radionuclide solution Uran-a was prepared using uranyl nitrate. The pH value of prepared solutions were adjused at pH 5.00 and pH 7.00. Prepared solutons were passed through a system of columns filled with mineral additives (zeolite, apatite). The samples are collected at different period times: 30, 60, 90, 120, and 180 min. In this way, 4 x 100 ml and 1 x 200 ml solutions for chemical analysis at the 5 different intervals based on the filtration coefficient were collected (Figure 1b). The second part of experiments involved adding of 20 g kg^{-1} zeolites and apatites in the soil (pseudogley pH=5.55, sand chernozem pH=7,05). In prepared soils the portion of 50 mL solution with 2 mL Pb-Zn-Cd syntetic solution were added. The concentration of syntetic solution was: Pb=50 mg cm^{-3}, Zn=30 mg cm^{-3}, Cd=1 mg cm^{-3}. After first and thirtieth days, water-soluble and accessible forms of added toxic metals (Pb, Zn. Cd) as well as their total content in prepared soil samples were determined.

Results and Discussion

The affinity of mineral adsorbents in reducing the mobility of toxic (Pb, Cd, Zn) metals and radionuclides (U) at different pH values (pH 5 and pH 7) of the solution was determined at the first part of experiments.

The change of pH value of a basic toxic solution at pH 5 in a column system with apatite and zeolite after passing through column are shown in Table 1. As can be seen from Table 1, the filtrates with the highest pH value at pH 5 have the basic solutions of Pb and U which passed throught apatite column at all investigated intervals (t1-t5). Also, the diferences in pH value between investigated solutions are minimal: Pb (7.75-7.80) and U (7.77-7.93) (Figure 1).

Slightly lower intensity of pH value change was detected in the basic solution at pH 5 contaminated with Zn and Cd.

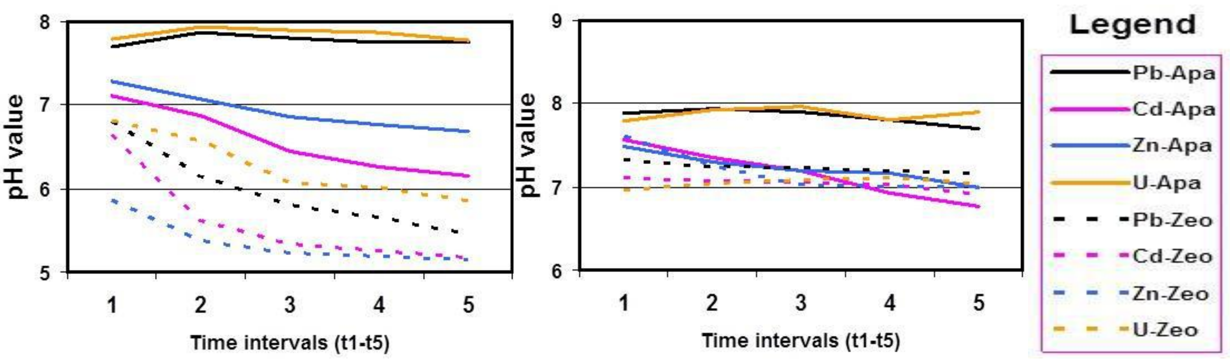

Figure 1. The change of pH value of basic solution (pH 5, left), (pH 7, right)with toxic metals after passing through column with apatite and zeolite

That solutions of Cd and Zn (pH 5) which passed through the apatite column, have lower pH of the filtrate and record a linear, slight decrease in the pH of the filtrate in Zn basic solution (7.28-6.68) and slightly faster in Cd basic solution (7.11-6.15) Knox *et al*. (2003).

The change of pH value of a basic toxic solution (Pb, Zn, Cd, U), pH 5, are also deceted in a column system with zeolite. As can be seen, the lower pH change intensity but with same distribution of contaminant (U, Pb, Cd, Zn) in comparison with experimental results from apatite column was observed.

Also, the pH value change was detected after passing of basic contaminated solution (Pb, Zn, Cd i U), pH 7, through apatite-zeolite column (Figure 1, right.).

The pH value changes at pH 7 are significantly less than the basic solution pH 5, and the variations range is in interval from 6.77 to 7.96. The same trend with the pH 7 solution (the largest pH changes) occurred in the Pb and U filtrate obtained through an apatite column. The

pH of the filtrate is quite uniform for the apatite column for contaminated solutions with Pb (7.70-7.94) and U (7.79-7.96). The obtained filtrate from the apatite column for Cd and Zn have linear decrease in pH over all investigated intervals t1-t5: from 7.56 to 6.77 and from 7.49 to 7.00 for Cd and Zn, respectively (Matusik *et al.*, 2012).
Zeolite adsorbent, as a filter in the columns, influenced the pH changes of the basic contaminated solutions (Pb, Zn, Cd, U), pH 7, but with a much smaller effect compared to the same conditions where the filter was apatite. Zeolite had a greater influence on the filtrates when the initial contaminated solution with toxic metals (Pb, Zn, Cd, U) was acidic.
Zeolite and apatite can successfully mobilize Pb at pH 5, stock solution through adsorption/precipitation processes (Figure 2). The U-ion is better immobilized by apatite than by zeolite, while Cd is better immobilized by zeolite and has a very similar affinity for immobilization of Zn over a 180-min in the acidic medium of stock solution, pH 5.
Zeolite and apatite, at the pH = 7.00 are very efficient in reducing the mobility of Pb, at all investigated intervals (t1-t5).

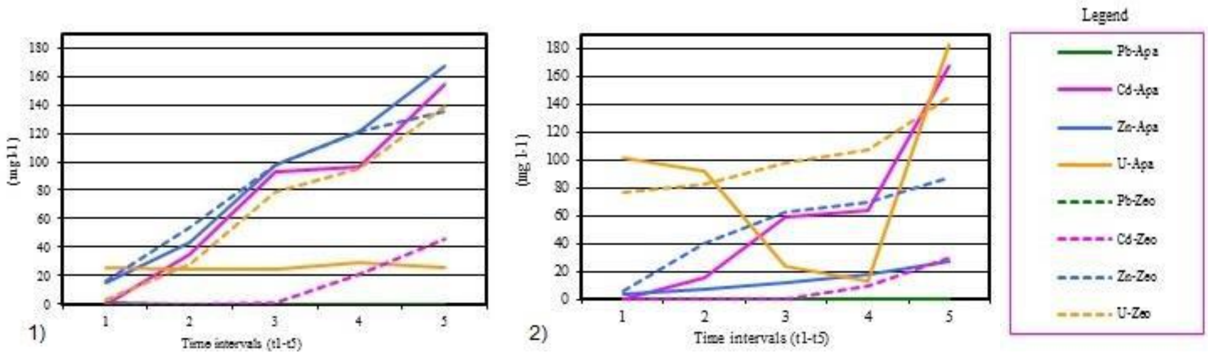

Figure 2. Dynamics of adsorption-precipitation of toxic metals and radionuclides in time, concentration of contaminants in stock solution was 300 ppm, pH 5 (1) pH 7 (2)

Zeolite is very efficient adsorbent for Cd, especially in the first three time intervals (Figure 2). Compared to zeolite, the efficiency of apatite is significantly lower for Cd immobilization. Zn stock solution (pH 7) after passing through apatite and zeolite columns was well imobolized. The Zn content in filtrate is lower than in the acidic stock solution.
The efficiency of zeolite and apatite for U imobilization in neutral stock solution (pH 7) is significantly reduced compared to the acidic stock solution (pH 5)
Immobilization, the process of precipitation of U ions was very slow under neutral reaction conditions, it took 60 minutes (t2) to initiate Ca ions from apatite and create stable complexes. The efficiency of zeolites in the immobilization of uranium ions in the neutral pH medium is weak, the U content in the filtrate increase linearly during the investigated time from 76.66 (t1) to 145.33 mg l/1 (t5).
The efficiency of adsorbent/precipitator mineral resources in the soil-toxic element system in two soil types (Table 1) was investigated in the second part of experiment.
The same amount of added toxic elements (Pb, Cd, Zn) in pseudogley and sand chernozem had a different influence on the content of readily available forms of the same elements, so the content of readily available Pb is 146.0 mg kg^{-1} in sand chernozem, while Pb content in pseudogley is 195.0 mg kg^{-1}. The content of readily available Cd in contaminated soil depends on the pH value, on th pseudogley Cd content is higher (2.70 mg kg^{-1}), while on sand chernozem is lower (1.12 mg kg^{-1}). The similar results were obtainet for the content of readily available Zn: in pseudoglej the content was 121.0 mg kg^{-1} while in sand chernozem was 47.7 mg kg^{-1}, as well as for the readily available form Pb (in pseudogley the content was 195.0 mg kg^{-1} while in sand chernozem 146.0 mg kg^{-1}).

Table 1. Content of water-soluble and easily accessible forms of toxic metals in soil, 24 hours after contamination with Pb, Cd, Zn

Soil type	Variant	Toxic element, (TE), (mg kg^{-1})					
		Pb		Cd		Zn	
		H_2O	DTPA	H_2O	DTPA	H_2O	DTPA
Sand Chernozem	Control (K)	0.2	1.2	0.07	0.44	0.16	0.60
	K+Apatite	0.2	0.6	0.08	0.22	0.14	0.38
	K +Zeolite	0.2	0.9	0.08	0.24	0.08	0.33
	K+Toxic Element	1.5	146	0.20	1.12	0.87	47.7
	K+Apatite+TE	1.4	110	0.18	0.95	0.12	29.5
	K+ Zeolite+TE	1.2	96	0.14	0.95	0.24	32.1
Pseudogley	Control (K)	0.1	2.2	0.08	0.26	0.10	1.24
	K+Apatite	0.05	1.8	0.08	0.22	0.08	0.98
	K +Zeolite	0.1	2.1	0.06	0.21	0.08	0.94
	K+ Toxic Element	1.0	195.0	0.16	2.70	0.82	121.0
	K+Apatite+TE	0.4	69.7	0.15	1.40	0.36	59.8
	K+ Zeolite+TE	0.8	79.2	0.15	2.10	0.56	85.8

The content of readily available forms of toxic metals Pb, Cd, Zn is much higher in the acidic pH of the pseudogley soil (pH in H_2O, 5.55) than in the soil of neutral pH (pH in H_2O, 7.05) in sand chernozem. According to experimental results it can be concluded that zeolite and apatite are efficient as reducants of the content of water-soluble and easily accessible forms of Pb, Cd and Zn in uncontaminated and contaminated soil, regardless of soil conditions (pH, mechanical composition, mineralogical composition, chemical composition), which is of great importance for the remediation of agricultural land. Also, a small difference between the forms of toxic metals for the 720 hour duration of the experiment is statistically insignificant. This indicates that there was no increase in the water-soluble and readily available forms of toxic metals, suggesting strong adsorption/precipitation process performed by zeolite and apatite.

Conclusions

The minelal raw materials (zeolite and apatite) from the territory of Serbia can be successfully used in groundwater and soil remediation technologies by using them as fillers for semi-permeable reactive barriers (PRB). These adsorbent precipitators are efficient in the column system in reducing the mobility of Pb, Zn, Cd and U at different pH values (pH 5.00 and 7.00). In this way, the wide use of non-metallic mineral raw materials from the territory of Serbia was once again confirmed. Zeolite and apatite can be successfully used as minerals for reducing the mobility of Pb, Cd, Zn and U in pseudogley and sand chernozem soils as well as surface irrigation waters. Short equilibrium time, efficiency, high sorption capacity, degree of stabilization are the main advantage for application of these materials from domestic raw material in the technology of immobilization of harmful elements in soil in a simple, inexpensive and successful procedure.

USAGE OF PARSLEY POWDER AS AN ALTERNATIVE CURING AGENT IN FERMENTED SUCUK PRODUCTION

Ali Samet BABAOĞLU*, Mustafa KARAKAYA

Selçuk University, Faculty of Agriculture, Department of Food Engineering, Konya, Turkey
*Corresponding author: asmtbb@gmail.com

Abstract

Sucuk is one of the most consumed traditional Turkish meat products and is a dry, cured, fermented and produced from beef meat, animal fat, curing ingredients and various spices. Nitrate and nitrite, which are used as curing agents in the production of sucuk, are very effective in extending the shelf life of product and in the formation of characteristic color and flavor. However, nitrate and nitrite cause toxic effects on human health. The control and reduce of nitrate and nitrite content in cured meat products is very important for the quality of the products and food safety. On the other hand, nowadays, consumers demand foods that do not contain chemical additives so that current studies focus on the usage of plant-derived natural additives as alternative curing agents. In this study two different groups of fermented sucuk were produced containing C: 100 ppm sodium nitrite (control group) and P: 1.17% parsley powder (100 ppm nitrate equivalent). The effects of parsley powder as an alternative curing agent on residual nitrate and nitrite contents, lipid oxidation, pH values, color and sensory properties of fermented sucuk during storage at 4°C for 45 days were investigated. After 30 days of storage, there was no nitrate in the P group. At the end of storage C and P groups had 2.23 and 2.86 ppm sodium nitrite contents, respectively. C group had lower pH values (4.89-5.05) than P (5.16-5.29). Overall acceptability scores of the sucuks containing parsley powder were higher than the control samples.

Keywords: *Alternative curing, Fermented sucuk, Parsley powder, Residual nitrate, Residual nitrite.*

Introduction

Fermented meat products are widely consumed in the world and sucuk is one of the most important fermented meat products (Karaçıl and Tek, 2013). Fermented sucuk is obtained by mixing ground meat and fat with salt, spices, curing ingredients and filling it into the intestines and ripening sucuk dough at a certain temperature and humidity (Gökalp *et al.* 2004). Nitrate and nitrite are widely used as curing ingredients in production of meat products. Nitrate and nitrite have been used in meat products for improvement of characteristic colour and flavour, preventing of lipid oxidation and antimicrobial effect on foodborne pathogens (Sindelar *et al.*, 2007). Despite these important roles in cured meat products, nitrate and nitrite have negative effects on human health. Nitrite reacts with secondary amines in the body and nitrosamines are formed. Nitrosamines are highly carcinogenic and/or mutagenic compounds (Connolly and Paul, 2001; Roberts and Dainty, 1991). Consumers are demanding natural foods that do not contain chemical additives because of their negative effects on health. This demand of consumers can be met by uncured or naturally cured meat products (Alahakoon *et al.*, 2015; Sebranek and Bacus, 2007; Winter and Davis, 2006). Nowadays, there are increasing studies to remove or reduce the amount of nitrate/nitrite from the formulations and to reduce the amount of residual nitrite in the final product by using plant-derived additives in meat products (Turp and Sucu, 2016). Vegetables have an important potential as natural nitrate sources in cured meat products. Vegetable powders and juices are commercially available and can be used in the production of natural meat products (Sebranek and Bacus, 2007). However, in order to perform the effects of nitrate

on meat products, it must be reduced to nitrite. The reduction of nitrate to nitrite is carried out by microorganisms present in the natural flora of meat, or by microorganisms capable of reducing the added nitrate (Sindelar *et al.*, 2007).
The concentration of nitrate in vegetables varies between 10 and 10000 mg/kg (Özdestan and Üren, 2010). Spinach, carrots, celery, lettuce, beet, dill, leek and parsley are vegetables with high concentrations of nitrate source (Erkmen et al., 1990). Some studies have been carried out on the use of vegetables such as spinach, celery (celery powder and celery juice) and leek as natural nitrate sources in meat products (Horsch *et al.*, 2014; Jackson *et al.*, 2011; Kim *et al.*, 2017; Krause *et al.*, 2011; Magrinyà *et al.*, 2009; Sindelar *et al.*, 2007; Tsoukalas *et al.*, 2011).
The average nitrate content of fresh parsley is 134.63 ppm (Matallana Gonzalez *et al*., 2010). There are few studies using parsley powder as nitrate source in meat products. Riel *et al.* (2017) used parsley extract powder as an alternative for the direct addition of sodium nitrite in the production of mortadella-type sausages. The other study is reduction in the amount of synthetic nitrite in fermented sausages by using parsley powders (Yüzlü, 2018). The aim of the present study is to determine the possibility of the use of parsley powder as natural curing agent (alternative to nitrite) in Turkish fermented sucuk.

Material and Methods

Fresh parsley was obtained from a local market in Konya, Turkey. After the parsley was washed, it was dried under natural conditions (in laboratory). The dried parsley was ground and parsley powder was obtained. It was sterilized for 2 hours at 120 °C.
Two different groups of fermented sucuk were produced containing C: 100 ppm sodium nitrite (control group) and P: 1.17% parsley powder (100 ppm nitrate equivalent). Sucuk batters were produced the following formulation per kg of beef meat: 0.35 kg beef fat, 0.04 kg garlic, 0.02 kg NaCl, 1.5 g dextrose, 45 g spice mixture (red pepper, black pepper, cumin, pimento, and clove). Each batter was inoculated with mixture of *Pediococcus pentosaceus* and *Staphylococcus carnosus* (BFL-T03, Christian Hansen, Hoersholm, Denmark) at a level of 10^7 CFU/kg of sucuk batter. Salt containing 100 ppm sodium nitrite was used for the production of control group and 1.17% (100 ppm nitrate equivalent) parsley powder was added to sucuk formulation for the group of P. Sucuk batters were filled into the casings and were placed in climatic room for fermentation and drying. The climatic room conditions were 24 °C, 90% relative humidity and 0.5 m/sec air flow rate for the first day. On other days, the temperature and relative humidity were gradually reduced until the moisture content of sucuks decreased to 36-39%. Sucuk samples were vacuum packed and stored at 4 °C for 45 days.
pH, color properties ($L*$, $a*$ and $b*$), TBARS, penetrometer, residual nitrate and nitrite analyses of the sucuk samples were conducted at 0, 15, 30 and 45 days of storage. Residual nitrate and nitrite contents were determined also in sucuk batters (before fermentation). Nitrate and nitrite contents were also determined at the beginning of the fermentation in sucuk batters. Sensory analysis of samples was performed on the 15th day of storage.
The pH values of the samples were determined according to AOAC (2000). Color analysis were conducted with colorimeter (Minolta, Japan) according to Hunt *et al.* (1991). The method described by Ockerman (1985) was used to determine the lipid oxidation (TBARS) of sucuks. Hardness of samples were determined using Penetrometer (K-936, Koehler Instrument Company, US) according to Anonymous (1975). Residual nitrate and nitrite contents of samples were determined according to the method described by Cortesi *et al.* (2015). Sensory analysis was conducted by using the method described by Gökalp *et al.* (2015).Results were analyzed by two-ways analysis of variance (ANOVA) using MINITAB 16.0 for Windows. Comparisons of mean values were made using the Tukey test.

Results and Discussion

pH, TBARS, *L**, *a**, *b** and penetrometer values of sucuks are given in Table 1. pH values of sucuks decreased with increasing storage days. Sucuks including parsley powder had higher pH values than control group. Similarly, Jin *et al.* (2014) reported that containing red beet powder increased the pH values of emulsified pork sausages. However, some researchers indicated that plant-derived natural additives such as leek, celery products, parsley extract powder caused decrease in pH of cured meat products (Eisinaite *et al.*, 2016; Fista *et al.*, 2014; Riel et al., 2017).

TBARS value is an indicator of lipid oxidation which is one of the important quality parameters for meat and meat products. TBARS values of samples were expressed as mg malondialdehide (MA) per kg of sample. TBARS values of samples increased with storage days but this increase was not significant ($p>0.05$). The group of P had the higher TBARS values than control group at 0 and 15 days of storage (Table 1). After 15 day storage, there was no difference between the groups of C and P in terms of TBARS values. This could be partly explained that on the 15th day, most of the nitrate was reduced to nitrite which plays an important role in preventing lipid oxidation (Sindelar *et al.*, 2007).

Table 1. pH, TBARS, *L**, *a**, *b** and penetrometer values of samples

	Day	Samples	
		Control (C)	Parsley (P)

Mean ± standard error

$^{A-B}$ Within the same column, values with different uppercase superscripts indicate significant differences ($p < 0.05$).

$^{a-b}$ Within the same row, values with different lowercase superscripts indicate significant differences ($p < 0.05$).

Parsley powder addition affected the lightness (*L**) values of the samples on the 15th and 45th day. *L** values of the group P were lower than control samples in these days. While *L** values of samples increased during storage for the group of P, the highest *L** values were observed at

15 and 45 days of storage for control group. Storage time did not affect the redness (*a**) values of control sucuks while *a** values of P group samples were significantly ($p<0.05$) different. The group of P had lower *a** values than control group due to the dark green color of parsley powder. Yellowness (*b**) values of the samples were not different during storage days. Parsley powder addition decreased the *b** values of sucuks. Similarly, Sucu and Turp (2018) reported that usage of beetroot powder as natural curing agent decreased the *b** values of fermented sucuks.

Penetrometer value indicates the tenderness of samples. There is an inverse relationship between the penetrometer value and the hardness of the sample. Parsley powder addition did not affect the penetrometer values of samples (Table 1.). Lower penetrometer values (decrease in tenderness) were determined in all groups at 30 and 45 days of storage. These results were in accordance with studies indicating that beetroot powder did not affect the textural properties of fermented sausages (Sucu and Turp, 2018) and red beet powder addition did not change the texture of emulsified pork sausages (Jin *et al.*, 2014).

Nitrate and nitrite contents of sucuk batters at the beginning of fermentation were determined as 9.65 and 5.04 ppm for the control group and 43.81 and 6.28 ppm for the group of P, respectively. The presence of nitrate in the control group is thought to be the cause of spices (Özcan and Akbulut, 2007). Figure 1 shows the residual nitrate and nitrite levels of sucuks during storage days. Final products had no nitrate in control group (C) while the group of P included 16.26 ppm nitrate on 0 day of storage. After 15 day of storage, nitrate content was also depleted in the group of P. The reason for the difference between the groups in terms of nitrate levels can be explained as follows: P group was produced with nitrate (plant-derived nitrate) and C group was cured using containing conventional (chemical) sodium nitrite. Residual nitrite levels of samples were ranged between 2.23 and 3.57 ppm during storage. Residual nitrite levels of the samples decreased during storage time (except on day 30 of P group). After 15 days of storage an increase in nitrite level was observed on day 30 due to the reduction of nitrate in the P group. Control group had lower nitrite contents than the group of P. Similarly, Horsch *et al.* (2014) and Sullivan *et al.* (2012) reported that hams including celery powder and celery juice concentrate had higher residual nitrite contents than control samples.

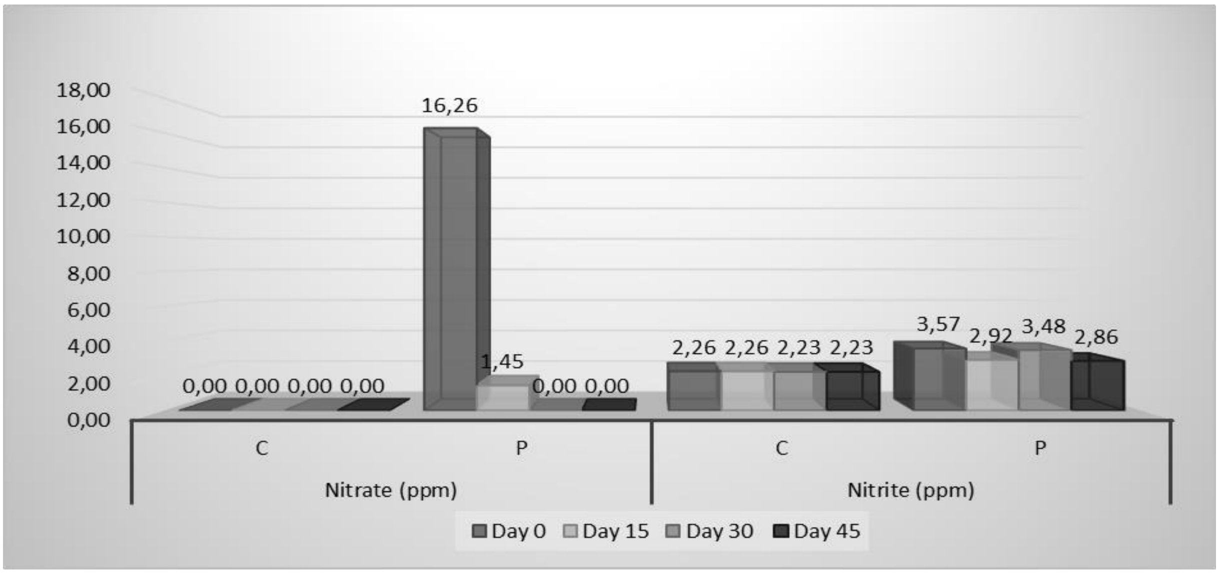

Figure 1. Residiual nitrate and nitrite levels of sucuks

Figure 2 indicates the scores of sensory parameters (odor, color, flavor, texture and overall acceptability) of sucuks. Panelists gave higher scores to group P in terms of flavor (8.07), texture (7.80) and overall acceptability (7.87). The differences between odor and color scores were not statistically significant (p>0.05).

Figure 2. Odor, color, flavor, texture and overall acceptability scores of samples

Conclusions

pH values of sucuks including parsley powder were higher than control. After 15 day storage, there was no difference between the groups of C and P in terms of TBA values. Parsley powder addition decreased the lightness and redness values of sucuks. The tenderness of samples was not affected the parsley powder. After 30 days of storage, there was no nitrate in the P group. At the end of storage C and P group had 2.23 and 2.86 ppm nitrite contents, respectively. Flavor, texture and overall acceptability scores of P group were higher than control group.

Abstract
Grey mold is an important yield loss causing disease in strawberry around the world. The growing resistance of the pathogens requires the continuous formulation of new plant protection products and one of the natural resources of bioactive ingredients are plants. Black pepper and allspice (pimento) are commonly used spices for foods. However, they also have active substances which provide these spices and their fruits aromatic, taste or medicinal properties. This gives a potential for antifungal activity of the extracts of these spices. The aim of the research was to investigate the inhibition of *Botrytis cinerea* growth by black pepper (*Piper nigrum* L.) and allspice (*Pimenta dioica* L.) extracts. The research was carried out at LAMMC Institute of Horticulture, Lithuania. Extracts from dried fruits of spices were produced using subcritical CO_2 extraction. Firstly, inhibition of *B. cinerea* was examined by mixing different concentrations of investigated extracts with PDA and inoculating each plate with 6 mm diameter, 7-day old pathogen disc. Secondly, strawberry leaves were sterilized and placed in Petri dishes with filter paper and 5 ml of sterile water. Leaves were sprayed with mixtures of extracts with sterile distilled water. Then each strawberry leave was inoculated with 9 mm diameter, a 7-day old disc of *B. cinerea.* Both experiments were incubated separately at 22±2 ^{o}C in the dark and evaluated after 2, 4 and 7 days. The results showed that allspice extract demonstrated higher inhibition of *B. cinerea* than black pepper extract both on the PDA and on strawberry leaves.

Keywords: *allspice, antifungal, black pepper, inhibition, pimento.*

Introduction
Botrytis cinerea cause grey mold of strawberries and is responsible for high yield losses in case of the occurred disease (Adebayo et al., 2013; Rasiukevičiūtė et al., 2019). The resistance of the pathogens is growing because of extensive use of chemical compounds in plant protection and the changes in *B. cinerea* genome may be provoked by conventional chemical fungicides (Valiuškaitė et al., 2010; Abbey et al., 2019), which will result in new strains and inefficiency of many plant protection measures against this strawberry pathogen. The resistant pathogens could also be spread through countries with the propagating material (Rasiukevičiūtė et al., 2018). Known as a diverse pathogen, *B. cinerea* insists on changing measures to control it. Finding a natural source of active ingredients for plant protection products may solve resistance problem (Dayan et al., 2009) and let to avoid the contamination of the environment, including human food, with chemical residues as it is known as biodegradable and non-toxic material (Abdel-Kader et al., 2011).
Black pepper (*Piper nigrum* L.) and allspice (*Pimenta dioica* L.) are used as spices for food making and in traditional medicine for their strong aromatic and antioxidant properties (Lorenzo-Leal et al., 2018). The major components of black pepper volatile oil are trans-caryophyllene, limonene and sabinene (Singh et al., 2004; Teneva et al., 2016; Hikal, 2018), meanwhile allspice consist mainly of eugenol or α-terpineol (Song et al., 2016; Chaudhari et al., 2018). Alkaloid piperine gives the bitter taste of black pepper. It is already stated that this component and black pepper oil had antimicrobial properties against several bacteria strains

and foodborne fungi (Nikolic et al., 2015; Teneva et al., 2016; Hikal, 2018). It was determined allspice extract (microwave assisted) ability to inhibit bacteria from food (Lorenzo-Leal et al., 2018). The growth of human pathogen *Staphylococcus aureus* was inhibited by the tannins, isolated from allspice leaves (Al-Harbi et al., 2017) and whole extracts from allspice leaves showed potential to be effective against several human pathogenic fungi (Bhat and Raveesha, 2016).
Some information about activity against plant pathogens could also be found in the literature. Previous studies (Sagitov et al., 2011) reported that black pepper extract reduced wilt (*Fusarium oxysporum* f.sp. *lycopersici*.) symptoms and disease severity on tomato plants. Moreover, black pepper essential oil was effective *in vitro* against *Fusarium graminearum*, and acetone extract was effective against *Penicillium viridcatum* and *Aspergillus ochraceus* (Singh et al., 2004).
There is a lack of studies on the effectiveness of allspice extract and few studies on black pepper extract against plant pathogens thus we aimed to determine whether these extracts have potential to be used in biocontrol of strawberry grey mold (*Botrytis cinerea*).

Materials and methods

The research was carried out at Laboratory of Plant Protection, Institute of Horticulture, LAMMC, Lithuania, in 2019. Dried grinded black pepper, and pimento was purchased from spice suppliers (Saldva, Lithuania). The 10 kg of each material was extracted with liquid CO_2 under these parameters: 40 bar pressure, 10 ^oC temperature and duration 6 hours. The extracts were collected, stored in the refrigerator at 5 ^oC and used in further experiments. Single spore isolate of *B. cinerea* was used in this study. The monoculture was obtained from infected strawberry fruits and identified by PCR (Rasiukevičiūtė et al., 2018). Inhibition of *B. cinerea* was examined by mixing 1000-2000 μl/l concentrations of investigated extracts with PDA. Petri dishes with extracts were inoculated with 6 mm diameter, 7-day old pathogen disc and incubated 7 days at 22 ± 2 ^oC in the dark. Evaluations of *B. cinerea* colony diameter were made 2, 4 and 7 days after inoculation. The diameter of the fungal colony was recalculated to percentage inhibition, using formula (Cherkupally et al., 2017):

Inhibition (%) = (C-T)/C x 100,
there
C – diameter of the pathogen colony in control, cm;
T – diameter of the pathogen colony in treatment, cm.

The inhibition of grey mold infection on detached strawberry leaves was examined with 6 ml/l, 12 ml/l concentrations of black pepper extract (BE) and 20 ml/l, 40 ml/l concentrations of allspice extract (PE). The extracts were mixed with 1% Tween 80 and sterile distilled water. Detached strawberry leaves were rinsed in 70% ethanol 2 min. and in sterile distilled water 1 min. Leaves were placed in Petri dishes with filter paper and 5 ml of distilled water, sprayed with 10 ml of a prepared mixture, inoculated with 9 mm diameter, 7-day old disc of *B. cinerea*, incubated 7 days at 22 ± 2 ^oC in the dark. Evaluations of *B. cinerea* colony diameter were made 2, 4 and 7 days after inoculation and data calculated as percentage inhibition.
Obtained data were analysed using SAS Enterprise Guide 7.1. programme. ANOVA procedure was performed, and means of four replicates were compared by Duncan test at a probability level of 95%.

Results and Discussion

Inhibition of *B. cinerea* colony growth on PDA is presented in Figure 1. Data varied between the investigated extracts and concentrations. Allspice extract had higher inhibition of *B. cinerea* and reached 84.56% at 2000 µl/l and inhibited the pathogen growth by 74.71% at 1400 µl/l and 1800 µl/l. The lowest inhibition by allspice extract was 56.32% at 1000 µl/l. Some information about the impact of allspice extract or essential oil on the various pathogens could be found. Previously, allspice leaves, extracted with petroleum ether and chloroform, was found to inhibit the growth of human pathogenic fungi *C. albicans*, *Microsporum canis* and *Microsporum gypseum* (Bhat and Raveesha, 2016). Furthermore, it entirely reduced the growth of mycotoxins producer *Aspergillus flavus* (Chaudhari et al., 2018). Essential oil of allspice had antifungal effect against *F. oxysporum*, *Fusarium verticilioides*, *Penicillium brevicompactum*, *Penicillium expansum*, *A. flavus*, *Aspergillus fumigatus* (Zabka et al., 2009). Our results could extend the effectiveness of allspice extract with strawberry pathogen *B. cinerea*.

Although Singh et al. (2004) stated that the essential oil of black pepper inhibited the growth of *F. graminearum* for 100% while the acetone extract was 100% effective against *A. ochraceus* and *P. viridicatum*, we found that black pepper extract was not so effective with the highest 46.76% inhibition of *B. cinerea* growth. The other concentrations suppressed the pathogen growth similarly and varied from 40.59% to 44.26%.

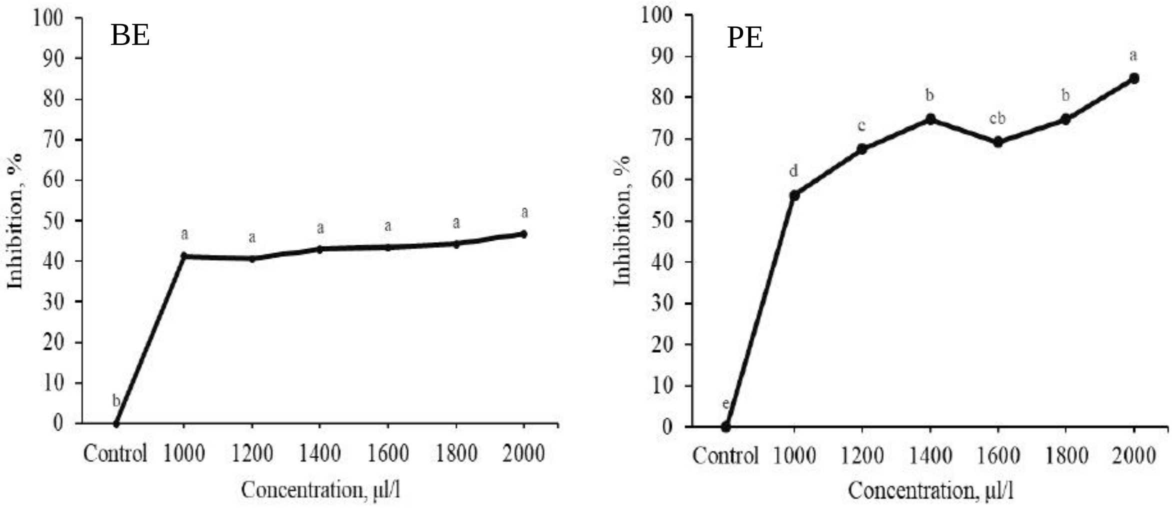

Figure 1. Percentage inhibition of *B. cinerea* colony growth by black pepper (BE) and allspice (PE) extracts *in vitro*

Control of grey mold on detached strawberry leaves was investigated by spraying leaves with the black pepper and allspice extracts. Inhibition of *B. cinerea* colony growth is shown in Figure 2. Only allspice extract reduced infection of grey mold on strawberry leaves, and the result is significant exclusively on the concentration of 40 ml/l, which distinguished from others with 91.89% inhibition 4 DAI. Besides, the mentioned concentration managed to maintain the inhibition of the pathogen growth 7 DAI (79.34%). The 20 ml/l of allspice extract demonstrated weak inhibition compared with control. As expected, black pepper extract had the lowest inhibition, and this result confirms the result of PDA. There is still a need of information about black pepper and allspice extracts effectiveness against grey mold on strawberry leaves. However, black pepper extract was found to reduce the spread of wilt infection on tomato plants after spraying with 4% concentration and showed less effect at 0.5% concentration (Sagitov et al., 2011). Results of our research are in contrast, as black pepper extract had even increased the growth of *B. cinerea* compared to control at 12 ml/l and is considered as ineffective against infection of grey mold on detached leaves. Presumably, the results of our and previous study may differ because of the different composition of the tested plant material due to the used extraction methods. Eugenol and its derivatives were found to inhibit *B. cinerea*, as these compounds are know for their antifungal activity through various mechanisms (Olea et al., 2019). Aguilar-Gonzalez et al. (2015) stated that *B. cinerea* was suppressed *in vitro* and on strawberry fruits by clove (*Syzygium aromaticum*) essential oil with more than 80% of eugenol and its derivatives in its composition. Our study results support the effectiveness of allspice extract and the idea of eugenol as one of the main components of it.

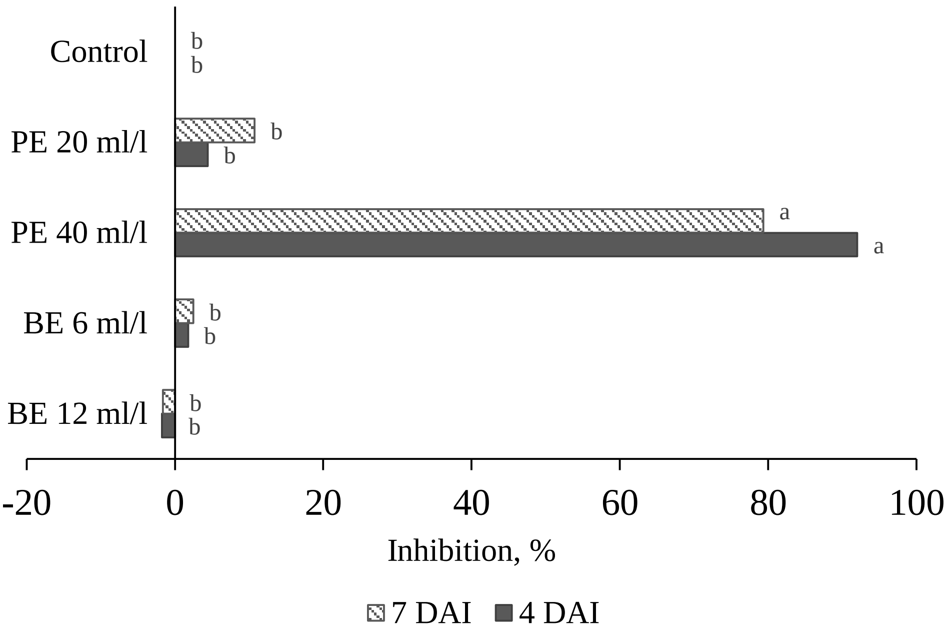

Figure 2. Percentage inhibition of *B. cinerea* colony growth by black pepper (BE) and allspice (PE) extracts on detached strawberry leaves 4 days after inoculation (4 DAI) and 7 days after inoculation (7 DAI)

Conclusions

Allspice inhibited the growth of the strawberry pathogen *B. cinerea in vitro* from 56.32% to 84.56% and black pepper extract consequently from 40.59% to 46.76%. Allspice extract significantly reduced infection of grey mold on detached strawberry leaves. Meanwhile, black pepper extract was not sufficient. To sum up, allspice extract was stronger measure against strawberry pathogen than black pepper extract both *in vitro* and on detached strawberry leaves.

Abstract

The article presents the results of environmental monitoring of wild plant species that are growing in various regions of the Republic of Kazakhstan during 2015-2018.The aim of the research was to study the species diversity of fruit and berry crops of natural flora, contamination of theirberriesby heavy metals.The geobotanical characteristic of wild-growing species of fruit crops was compiled by the route survey method. In the laboratory species of wild-growing plants were identified and a list of species biodiversity were compiled.It was established that the composition of biological diversity includes 34 species of fruit and berry crops from 10 families.In laboratory conditions, the fruit crops contamination by heavy metalssuch asPb, As, Cd, Zn, Cu, Mg has been studied.The completed studies on environmental safety were aimed at studying the gross concentrations of heavy metals in berries. The results of the study of fruits contamination by heavy metals showed that their existance was noted in all the selected samples.*Berberissibirica* Pall.accumulates increased concentrations of Pb (0, 042 mg/kg), *Ribesrubrum* L., *Fragariavesca* L., *Loniseraaltaica* Pall.- As(0.019-0.038 mg/kg); *Crataegus sanguine* Pall. Cd (0.04 mg/kg).It was determind that the number of the accumulation of heavy metals in the examined fruits did not exceed the limits of permissible levels.The results of research characterize the wild berries of the regions of Kazakhstan as safe for widespread use in food and medicinal purposes.

Keywords: *ecology, natural flora, biodiversity, fruits, food security*

Introduction

Now in the world the steady trend of increase in demand for vegetable raw materials and it types of products is observed. Knowledge of the population leads to increase in number of consumers of phytoraw materials, expansion of the range of food, medicinal, perfumery and cosmetic products in economic use. Among forest resources the wild-growing wild berries tooka big place as foodstuff. Their number includes many officinal and vitamin plants (Development Initiatives, 2017.; Termentzi et al. 2006)

The biodiversity of flora of forest fruit crops of Kazakhstan considerably varies, as well on structure and number of various taxons (types, sorts, etc.), and on geography. The major factors causing distribution of plants are confinedness of types to climatic zones and high-rise belts. Estimated works of experts showed that the resource potential of wild-growing fruits is sufficient for satisfaction of domestic demand for vegetable raw materials. In the region of the Kazakhstan part of Altai there is the considerable specific variety of flora and the vegetable resources applied in alternative and traditional medicine (Kotukhov, 2015).

In different regions of Kazakhstan various industrial enterprises of the Republic of Kazakhstan having the considerable technogenic impact on natural ecosystems and health of the population (Alinov, 2017) adjoin to forests. Thus, carrying out biocomplex researches of fruit and berry plants of the woods in these territories is necessary for ensuring food safety of the population, perspective for preparation. Taking into account the above mentioned data, studying of questions according to the resource capacity and environmental safety of wild-growing fruit and berry plants of the regions of Kazakhstan available to consumers became the purpose of the conducted researches.

Material and Methods

Forwarding field researches are conducted by us in forests Eastern (suburbs of Ridder, Pikhtovsky and Riddersky forestries), Northern Kazakhstan (suburbs of the State national natural park "Burabay"). In work the standard geobotanical and resource knowing methods were used. Route reconnoitring methods studied cenopopulationof fruit and berry plants (Bykov, 1957). In field conditions geobotanical methods determined features of body height, development, occurrence and abundance of plants (Bykov, 1970). The visual assessment of quantity of individuals was carried out on G. Drude's scale (Determination methodics, 1986). Identification of plant species was carried out on "Flora of Kazakhstan" (Flora of Kazakhstan,1956-1966). The nomenclature of types was provided according to Cherepanov S.K. report (Cherepanova, 1995).

Objects of research were wild-growing types of berries of the forest territories in Kazakhstan prepared by local population for use as food. Tests of berries of a mountain ash Siberian (*Sorbus sibirica* Held.), guelder-roses ordinary (*Viburnum opulus* L.), bilberries ordinary (*Vaccínium myrtíllus* L.), sea-buckthorn krushinovy (*Hippophae rhamnoides* L.), currants red (*Ríbes rúbrum* L.) were selected during expeditions in 2016-2018 in territories of forest ecosystems of the Kazakhstan part of Altai, Akmolaregions. The scheme of the experimental platforms of forest territories in Kazakhstan is provided on Figure 1. For assessment of the current ecological state of the studied plant species the methods of radiation control of a surrounding medium were used (Instruction on ground examination, 1989).

Figure 1. Location of the experimental sites in the regions of the Eastern and Central Kazakhstan.

Concentration of heavy metals in the tests of medical herbs were defined according to the requirements for carrying out an atomic absorption spectrometry (Interstate standart, 1996). On the basis of the received characteristics the assessment of food safety of the specified types was carried out.

Results and Discussion

Long-term monitoring of climatic conditions of East part of Kazakhstan shows that the remoteness from oceans and a mountainous terrain is defined by degree of continentality, humidification and a temperature schedule during all annual cycle of climatic parameters of the region. Weather conditions of winter are defined by the Mongolia-Siberian atmospheric high bringing cold weather within five months. In spring and winter northeast, east winds prevail. Average height of snow cover on open spaces reaches 50-60 cm with a depth of a freezing of the soil from 40 to 119 cm. The sum of an annual atmospheric precipitation varies on average from 400 to 550 mm. Average temperature of winter is-12,6ºC with short-term frosts in the range 35-45ºC. In Kokshetau mountain region (the northern region) average annual temperature fluctuates in limits 1-2ºC, absolutely maximum temperature reaches to-51ºC, absolutely minimum temperature equals +41ºC. Height of snow cover reaches 30 cm, the amount of precipitation reaches 400 mm (National report, 2018).

In Table 1 the data including information on administrative location of registration platforms, geographical coordinates of the area, height above sea level, exposure dose rate (EDR) are consolidated.

Table 1. Main parameters of the conditions of the experimental sites in places of growth of fruit and berry plants in Kazakhstan

In east regions of Kazakhstan during inventory of the higher vascular plants about 2500 species are established that makes about 44% of total number of species of the higher plants. The list of medical herbs of the Kazakhstan part of Altai includes 783 species 131 families where 87 species are successfully applied in traditional medicine, considerably the bigger number is used in alternative medicine (Kotuhov, 2015].

The total area of studied territories in Akmola region in SNNP "Burabay" occupied with fruit and berry cultures is subdivided into zones: limited economic activity – 3958.8 hectares; tourist – 261.9 hectares; reserved – 620.9 hectares; ecological stabilization – 2372.2 hectares.

In the territory of east Kazakhstan 66 hectares of the territory of the mountain woods are examined. It is established that in the territory of the East Kazakhstan region free air of Ridder city in general is characterized by the increased pollution level. In general, around the city average concentration of dioxide of sulfur made-1.2 MAC, ozone-1.7 MAC, other pollutants – didn't exceed maximum allowable concentration. The background radiation varied 0.11-0.22 mkSv/hwithin two areas. On average in area the radiation gamma hum noise made at the level of 0.13 mkSv/hand was in tolerance limits.
The surveyed registration platforms are carried to the following types of the wood: larch-grassy, fir birch mixed herbs, birch forest mixed herbs. Distribution of berry wild plants in various regions of Kazakhstan is characterized by inhomogeneity. A bigger specific variety is noted in forest and forest-steppe zones. Forest vegetable communities are presented by wide specific structure. By geobotanical researches it is established that 33 species from 9 families of fruit and berry cultures are a part of biological diversity. They are almost widely used in the food purposes, many of them are successfully applied in traditional medicine, separate types (bilberry, dogrose, hawthorn) are applied in pharmaceutics and medical practice (Kubentaev S.A.,2018). Fruit and berry cultures in Kazakhstan grow on plains of northern, east part of the republic and in mountain forests (the Altai, theTarbagatai, the Dzungarian Alatau, the Ulytau). Berry thickets meet on forest edges, on crude shrubby thickets, gorges, stony slopes. In a natural environment many types of wild-growing berries grow on loops of slopes and in deep hollows of a steppe zone.
Possible wind-dust-tranfer can promote accumulation of ecologically dangerous pollutants in fruits of plants. The industrial enterprises, the motor transport are the main sources of the environment of regions pollution (National report, 2018). Considering this fact, for ensuring environmental safety of phytoraw materials, the regions prepared in forest ecosystems, environmental monitoring of quality of the prepared products is carried out. During the research we defined concentration of heavy metals in the studied species of berry plants and the comparative analysis of compliance of raw materials to standards of the maximum-permissible concentration (MAC) is made. Data of results of researches are consolidated in table 2.

Table 2. Central cases of heavy metalscontent in berries, mg/kg

Name of culture	Region	Pb	As	Cd	Cu	Zn	Mg
MAC		0.4	0.2	0.03	5.0	10.0	-
Crataegus sanguine Pall.	Northern Kazakhstan	0.029	0.017	0.003	3.58	6.70	31.72
Crataegus sanguine Pall.	Eastern Kazakhstan	0.030	0.018	0.040	4.84	9.30	32.70
Fragari avesca L.	Northern Kazakhstan	0.023	0.019	0.001	2.4	8.70	29.56
Fragari avesca L.	Eastern Kazakhstan	0.040	0.020	0.004	1.8	9.02	32.50
Berberis sibirica Pall.	Eastern Kazakhstan	0.042	0.019	0.005	2.9	8.90	35.8
Hippophae rhamnoides L.	Northern Kazakhstan	0.031	0.012	0.004	2.9	7.3	25.4
Hippophae rhamnoides L.	Eastern Kazakhstan	0.033	0.021	0.002	3.8	8.8	36.1

Lonisera altaica Pall.	Eastern Kazakhstan	0.028	0.021	0.004	3.2	7.6	34.7
Ribes rubrum L.	Northern Kazakhstan	0.004	0.002	0.004	3.4	9.0	35.8
Ribes rubrum L.	Eastern Kazakhstan	0.029	0.038	0.002	4.2	9.02	36.6

Results of the experiments showed that the range of accumulation of the most dangerous heavy metals in wild berries was in limits: Pb - 0.004-0.042 mg/kg, As- 0.002-0.038 mg/kg, Cd - 0.001-0.040 mg/kg. Wild-growing berries of forest territories of east Kazakhstan accumulate a little high concentration of pollutants, than the fruits collected in forests of northern regions. But distinctions donot have significant sizes. It is possible to explain it with the fact that registration platforms of northern areas are located in a zone of especially protected areas, and the potent industrial enterprises of the republic in the east are concentrated. However, registration platforms of east area are located in the depth of forests at the considerable distances from the industrial enterprises.
The comparative analysis of safety of wild-growing berriesfruits as food and medicinal raw materials showed that noted levels of heavy metals don't exceed values of threshold limit values. These results allow carrying out their preparation for practical application. We noted the single case of insignificant excess of impurity by cadmium of tests *Crataegus sanguine* Pall berries (Table 2). By results of the executed research it is possible to draw an important basic conclusion about the wild-growing berries prepared in forest ecosystems of Kazakhstanregions meets the standards of maximum-permissible concentration accepted in the republic. This conclusion is caused by the fact that the chosen experimental platforms are located at the considerable distances from polluters.

Conclusion

Thus, we executed researches on assessment of environmental safety of fruit and berry plants of various regions in Kazakhstan available to locals and suppliers. Among the used types of phytoraw materials the most widespread 6 types of the wild-growing berries which are widely used by consumers of the region were selected. Results of the executed researches supplement information on the quality of food of forest not wood products of regions in the territory of Kazakhstan for needs of pharmacy stretch, individuals, industrial enterprises.

Acknowledgement

Researches are executed within the project on grant financing of the Ministry of Education and Science of the Republic of Kazakhstan AP05136154 "The resource potential of not wood forest materials and their environmental safety for social and economic development of Kazakhstan regions" (2018-2020).

COMPARING OF PREEMERGENT WEED CONTROL TECHNOLOGIES IN SOYBEAN (GLYCINE MAX)

György PÁSZTOR*, Bálint VÁRADI, Veronika DOBSZAI-TÓTH, Erzsébet NÁDASY

Plant Protection Institute, University of Pannonia, Georgikon Faculty, Hungary
*Corresponding author: pasztor018@gmail.com

Abstract

Soybean is one of our most important protein crops, with worldwide production reaching 320 million tons. It is grown in Hungary at 60,000 ha in the southern part of the country. Its yield is currently around 180,000 tons. Currently it is forbidden to cultivate genetically modified soybean in Hungary, which is why Hungarian soy production has a great value. Current legislation does not allow all of the preemergence herbicides to be used, as well as the use of post-emergence herbicides. Soybean is a very bad weed supressant at the initial stage of development. During this period, herbicide control is warranted, for which at present there are not enough active substances available. The aim of our experiment was to investigate the effects of five preemergent herbicides on soy weeds in field trials. We also examined the phytotoxic effect of the herbicides on soy. The tested active ingredients were s-metolachlor, metobromuron, flumioxazine, metribuzin, and dimethenamid-p + s-metolachlor. The weeds in the experimental area were: *Echinochloa crus-galli*, *Datura stramonium*, *Chenopodium album*, *Ambrosia artemisiifolia*, *Hibiscus trionum*, *Sorghum halepense*, *Cirsium arvense*. During the evaluation, we examined the effect of each active substance on the weeds mentioned earlier. The active substances were classified according to official regulations based on herbicidal efficacy and phytotoxicity.

Keywords: *Soybean, weed control, preemergence, field experiment.*

Introduction

Soybean protein is more than 25% of the total vegetable protein produced in the world. In the period 2016-2017, the total amount of soybean in the world reached 320 million tons. In recent years, the area and quantity of soy have grown in the world (Bányai, 2015).
We have information about the exact area of soy sowing since the 1930s. By 1939, 13 million tonnes of soy has been produced worldwide. At that time, 72% of the beans was produced in China and the rest in other parts of the world, mostly in the USA.
Today, soy is grown on over 100 million hectares worldwide. The main reason for its spread is that it has become the most versatile industrial crop (Balikó et al. , 2007).
In 2018, Brazil take the lead from the US as the world's largest soybean producer, with net total 118 million ton. Total production in 2017 was 338-339 million ton.
From the *Fabaceae* family, the soy has the highest amount, biologically complete protein content (36%). The most important amino acids are found in it, such as lysine, valine or leucine. It can be used to replace animal protein in human food. In addition to its valuable protein content, it also increases the importance of having a fat content of 18%. Its oil is almost 100% digestible, which is an excellent food oil (Radics, 2012). Of our cultivated plants, soybeans play an extremely important role. It has an exceptional role mainly in animal nutrition (poultry, pigs) but also in human nutrition. The great advantage is that it can be easily inserted into the crop rotation, thus reducing the production of cereal crops (Balikó, 2015). Looking at yields, we produced 181,000 tons of soybeans in 2016, ranking 4th in Europe. Only GMO-free soybeans can be produced in Hungary, which makes us competitive in Europe.

Soy has poor weed suppression during its initial development and has a lot of dangerous, hard to control weeds. Soybean production without weed control is not profitable.
Soybean weed control can be done in mechanical, agrotechnical methods, and also with herbicides, that we can use in pre-emergence and post-emergence. Chemical weed control can only be done with the knowledge of weed conditions and we also choose technology based on it (Balikó et al., 2005).
The main problem with the weed control using herbicides, that we have a low number of active ingredients, and the low herbicide tolerance of the crop. We can successfully protect against perennial weeds in the previous year on a cereal fields. However, post-emergence treatments show good herbicidal efficacy (Bárány, 2017).
In order to select herbicides acting on the soil, we need to know the soil's humus content and boundness. The one-year-old monocots are first-class weeds in soy. When selecting herbicides, the longer duration of action is given priority, because the germination time of soy is long. In areas infected with perennial monocotyledons, stubble management is absolutely necessary.
Preemergent technology is used after sowing and before the germination of the weeds. The herbicides sprayed to the soil and sometimes rinsed into a few centimeters of the top layer of soil, from which the majority of weed seeds germinate (Reisinger, 2000). The advantage of this method is that it can be used in any soil tillage system. Its disadvantage is that its effect depends on the amount of rain that has fallen (at least 10 mm) (Dobszai-Tóth, 2014).
The preemergent herbicides are effective against the weeds, tha germinate from the upper part of the soil (monocotyledonous and dicotyledonous plants also), but they are ineffective against the weeds that germinating from a deeper soil layer, such as *Ambrosia artemisiifolia, Abutilon theophrasti* or *Datura stramonium* (Kádár, 2016).
The aim of our experiment was to investigate the effects of five preemergent herbicides on soy weeds in field trials.

Material and Methods

In our study, authors analyzed the differences between herbicidal efficiencies against mono- and dicotyledonous seeds. Against perennial weeds authors did not evaluate herbicidal efficacy, knowing the spectrum of action of the active ingredients. During this study, the following formulations (Table 1) were delivered preemergently in 2019 in 2019.

Table 1. The active ingredients and the herbicides, that were used

Name of the herbicide	**Active ingredient**
Dual Gold	960 g/l S-metolachlor
metobromuron	500 g/l metobromuron
Pledge 50W	500 g/kg flumioxazine
Sencor 600 SC	600 g/l metribuzin
Wing -P	212,5 g/l dimethenamid-p+250 g/l pendimethaline

The active ingredient metobromuron has been previously authorized for use in herbicide testing in soya in recent years.
Untreated control plots did not receive herbicide treatment and were used to compare the herbicidal efficacy of each preparation. Treatments were done in four replicates, and the plots

were randomized. Size of plots: 8m x 3m, 24m^2. The weeds and their development on untreated control plots were recorded at the time of each evaluation. The average weed coverage was determined on 1 m^2 by counting weed species.
On the untreated control plots, we recorded the weeds according to the Balázs-Ujvárosi shooting scale.
Table 2 shows the dosage of the herbicides sprayed to the fields.

Table 2.: Threatments, dosages and method of application

Number of threatment	Threatment	Dosage (l, kg/ha)	Method of application	
1.	Unthreated control			
2.	Sencor 600 SC	0,55	A	preemergence
3.	Dual Gold	1,6	A	preemergence
4.	Wing -P	3,5	A	preemergence
5.	Pledge 50W	0,06	A	preemergence
6.	Pledge 50W	0,08	A	preemergence
7.	metobromuron	3	A	preemergence
8.	metobromuron	4	A	preemergence

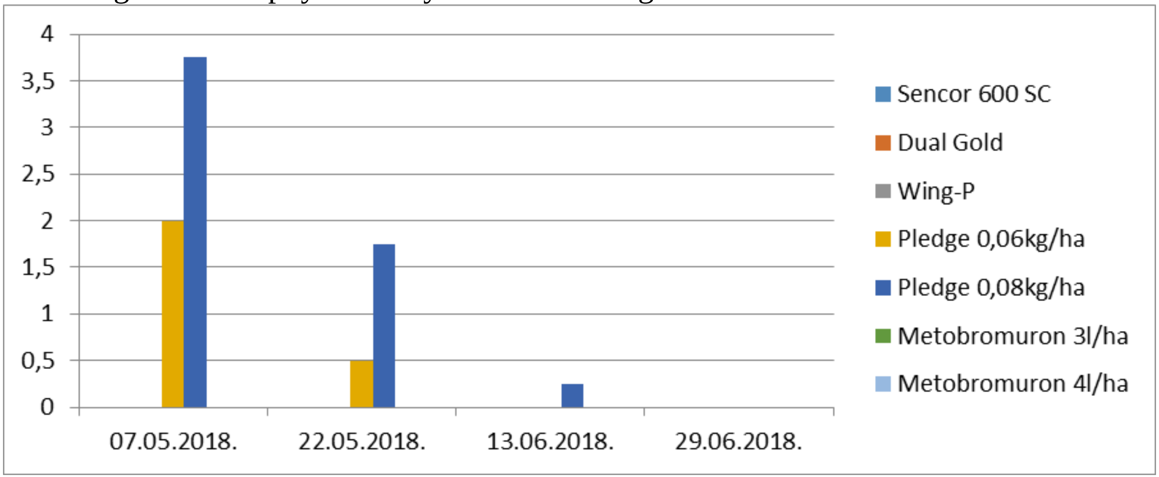
Treatment took place on the 4th day after sowing, when the soy had not yet germinated.
Results were evaluated by one-factor analysis of variance at 5% significance level ($p < 0.05\%$). Hypothesis H1 is that there it is at least one herbicide that has significantly different herbicidal properties. Hypothesis H1 is accepted if p is less than 0.05.

Results and Discussion

The experiment was evaluated for herbicidal efficacy and phytotoxicity according to the official Herbicide Testing Methodology (FVM, 2004).
The first evaluation was performed after weed control, on the untreated control plots (day 8 after treatment) and then on days 23 and 45 of post-treatment.
Between 29 April and 13 May, 19 mm of rain fell, so the preemergic agents were able to exert their herbicidal effects.
All products except *Hibiscus trionum* were properly removed by Dual Gold. Slightly weaker efficacy was seen with Wing-P.
The threatments against *Ambrosia artemissifolia* with the exception of Dual Gold had good efficacy.
With the exception of Dual Gold, other formulations against *Chenopodim album* showed herbicidal efficacy above 90%. We can conclude from this that if the *Hibiscus trionum, Ambrosia artemisiifolia* and *Chenopodium album* in our area are predominant, we do not use S-metolachlor as a preemergent active ingredient. S-metolachlor mainly kills monocotyledon seedlings.
Good efficacy against *Datura stramonium* was observed only at two doses of Sencor 600SC and Pledge 50WP. The other active ingredients are practically ineffective against the tested weed.
Against Echinochloa crus-galli only the Dual gold and Wing-P has very good herbicidal efficacy. The other herbicides have weak herbicidal efficacy against the weed.

Phytotoxicity was observed only with the use of the Pledge 50WP formulation of flumioxazine in the 1-2 leafy state of the soya (Figure 1.), but did not affect the subsequent development and yield of the crop. The weed control efficiencies decreased slightly on the last evaluation date (June 29), and their effects are not exerted during the entire vegetation period. In our study, we concluded that based on preemergent (basic) treatments, mono- and dicotyledonous weeds cannot be efficiently controlled.

Figure 1. The phytotoxicity of the active ingredients in different evaluation dates.



There is a high risk of using preemergent formulations, because they need a 10-20 mm rain in precipitation within 2 weeks of spraying. They are less effective if they do not reach the root zone of weeds, and on the other hand, preemergic herbicides kill mono- and dicotyledon weeds, that germinates in the upper part of the soil layer. They are less effective against weeds germinating from deeper soil layers.

Preemergent threatment is therefore necessary, but it is not enough to maintain the crop in the whole vegetation period, so there is a need for postemergent management as well. The advantage of post-emergence spraying is that we already see the weeds on the board, so we can choose the right active ingredient and preparation for effective protection. We need to recognize the weeds in a few leafy states, because it is advisable to protect against dicotyledons in a 2-4 leaf state, and against the monocotyledons in a 1-3 leaf state. If the spraying is delayed and the weeds are at a more advanced stage, the defense may become ineffective.

Postemergent weed management is especially needed in years when there is no precipitation after the application of preemergent agents, and thus the management is ineffective.

Conclusions

The portion of soy protein in the consumption of the animal feed proteins is 35%, and soy beans exceed 20% of the total plant protein produced in the world. From these informations it can be seen that soybeans play an outstanding role among the cultivated plants. The role of soybeans is extremely important in animal nutrition as well as in human nutrition, and we cannot neglect it.

The biggest challenge of soy cultivation is weed control, weeds directly and indirectly pose a serious threat, thus putting the soy's cultivation and profitability at high risk. The extra costs of weed control greatly increase the costs of cultivation. Soybean suppressed by weeds produce less and the high weed infectation make it difficult to harvest. Soybean production is significantly determined by the appropriate weed control technology. It can not be produced profitably without herbicide usage.

Soybean is both damaged by annual and perennial monocotyledonous and dicotyledonous weeds. Nowadays in hungary there are few problems with the number of active ingredients that can be used. Preemergently only 7, post-emergence 8 active ingredients can be used. The production and placing on the market of potential new active substances can take up to 10 years, which further complicates weed control, and the continuous withdrawal of the active ingredients does not help the plant protection of the soy.
S-metolachlor and pendimethalin + dimethenamid-p are the most effective against seedlings. Flumioxazine and metribuzin are the most effective against weeds that are constantly germinating, but they can be relieved by post-emergence treatment. Metribuzin, flumioxazine, and metobromuron showed the best results against dicotyledonous weeds.
Our studies have shown that although the initial development of soybean is facilitated by pre-emergence weed control under favorable weather conditions, it should not be based on pre-emergence spraying. In a rainless period, preemergent management is ineffective, so post-emergence management is inevitable. In order to keep the soybean free of weeds throughout the vegetation period, post-emergence treatments are also required.

Abstract

In plants, some metals play important role as micronutrient components, significant for growth in low concentrations. If present in higher concentrations than necessary, they can be phytotoxic and cause product contamination. Analysed soils are classified from clay loam to heavy clay, medium to high supply with soil basic fertility parameters, acid to neutral soil reaction. Analysing total content of Cu, Zn, Co, Ni, Cr in soils under apple and plum plantations, an averaged higher content of Cu (13,88 mg kg^{-1}), Zn (33,78 mg kg^{-1}), Co (22,05 mg kg^{-1}), Ni (52,38 mg kg^{-1}) has been measured under plum plantations and the content of Ni (9,55 mg kg^{-1}) under apple plantations. Results of the examination on the presence of the above elements in fruits have shown differences in relation to the content in the soil. Content of Cu, Zn, Co, Cr have had higher average values in fruits of apple and the Ni content has been higher in plums, with higher measured values in individual fruits of plum Cu 3,11 mg kg^{-1} of dry matter), Zn (4,08 mg kg^{-1} of dry matter), Ni (1,32 mg kg^{-1} of dry matter). Adoption of metal from the soil depends on the pH value of the soil, organic composition, the soil type and the concentration of metals in the soil itself. It also depends on the percentage of metal adoption through the plant root, water, metabolic capacity, ion absorption and other. Monitoring the content of metals in soil and fruits is significant in sustainable land use and health food safety.

Keywords: *Metals, Apple, Plum, Soil fertility, Health food safety.*

Introduction

Fruit growing in Serbia is ever increasing with increased area under intensive fruit plantations. Most prevalent are plantations of stone fruits among which two thirds is under plum. Plum has long been the leading fruit species though apple, which is grown on 23.737 ha is dominant in modern production. In European scales, Serbia ranks 12th in areas under apple (Keserović et al., 2014).

For achieving high yields and production of health safe fruits, of particular importance is to choose land as a major source of nutritional substances necessary for plant growth and fruiting. Chemical analysis of soil is important for monitoring conditions of the environment and legislation. (Merry, 2010). Modern growing systems demand soil fertility monitoring but also the analysis of other nutrients of calcium, magnesium, sulphur and microelements: iron, manganese, zinc, copper, boron and molybdenum which plants need in smaller quantities than macroelements. Excess nutrients and those with no physiological significance belong to the group of hazardous and deleterious substances among which the most common are: Cu, Zn, Ni, Pb, Al, Cr. Natural content of hazardous and deleterious substances in soil is of geochemical origin and mostly so negligent that it has no significant effect on agroecosystem contamination. Hazardous and deleterious substances deriving from anthropogenic sources in soil are found in forms that are easily accessible. Accessibility of nutrients and their further transport in plants is affected by mechanical composition, soil reaction, humus content, calcium carbonate content and available phosphorous in the soil.

Different fruit types have different needs for adoption of biogenic elements. Deposition of certain elements is also different so in some plants, the largest concentration is in the root, in

others, in leaves or buds while the maximum allowable concentration in fruits is determined based on different parameters including human medicine. Absorption and accumulation of heavy metals in plants depend on bioaccessibility and contents in the soil, genetic properties of plants, edaphic and other ecological factors. These differences are mostly conditioned by plants' genetic base or other parameters.
The aim of the investigation is determining effects of Cu, Zn, Co, Ni, Cr presence in soil on the content of the same elements in fruits of plum and apple.

Material and Methods

Investigations were carried out in September 2018 by sampling of the soil in the rural area of Čačak, in apple and plum orchards of the following cadastral municipalities: Baluga Trnavska, Trnava, Prislonica, Pridvorica, Vranići, Gornja Gorevnica, Vranići and Miokovci. Sampled orchards were marked by GPS coordinates: N from 4352028 to 4357480 and E from 2016305 to 2027156. Sampling depth was 0-30 cm. Analysed soil under plum plantations was classified as clay loam and light clay with 15.80-27.50% share of clay fraction and 42.10-58.00% of physical clay. Soils under apple plantations are classified as heavy clays on three sites with about 46.0% share of clay fraction and 71.40-79.20% physical clay. In apple orchards in Baluga Trnavska, the soil is classified as clay loam. Agrochemical characteristics of soil are analysed at the laboratory of the Fruit Research Institute, Čačak using the following methods: pH value in H_2O and 1N KCl-u (potentiometrically); humus (method by Kotzman); total nitrogen (method by Kjeldahl); easily accessible phosphorous and potassium (AL method, P_2O_5- colourmetrically, K_2O flame photometrically). The samples were previously dried at ambient/room temperature and sieved through a sieve ≤2 mm. The total content of macro and micro elements is specified by mineralization of soil samples with HCl and H_2SO_4, and the contents of the same elements in fruits upon a modified procedure (Morais et al., 2017) and reading on AAS (Perkin Elmer, 2018).

Results and Discussion

Numerous studies point to the influence of mechanical composition, soil reactions, humus content on the availability of nutrients. Strongly acidic soils are poor in available forms of macroelements and certain microelements for plants, while at the same time these soils contain higher amounts of ions of Al, Fe and Mn, available to plants, which in high concentrations, have toxic effect (on plants) (Dugalić et al., 2008). Research results (Tab. 1) have shown that the analysed soil is of weakly acid to weakly alkaline reaction. Average values of the active soil acidity (pH/H_2O) in the humus horizon (0-30cm) under plum and apple plantations is about 6.82. Substitutional soil acidity (pH/KCl) was higher in soils under apple plantations, which is caused by the mechanical composition of soil. Acidification process can be regarded as a primary cause of the reduced productivity of agricultural land (Mrvić et al., 2012), which was in the past substantially accelerated by anthropogenic factor, primarily increased emission and deposition of acidic contaminants, improper use of mineral fertilizers and other (Sparks et al., 2002). Humus supply is low to medium, of higher average values under apple plantations of 3.09%. Total nitrogen is, on average, of medium content up to 0.16%. The content of easily accessible phosphorous varies on the sampled parcels. The lowest value 4.15 mg/100g of soil is in acid reaction soil in Prislonica while the content of easily accessible P_2O_5 is high in other parcels. Under conditions of increased soil acidity, phosphorus as one of the most important macronutrients in the forms bound with Al and Fe becomes inaccessible to plants (Barber, 1995). The investigated soils are optimally supplied with easily available K_2O. The research results of all analysed parameters are consistent with the results of Milivojevic et al., 2017.

*parcels under apple (1-4)
*parcels under plum (6-9)

In soils with alkaline reaction, mobility and accessibility of phosphorus, potassium, magnesium, iron, manganese, boron, cobalt, copper and zinc is decreased. Exceptions are (found in) molybdenum, sulphur, nitrogen, which are better adopted with an increase of pH value of the soil solution. Results of the content of macro and micro elements are shown in tab. 2. The average Cu content in the analysed parcels ranged from 9.2-25.3 mg kg^{-1}. According to the literature (Pendias Kabat et al., 2001) zinc content in soil should not be higher than 200-300 ppm. It is believed that high values of the content of total copper (> 60 mg kg^{-1}) are caused by fungicide application based on copper compounds (Schramel et al., 2000; Pietrzak and McPhail, 2004; Wightwick et al., 2006; Rusjan et al., 2007). The research results of the total copper content in smonitsas of Western Serbia (Milivojević et al. 2017) amounted to somewhat higher values in relation to our investigations. The content of Co was 12.8-31.0 mg kg^{-1}, and the content of Zn varied considerably between the analysed parcels 7.3-59.4 mg kg^{-1}.

Table 2. Content of micro elements in soil

No. of sample	**Cu**	**Co**	**Zn**	**Cr**	**Ni**
	mg kg^{-1}				
1	10,4	12,8	26,5	10,2	60,8
2	9,2	18,5	51,8	9,8	30,8
3	17,2	21,3	13,0	8,9	63,9
4	17,5	18,5	21,5	9,3	2,9

8	11,6	24,8	33,5	9,0	50,8
9	25,3	31,0	59,4	10,1	112,3
average	**13,88**	**22,05**	**33,78**	**9,38**	**52,38**

*parcels under apple (1-4)
*parcels under plum (6-9)

The presence of the total Cr did not show greater interval variation from 8.9-10.2 mg kg^{-1}, in contrast to the presence of Ni, with the content from 2.9-112.3 mg kg^{-1}. Boskovic Rakočević et al., 2014: found lower values of the Cu and Zn content in the soil, and the lower value of Zn in the fruits of plums, and an approximate value of Cu in relation to our investigations. Minerals and toxic element concentration in fruit are often variable and impacted by the species and cultivar, climatic conditions, geological origin of soil, the usage of fertilizers and other agricultural chemicals, plant growth stage and soil elements availability (Ekholm et al., 2007). The usage of fertilizers and pest control chemicals, urban industrial activities, and irrigation and fertilization type may affect the accumulation of microelements in soils (He et al., 2005). Microelements which have a role of regular enzyme functioning may also have adverse effects on human health depending on the intake quantity.

Investigation results show that, on average, the content of all analysed metals in apple fruits is higher in relation to plum fruits. However, looking at individual samples, there are deviations from previously mentioned. Cu content in the fruits apples ranged from 1.63-2.87 mg kg^{-1}, and in plum fruits 1.18-3.11 mg kg^{-1}. Miclean et all., 2000 report that the Cu content in agricultural products should be between 4 and 15 ppm, and according to the limit values of the World Health Organization, it is 3 mg kg^{-1} and less. The presence of Co in certain samples is below the level of detection to a content of 0.55 mg kg^{-1}. Zn is present in the amounts of 1.88-2.95 mg kg^{-1} in apple and 0.50-4.08 mg kg^{-1} in plum. According to the FAO/WHO (1984) allowable Zn in fruits is up to 27.4 ppm. The content of Zn in our investigations is within the range of optimal values whereas the Cu content is above the values allowed according to FAO/WHO and optimal values, according to Miclean et all., 2000. There are not many data on levels of cobalt (Co) in foods of plant origin in the scientific literature. The available data showed low levels of this micronutrient, often under 0.001 mg/100 g.

Table 3. Content of micro elements in fruits

No of sample	**Cu**	**Co**	**Zn**	**Cr**	**Ni**
	mg kg^{-1}				
1	2,87	<0,05	2,95	0,85	1,21
2	1,63	0,55	2,89	0,46	0,53

*apple fruits (1-4) *plum fruits (6-9)

Results of Osmanovic et al., 2014, show significantly higher levels of Zn and Cu, and the approximate values of Cu in the fruits of plum in relation to our investigations. Hegheđűş-Mindru Ramona et al., 2014 found similar values of the Cu content in fruits of apple and plum, and the content of Zn and Co. was higher in our investigation results.

Average contents of Cr and Ni in apple is of approximately values (0.77-0.79 mg kg^{-1}), and in plum fruits the content of Ni is increased. FAO/WHO, 2001 anticipates a limit of 2.3 ppm for the content of Cr, which is within the limits of our values. An upper tolerance limit for the fruits of Ni is 0.5 mg to 100 g^{-1} of Ni and the values are within the allowable value for our investigations. Fruits usually present Ni between <0.004 and 0.05 mg 100 g^{-1} (Szefer and Grembecka, 2007). The recommended daily intake of Ni is in the range of 302–735 µg (Roychowdhury et al., 2003). A RDA for Cr is not well defined, but it is considered to be between 25–35 µg/day, fruits and vegetables being the major dietary contributors of Cr intake. Increased heavy metal concentrations in food may adversely affect human health due to the predominating soil-plant pathway for their entry into the human body (Liu et al. 2013).

According to the data from the studies on phytotoxicity (Kabata - Pendias, 2011), Ni is, unlike others, a very mobile element in plant (Cr), and its transfer to fruits is the result of the phloem mobility. Accessibility of heavy metals, as well as their adoption by plants, depends on a number of factors, primarily on their overall and available content in soil, followed by soil reaction, organic matter content, oxidation-reduction conditions and other (Adriano, 2001; Kabat - Pendias, 2011), while the uptake of heavy metals depends on the plant type too (Overesch et al., 2007). Particularly outstanding is the influence of soil pH where the higher the acidity the greater the adoption of metal and vice versa, i.e. alkalinity increase leads to metal immobilization.

Conclusions

Investigation results show that the analysed soil is slightly acid to slightly alkaline. Humus supply is low to medium, of higher values, on average, under apple plantations with 3.09%. Total nitrogen is, on average, of medium content up to 0.16%. The content of easily available phosphorus differs on sampled parcels with the lowest values 4.15 do 74,81 mg $100g^{-1}$ of soil P_2O_5. The investigated soils are optimally supplied with easily available K_2O.

Total content of deleterious and hazardous substances in soil shows that the average Cu content in the analysed parcels ranged from 9.2-25.3 mg kg^{-1}. The content of Co was 12.8-31.0 mg kg^{-1} and the content of Zn varied considerably between analysed parcels, 7.3-59.4 mg kg^{-1}The presence of the total Cr did not show greater variation in the interval from 8.9-10.2 mg kg^{-1}, in contrast to the presence of Ni, having a content from 2.9-112.3 mg kg^{-1}.

The presence of heavy metals in fruits of apple and plum show that Cu in apple fruits ranged from 1.63-2.87 mg kg^{-1}, and in fruits of plum 1.18-3.11 mg kg^{-1}. The presence of Co is in certain samples below the level of detection up to 0.55 mg kg^{-1}. Zn is present in the amounts from 1.88-2.95 mg kg^{-1} in apple and 0.50-4.08 mg kg^{-1} in plum. Average content of Cr and Ni in apple is of approximate values (0.77-0.79 mg kg^{-1}), and in plum fruits, an increased Ni content is noticeable.

Availability of metals, as well as their adoption by plants, depending on their total and available content in soil, the reaction of soil, which has a significant effect, the content of organic matter, the oxidation-reduction conditions and the presence of heavy metals depend on the fruit type as well. In order to obtain health-safe food and assess the amount of fruit consumption, it is necessary to analyse each sample of soil and fruit individually.

Acknowledgments

Investigations in this work were realized by the funds of the Ministry of Education, Science and Technology Development RS, "Biodiversity as a potential in eco-remediation technologies of the damaged ecosystems", TR-31080, and through the project funded by the Ministry of Agriculture, Forestry and Water Management entitled "Determination of tolerance of various fruit species on the analysed contents of deleterious and hazardous substances in agricultural land and irrigation water".

EFFECTS OF TEA WOOD ESSENTIAL OIL ON *TRIBOLIUM CONFUSUM* DU VAL. AND *ORYZAEPHILUS SURINAMENSIS* L.

Dragana BOŠKOVIĆ*

University of Novi Sad, Faculty of Agriculture, Novi Sad, Serbia
*Corresponding author: dragana.boskovic@polj.edu.rs

Abstract

Tribolium confusum Du Val. and *Oryzaephilus surinamensis* L. are important storage pests which cause a significant decrease in yield. For controlling storage pests, chemical pesticides have been used for years. However, their application can leave residues in food, have a negative influence on human or animal health and manifest high ecotoxicological influence on the environment. Therefore, there is a justifiable need for safe and eco-friendly measurements against these two storage pests. One of the ways is using essential oils or plant extracts. The aim of this study was to explore the contact, the contact – digestive and the repellent effects (Y tube olfactometer) of tea wood essential oil (*Melaleuca alternifolia*) on *T. confusum* and *O. surinamensis*, applied at concentrations of 0.5%, 1% and 2%. Methanol and water were used for the control treatment. The experiment was performed in four replications with 10 insects in each, at a temperature of 25±1˚C and 45–70% RH. Effects were determinated 24, 48 and 72h after the application. Tea wood essential oil caused the highest mortality of *T. confusum* (95%) in the concentration of 2% after 72h in contact test, while in the contact–digestive test, the mortality ranged from 22.5 to 80%. Essential oil of tea wood did not have such a good influence on *O. surinamensis*. The highest mortality of *O. surinamensis* was in contact-digestive test with efficiency of 52.5% after 72h, while in the contact test caused mortality in the range of 15-50%. Tea wood oil showed an excellent repellent activity to both species in concentration of 2%.

Keywords: *Tribolium confusum, Oryzaephilus surinamensis, tea wood, essential oil.*

Introduction

Storage pests are important pests worldwide of many crops, including flour, grain, stored food or other stored organic matter in warehouses, stockrooms, grocery stores, homes, and silos. These pests can make damage by completely destroying products or partially damaging it what causes less quality of the products, especially grains. These damaged grains have less or no ability to germinate what causes significant economic loss. It is estimated that around 30-35% of the yearly harvest in the world is decreased because of damages caused by stored pests (Dubey *et al.*, 2008; Pavela, 2016). The growing population of humans requires a greater amount of available food and there is constant importance of protecting and preserving stored products in order to reduce losses from harvesting to consuming food. Reduce of harms of stored products was achieved by using chemical pesticides for years. However, uncontrolled and more frequent uses of chemical pesticides caused many problems, like leaving toxic residues in food, having a negative influence on human or animal health and manifesting high ecotoxicological influence on the environment (Wilson & Tisdell, 2011). Therefore, there is a justifiable need for safe and eco-friendly measurements against storage pests.

One of the possibilities is using essential oils or plant extracts. Application of botanical insecticides has a long history even if their use was suppressed by new synthetic pesticides. Botanical insecticides were even used in ancient lands like Greece, India, and China (Isman, 2006). Many essential oils have insecticide activity. It is hard to determine essential oils mode of action because these oils are a complex mix of secondary metabolites with volatile characteristics. Separation and extraction of the active substance in the aim of studying the mechanisms is a difficult task (Wu *et al.,* 2015). Tea tree (Picture 1a) essential oil derived from the Australian native plant *Melaleuca alternifolia* (*Myrtaceae)* shows antifungal, antibacterial and insecticide activity (Arweiler *et al*., 2000; Hammer *et al.,* 2003). A monoterpene - terpinen-4-ol is the main component in tea tree essential oil which shows fumigant toxicity against the pests of stored grains (Liao, 2018).

Picture 1: a) Tea tree (http://hennacaravan.com); b) *Tribolium confusum (*https://e-insects.wageningenacademic.com) c) *Oryzaephilus surinamensis* (https://keys.lucidcentral.org)

Tribolium confusum (Jacquelin du Val) or confused flour beetle (Picture 1b) is a cosmopolitan insect which attacks and infests numerous grains or grain products (Park, 1934; Ajayi *et al*., 2019). It is very similar to the red flour beetle - *Tribolium castaneum* and the destructive flour beetle - *Tribolium destructor*. Confused flour beetle feeds on broken grains, grain dust, flour, cereals, rice, pasta, dried fruits, nuts, and beans but cannot feed on whole grain (https://entnemdept.ifas.ufl.edu). Grains infested by this pest have reduced weight, lower quality, bad baking properties followed by displeasing smell which reduced the marketability (Vayias, 2006).

Oryzaephilus surinamensis (Linnaeus) or saw-toothed grain beetle (Picture 1c) is a pest on whole grain and grain products but feeds on other products too, like dried fruit, chocolate, cereals, tobacco, nuts, and spices making them unsaleable and unappealing (Pricket *et al.*, 1990). There is a similar species called *Oryzaephilus mercator* or Merchant grain beetle. One of the main differences is the fly ability of *O. mercator*. The main problem of their infestation is the contamination of food with feces and dead bodies (Lyon, 1991).

Material and Methods

The experiment was conducted during 2019 at the Laboratory for Biological Research and Pesticides, Department of Phytomedicine and Environmental Protection, Faculty of Agriculture, University of Novi Sad. Laboratory studies were conducted to assess the effect of tea tree oil against confused flour beetle and saw-toothed grain beetle. In the study commercially available essential oil is used. Adults of *T. confusum* and *O. surinamensis* were obtained from laboratory cultures maintained in the dark in incubators at 25±1˚C and 70-80% RH. *T. confusum* was reared on wheat flour and *O. surinamensis* on cereals. The repellent effect of two solution of essential oil (1% and 2%) was evaluated using a Y - tube olfactometer. After 24h, the tested repellency was determined and expressed by the pre-referendum index (PI). Effect of essential oils on the mortality of these two pests was tested using two different methods for contact and contact - digestive treatment. The essential oil, firstly dissolved in methanol, was applied at concentrations of 0.5, 1 and 2%. The bottom of the Petri dish was treated with 0.3 ml of essential oil solution with different concentrations in the contact test and let to dry at the room temperature. In the contact digestive test, firstly are made flour disks at the bottom of the Petri dish and treated with all 3 solutions (0.3 ml). Of each species, separately, 10 adult insects were placed into Petri dishes. The experiment was set in four replicates. Methanol and water were used for the control treatment. Petri dishes were incubated in a thermostat at 25°C and 45-70% RH. Mortality was checked after 24, 48 and 72h. Datas were processed with Statistica 10 statistical software. One-way analysis of variance (ANOVA) of mortality was used to determine the statistical significance compared with the controls ($p<0.01$ were considered significant).

Results and Discussion

The results of this bioassay with tea tree essential oil in different concentrations on *T. confusum* and *O. surinamensis*, depending on the mode of exposure, are presented in Tables 1-4. Tea wood essential oil caused the highest mortality of *T. confusum* in the concentration of 2% after 72h in contact test, where mortality ranged from 57.5-95%. In contact-digestive test the mortality ranged from 32.5 to 80% after 72h. The lowest mortality was in contact-digestive test in concentration of 0.5% after 24h where only 5% were dead.

During the study it was found that tea tree has the repellent effect at both concentrations (1% and 2%). The oil showed an excellent repellent activity to both species in concentration of 2% (Table 5).

Table 5. Repellent activity

Tea tree essential oil			
	PI 1%	PI 2%	Repellent activity
T. confusum	-0.4	-1	Repellent
O. surinamensis	0	-1	Repellent

-1.00 to -0.10 repellent activity; -0.10 to +0.10 neutral activity; +0.10 to +1.00 attractant activity

In the laboratory studies of Callander and James (2012) the effect of tea tree oil (terpinen-4-ol chemotype) was assessed against different stages of the *Lucilia cuprina,* where formulations containing 1% oil caused 100% mortality. Klauck et al., (2014) evaluated the insecticidal and repellent effects of tea tree and andiroba essential oils on *Haematobia irritans* and *Musca domestica*. Tea tree oil at a concentration of 5.0% had 100.0% efficacy after 12 h of exposure to *M. domestica*. Cutler *et al*., (1996) explored the effect of thirteen essential oils on *T. confusum*. Eucalyptus oil showed the very best results. The induced mortality was 100%. Liao *et al.,* (2016) determined but not with certainty that tea tree essential oil acts on the mitochondrial respiratory chain in insects. In the study of Liao *et al.*, (2018) it was established that tea tree has fumigant toxicity on *T. confusum* which increases over time with the mortality of 98.86%. *Ocimum gratissimum* essential oil showed insecticidal activity against *O. surinamensis* (LC50 0.19 µL/L) (Campolo et al., 2018). Monoterpenoid, 1,8-Cineole, which can be found in tea tree essential oil possess strong larvicidal, insecticidal, fumigant toxicity repellent and antifeedent activities against *O. surinamensis* (Padalia et al., 2015).

Conclusions

Essential oils have substantial potential for pest management in stored places and in the fields. These compounds reduce negative impacts on human health and the environment. Tea tree essential oil shows insecticidal and repellent activity against many insects, as shown in this study on T. *confusum* and *O. surinamensis.* The better effects were on *T. confusum* than on *O. surinamensis*, with mortality range of 57.5-95% in contact test after 72h. Highest mortality of *O. surinamensis* was in contact-digestive test with efficiency of 52.5% after 72h in concentration of 2%. Essential oils from plants are natural and biodegradable sources of bioinsecticides which are expected to spread use in the near future.

THE EFFECT OF SOME CHEMICAL ADDITIVES ON THE FOAMING PERFORMANCE OF THE PASTEURIZED LIQUID EGG WHITE

Mehmet Musa ÖZCAN[1*], Hatice Kübra YAVUZ[2]

[1]Department of Food Engineering, Faculty of Agriculture, Selçuk University, 42079 Konya, Turkey;
[2]ANAKO Food Engineering**,** Food Safety Manager Konya, Turkey.

Abstract

The foam stability of egg white changed between 46.7(0.5 mg/kg phospholipase at 24h) and 64.6 (0.5 mg/kg phospholipase.48 h). When tartaric acid was added to egg white in the rate of 5 %, an increasing in foam capacity and stability was observed. In the use of sodium acid pyrophosphate **(**SAPP), especially on performance effects, it was seen that the similar results to citric acid and tartaric acid were obtained. In control group 1., while the effect on foam capacity is 200 units, due to the fact that it was not been form cream of lump of dough. In group 2, whose contamination of egg yolk is low, it was seen that it was only 40 units. In the use of citric acid, that important effects on foam capacity can be provided on condition that the content of egg yolk is kept at a certain levels. In control group 1 having low contamination, while the effect on foam capacity is 200 units, due to the fact that it does not been form cream of lump of dough, in group 2, whose contamination of egg yolk is low, it was seen that it was only 40 units. In the rates of tryethyl citrate of 0.1 -1 ml/kg, in the studies on two different control group, in pH and brix, any variation was not observed. While foam capacity values change between 640 and 690, and in stability values ranged from 60.3 to 67.4. It is considered that the rate of maximum using was around 0.2 ml/kg. Triethyl citrate protects egg white against the detrimental effects of egg yolk.

Introduction

Eggs are used in the preparation of many food products. The most well-known uses of eggs are based on the liquid eggs coagulate or solidify when heated (cakes, breads, crackers); whipping of egg white produces lighter and airier products (meringues, angel cake); and emulsifying egg yolk phospholipids and lipoproteins produces mayonnaise, salad dressing and sauces (Davis and Reeves, 2002). A foam is a colloidal dispersion in which a gaseous phase is dispersed in a liquid or solid phase. Food foams are dependent on the surface activity and film forming properties of specific protein components (Kinsella, 1984). Many proteins are too hydrophobic or too hydrophilic for good foaming properties, and so chemical or enzymatic modification of them makes them more surface active. Foaming agents generally used in the food industry are modified natural proteins of soy, casein, egg white, whey, whey protein isolate lactoglobulins, lyzosyme (Mita *et al.*, 1978; German and Phillips, 1994;Narchi *et al.*, 2007; Patino *et al.*, 2008; Kralova and Sjöblom, 2009). Protein film stability and elasticity vary due to the fact that proteins consist of different amino acids so that different intermolecular interactions ocur (German and Phillips, 1994; Kralova and Sjöblom, 2009). Hen eggs are very well known foaming ingredients (Kamat *et al.*, 1973). They produce large volume, stable foams which coagulate during heating. When egg white was beaten, air bubles were trapped in the liquid albumen does. During the beating of egg white, the air bubbles, decrease in size and increase in number, and the translucent albumen takes on an opaque but moist apperance. As increased amounts of air are incorporated, the foam becomes stiff and loses its flow properties (Lowe, 1955). Overwhipping insolubilizes too much of the ovomucin and lowers the elasticity of the bubbles (MacDonnel *et al.,* 1955). If the first foam is beaten for a long period, the darinage liquid exhibits poor whipping properties (Forsythe and Bergquist, 1951). The greatest amount ovomucin is removed with the first whipping (Macdonnell *et al.,* 1955) but about one third of the ovomucin can be recovered form the drainage after the third whipping (Cunningham, 1976). In addition to ovomucin, lysozyme, globulins A1 and A2 and conalbumin are retained in the foam (Cunningham, 1976). The structure of egg albumen allows it to perform well in foams and each component carries out a different function (Stadelman ve Cotterill, 1994). Globulins are excellent formers but the foaminess is significantly affected by the protein interactions with ovomucin, lysozyme, and, to a lesser extent, ovomucoid, ovotransferrin, and ovalbumin (Johnson and Zabık, 1981). The aim of this study is facing the egg whites industry, the biggest problem is yolk-white distinction, during the egg yolk with contamination as a result of decrease foam capacity and stability, to investigate the food additives that may be used for improvement.

Material and Methods

Pasteurized egg whites were provided from ANAKO Liquid Egg Industry in Konya in Turkey. Pasteurized egg whites were used in the study because of hygiene.

Different properties are different batch production reference egg whites are used for each additive and at different times because of the realization of the trial, the control group showed changes as a result of egg whites. Two different control group has been compared result for each additive.

Kitchen Aid Professional sample is taken and transferred to the mixer. 6th cycle in the mixer for 1 minute, blended for 2 minutes at the 10th cycle. After the beating, the foam formed is transferred to measuring cup to 1000 ml. Leaves no residue in the mixer vessel is attempted whenever possible (Yavuz and Özcan, 2016). For measuring, sample was heated to 20^{o}C.

Foaming capacity relative reading of the following formula

%RWC= V*100/75

Foam do not fall, after measuring whipping capacity, and at the end of an hour amount of leakage weigh and calculated whipping stability by the Formula:

S: Whipping stability

%S= (1 - W/77,25) x 100

pH measurements was used in table-top type device. Device was calibrated by the buffer solutions for 4.01, 7.0 and 10.0. pH meter probe was pressed into the sample immersed in pH measurement button and wait 40 sec. After measuring the pH value was recorded as time runs out on the screen. For brix, refractometer at 20 °C the calibration was done with distilled water. The prepared egg white samples were incubated in a warm water bath until 20 °C. For Brix, the refractometer was used. Reading sample is brixs% (MacDonnell *et al.,* 1955).

200 ml egg white's samples was heated at 20 °C. About 200 g was provided to dissolve by the addition of sugar. Sugar and egg white mix to 4th cycle for 1 min and 10th cycle for 4 minute were mixed. After blending, caliper measurement was taken from the high portion of non-container mixer. So, merinque dough performance was measured (Yavuz and Özcan, 2016).

Results and Discussion

Effect of phospholipase enzyme on egg white performance at different times are given in Table 1. With addition of phospholipase to the environment, there were not any important deviation in pH and Brix (Table 1).

Table1. Effect of phospholipase enzyme on egg white perfornance at different times

Samples	pH	Brix (%)	Foam capacity (%)	Foam stability (%)	Heigh of meringue crema(cm)
Control	8.9	14.1	513	51.7	-*
0.25 ml /kg phospholipase 24h	8.9	14.1	1066	54	7.3
0.25 ml/kg phospholipase 48h	8.9	14.1	1066	54.7	7.5
0.5 ml/kg phospholipase 24h	8.9	14.1	1100	51	7,9
0.5 ml/kg phospholipase 48h	8.9	14.1	1113	56,4	8,3

*cremadid not form

In term of the capacity of foam, an important increase occurred in those treated compared to the control (Table 1). In Brix, an important variation was not observed, and it was considered that the decrease of 0.2 units in the first control group may be related to the precision of instrument (Yavuz and Özcan, 2016). Foam capacity values of samples changed between 513% (control) and 1113% (0.5 ml/kg phospholipase for 48h. The highest foam capacity was established in the sample with addition of 0.5 mg of phospholipase for 48 hours (Table 1). It is considered that this increase may probably be due to protein interaction. When regarded to the foam stability, it was seen that there was a fluctuation depending on the concentration of enzyme added and the time. In general, foam stability ranged from between 46.7 (0.5 mg/kg phospholipase for 24h) and 64.6 (0.5 mg/kg phospholipase for 48 h). When the height of lump of dough compared to the control, an important increase was observed, and maximum height of lump of dough became 9.3 (0.5 mg/kg phospholipase for 48 h). At the beginning, egg white having a foam capacity of 1200 mg/100 g, with addition of egg yolk of 0.3%. It was seen that foam capacity regressed to 300 ml/100 g and that phospholipase enzyme, added at the rate of 200 ml/ton, rearranged the foam capacity at 0-4 º C and improved it at the levels of 1200 ml/100 g. In foam stability, it was observed that pure egg white of 87 ml/ 60 min with contamination of 0.3% egg yolk, regressed to 35 ml/60 min, and with phospholipase enzyme, that there was again an improvement at the levels of 80-85 ml/60 min. While 50 units of improvements in stability are provided and 900- 1000 units in foam capacity, in this study, the amounts of improvements remained at lower levels. As the reasons for this, it was considered that the foam capacities and stabilities were low. Contamination of egg yolk was higher than the study we made a comparison. In addition, it was thought of that this would result in low improvement rates.
On condition that the content of egg yolk is kept at a certain level, when tartaric acid is added to egg white in the rate of 5 %, an increasing in foam capacity and stability were seen. The effect of tartaric acid on egg white performance at different times are shown in Table 2.

Table 2 . The effect of tartaric acid on egg white performance at different times

Samples	pH	Brix (%)	Foam capacity(%)	Foam stability (%)	Heigh of meringue cream (cm)
Control 1	8.8	13.8	659	56.2	7.7
1% cream tartar	8.33	14	720	65.7	8.1
3% cream tartar	7.5	14.1	700	70.9	6.7
5% cream tartar	7.0	14.1	770	68.8	7.1
10% cream tartar	6.3	14.2	713	66.7	6.3
12 %cream tartar	5.8	14,3	650	64.5	7,4

In the uses over 5%, also with the effect of increasing acidity, the losses were again seen in the foam values. In view of this, in the uses of cream of tartar, it is considered that pH should be lowered below the levels of 7-7.5. In addition, in egg whites, whose the concentration of egg yolk is high (Control Group 2), it did not show any effect on lump of dough performance and it was seen that the formation of cream of foam could not possibly be provided. Foam stability of egg White were determined between 56.2% (control) and 70.9% (3% cream tartar. In heated white egg, by using lactic acid, hydrochloric acid, or potassium acid tartrate (tartaric acid), it was reported that pH should be kept around 6.0 – 6.5 (Slosberg, 1948). However, due to leakage in "lump of dough" product, reducing a beaded structure forming near it cannot be provided by potassium acid tartrate (Hester and Personius, 1949). About the quantity of the use of potassium acid tartarate /tartaric acid), also in our study, pH related literature results were reached. In egg white having the rate of 10%, determined at pH 6.12, some decreases occurred in foam capacity, foam stability, and the height of cream of lump of dough, which are performance values.

In the use of SAPP, especially on performance effects, it was seen that the similar results to citric acid and tartaric acid were obtained. Again, if the first performance of control group at a certain level, some improvements were observed; otherwise, it was seen that it did not have any positive effect on cream of lump of dough but considerable increase in the values of stability and foam was not observed. For being able to obtain maximum result, maximum rate of use should be around 3% (Table 3) due to the fact it is an acidic agent, pH ranges in a wide range.

Table 3. The effect of sodium acid pyrophosphate on egg white perfornance at different times

Samples	pH	Brix (%)	Foam capacity(%)	Foam stability (%)	Heigh of meringue crema(cm)
Control 1	8.9	14.0	533	44	-*
0.6 %SAPP	8.7	14.0	533	52	-
1%SAPP	8.6	14.0	626	68.6	6.2
3 %SAPP	7.9	14.0	683	57.8	6.2
5 %SAPP	7.5	14.0	608	46.8	6.0

*cremadid not form

In the use of citric acid, that important effects on foam capacity can be provided on condition that the content of egg yolk is kept at a certain levels (Table 4). In control

Group 1 having low contamination, while the effect on foam capacity was 200 units, due to the fact that it does not form cream of lump of dough, in Group 2, whose contamination of egg yolk is low, it was seen that it was only 40 units (Table 4). For increasing foam properties of duck egg, lemon juice was used (Rhodes, 1960).. Apparently, it was seen that, addition of acid, influencing ovomucin, reduced whisking time. In angel cake, made with acid added duck egg, it was seen that a better result was obtained compared to that made with chicken white egg white (Rhodes et al., 1960). Acid increases the internal brightness of cake and acid and acid salts develop stability. In addition, acid and acid salts develop foam stability of albumin (Grewe and Child, 1930). Also in our study, in control 2, while foam capacity falls with the amount of citric acid that increase, it was seen that there was an increase in foam stability. Again, in control 1, while height of cream of lump of dough falls, seeing that there was not any decrease in stability and that acid has an effect increasing the stability, an equivalent result to literature was obtained.

Table 4.The effect of citric acid on egg white performance at different times

Samples	pH	Brix (%)	Foam capacity(%)	Foam stability (%)	Heigh of meringue crema (cm)
Control	13.0	8.92	1000	54.6	6.9
0.1% citric acid	12.4	7.14	1133	68	7.0
0.3% citric acid	12.8	6.03	1200	69	6.8
Control2	13.4	9.0	720	45.2	-*
0.1 % citric acid	13.4	7.4	760	48.6	-
0.3% citric acid	13.4	6.4	640	51.6	-

*cremadid not form

In the rates of tryethyl citrate of 0.1 -1 ml/kg, in the studies on two different control group, in pH and brix, any variation was not observed. But its positive effects was seen on the performance criteria. In foam capacity, the values between 640 -690 were identified and in stability, the values ranging 60.3-67.4. It is considered that the rate of maximum use was around 0.2 ml/kg (Table 5).

Table 5. The effect of triethyl citrate on egg white performance at different times

Samples	pH	Brix (%)	Foam capacity (%)	Foam stability (%)	Heigh of meringue crema (cm)
Control	9.1	14.1	666.5	60.6	6,5
0.1 ml/kg triethyl citrate	9.1	14.1	715	62.9	6.5
0.2ml/kg triethyl citrate	9.1	14.1	825	64.5	6.7
0.5 ml/kg triethyl citrate	9.1	14.1	715	63.9	6.0
1 ml/kg triethyl citrate	9.0	14.2	700	64.2	6.0

Triethyl citrate protects egg white against the detrimental effects of egg yolk. While it reduces whisking time in white eggs that contains yolk or not, its detrimental effect on cake was only seen as increase of cake volumes made with white egg containing egg yolk (Yavuz and Özcan, 2016) As indicated in the literature, also in our study, it was seen that triethyl citrate provided improvement in even Control 2, whose contamination of egg yolk is high. In foaming agents such as citric acid and SAPP, since cream of lump of dough did not form, in white eggs, in which it is considered that it contains high yolk contamination, while the desired improvement cannot be provided, triethyl citrate, even if its cream height is low, it is possible for it to form a firm cream. In the other additives used, while improvements in control group show a variability compared to the beginning concentration and the amount of egg yolk contamination, in NaOH, these variabilities were not seen in the considerable rates. (Yavuz and Özcan, 2016).

Conclusion

When tartaric acid was added to egg white in the rate of 5 %, an increasing in foam capacity and stability was observed. In the use of sodium acid pyrophosphate **(**SAPP), especially on performance effects, it was seen that the similar results to citric acid and tartaric acid were obtained. In the use of citric acid, that important effects on foam capacity can be provided on condition that the content of egg yolk is kept at a certain levels. Triethyl citrate protects egg white against the detrimental effects of egg yolk.

CHEMICAL PROTECTION OF WINTER WHEAT AND ITS ENVIRONMENTAL IMPACT IN DIFFERENT SOIL TILLAGE SYSTEMS

Małgorzata HOLKA*, Jerzy BIEŃKOWSKI

Department of Agricultural Production Systems, Institute for Agricultural and Forest Environment, Polish Academy of Sciences, Poznań, Poland
*Corresponding author: malgorzata.holka@isrl.poznan.pl

Abstract
The aim of the study was to assess the environmental impact of chemical protection of winter wheat in three soil tillage systems: conventional tillage, reduced tillage and direct sowing. The study was conducted in 15 farms in the Wielkopolska region (Poland), in the years 2015-2017. The highest intensity of winter wheat protection, in terms of the number of chemical protection treatments was in the conventional tillage (4.1), followed by the reduced tillage and the direct sowing (3.4 and 3.1, respectively). The largest consumption of active substances was found in the reduced tillage system (2.16 kg a.s./ha). Smaller quantities of active substances were used in the conventional tillage (2.04 kg a.s./ha) and the direct sowing (1.43 kg a.s./ha). In the analyzed soil tillage systems, the costs of winter wheat protection per hectare ranged from 272 to 353 PLN/ha. The direct sowing was characterized by the lowest cost of plant protection products used. Among the analyzed tillage systems, the most negative values of the potential toxicity index had the reduced tillage and the conventional tillage (-68.1 and -55.5 points, respectively) which resulted from larger consumption of active substances with properties associated with higher environmental threats. In turn, less negative points had the direct sowing (-39.5 points). The environmental impact of chemical protection of winter wheat in the studied tillage systems was mainly related to a high risk of volatilisation of substances into the atmosphere, followed by surface water contamination and leaching into groundwater, while there was the lowest risk of bioaccumulation.

Keywords: *Plant protection products, Costs, Potential toxicity index, Soil tillage systems, Winter wheat.*

Introduction
Winter wheat (*Triticum aestivum* L.) is a dominant crop in cereals production in Poland. In 2018, the area under its cultivation was over 1.9 million hectares and production amounted to 8.3 million tonnes (CSO, 2019b). Wheat is cultivated primarily in a conventional tillage system. This system also known as traditional, based on ploughing allows to cover crop residues or organic and natural fertilizers, reduce the losses of fine soil particles and nutrients, achieve good soil scarification, deepening the growth zone of the root system and destroying root-weeds. However, when it is being intensively carried out then contributes to a degradation of the soil environment by accelerating the mineralization of organic matter, increasing the risk of wind and water erosion, and soil drying (Mikanová *et al.*, 2012; Stanek-Tarkowska *et al*., 2018). A large consumption of fuel in conventional tillage system as well as bad weather conditions like drought which more and more often cause difficulties in carrying out soil tillage operations before sowing lead to greater interest in no-ploughing tillage systems (Smagacz and Madej, 2012). The main difference with respect to conventional tillage system consists in replacing a plow by other machines such as cultivator with rigid tines to till to a depth of 10-15 cm or total abandonment of soil tillage and adopting so called direct sowing in the soil with maintained crop residue on the soil surface. The beneficial effects are economic savings and protection of the environment due to energy savings, smaller use of

machinery and thus reductions in consumption of natural resources, fossil fuels and air pollution from fuel combustion (Smagacz, 2012; Sørensen *et al*., 2014).
Plant protection products are widely used in wheat protection. Oerke (2006) estimated the potential loss in wheat cultivation without any protection treatments is around to 55% and the actual loss in case of low efficient wheat protection amounts to 30%. Since 2014, plant protection in Poland must comply with principles of the integrated pest management (IPM). The IPM recommends taking into account primarily non-chemical methods and limiting the intensity of plant protection product use to the necessary minimum. Despite these challenges chemical method plays a dominant role due to a high efficiency in limiting crop losses caused by pests activity (Podleśna *et al*., 2018). According to scientific literature, the use of no-ploughing tillage systems may lead to an increase in the occurrence of diseases and pests (Bankina *et al*., 2018; Hurej *et al*., 2012; Małecka-Jankowiak *et al*., 2015). This is related to more intensive plant protection and its higher cost in comparison with conventional tillage (Jankowiak and Małecka, 2008). Higher use of plant protection products is associated with more harmful effects on various elements of the environment e.g. air, soil, ground water, surface water and living organisms. Moreover, this impact may vary dependent on the potential toxicity of active substances of plant protection products (Holka, 2017).
The aim of the study was to evaluate a cost and a potential environmental impact of chemical plant protection in winter wheat under different soil tillage systems.

Materials and Methods

The study was conducted in 15 farms, located in the Wielkopolska voivodship (Poland), during the period 2015-2017. The chemical protection of winter wheat in three soil tillage systems: conventional tillage, reduced tillage and direct sowing was analyzed. Detailed data on chemical protection treatments and the purchase prices of plant protection products were collected from the surveyed farms. Assessment of the impact of plant protection products on the environment was performed using the potential toxicity index, which results from the selected physico-chemical properties and quantities of active substances (Lewis and Tzilivakis, 1998). The following properties of active substances were taken into account: octanol-water partition coefficient, solubility in water, Henry's constant and ground-water ubiquity score index. Each of the variables indicates one of the four different potential environmental risks, which are the components of the potential toxicity index (Figure 1).

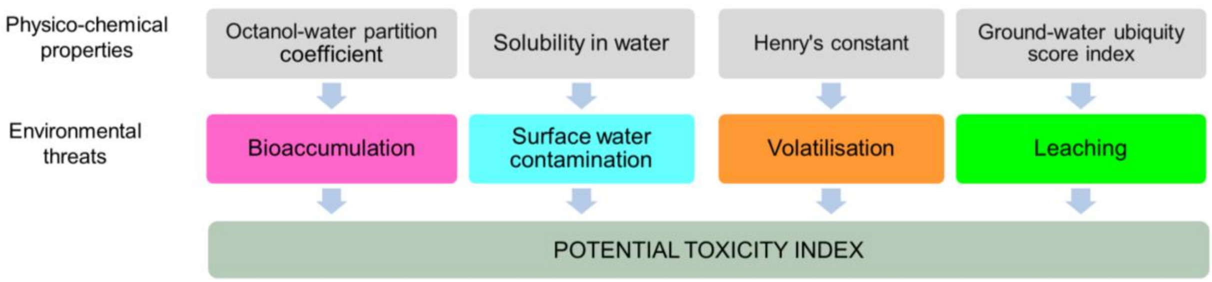

Figure 1. Scheme of assessment of a potential toxicity index of plant protection products.

The potential toxicity index was calculated as follows:

$$EMA = \sum_{i=1}^{n} \left(E_i \cdot Q_i \right),$$

where:
E_i - sum of points obtained by the i-th active substance on the basis of its physico-chemical properties,

Q_i - the amount of the i-th active substance used, in kg/ha,
n - the number of active substances.
The point assessment of each active substance was performed based on the properties data (EU Pesticides Database, 2019; Pesticides Properties Database, 2019), and the criteria adopted (Bieńkowski, 2011).

Results and Discussion

Figure 2 shows the differences in the number of chemical protection treatments in winter wheat between the soil tillage systems. The most treatments were carried out in the conventional tillage system (4.1), followed by the reduce tillage (3.4), and the direct sowing (3.1). The most treatments were based on fungicides (their share was in the range from 48.1% in the direct sowing to 41.5% in the conventional tillage) and herbicides (ranged from 28.7% in the direct sowing to 39.0% in the conventional tillage). There were smaller numbers of insecticide treatments (they ranged from 9.9% in the direct sowing to 14.9% in the reduced tillage) and growth regulator treatments (from 7.3% in the conventional tillage to 13.3% in the direct sowing). Hołaj (2011) also noted 4 chemical protection treatments of winter wheat in the conventional tillage.

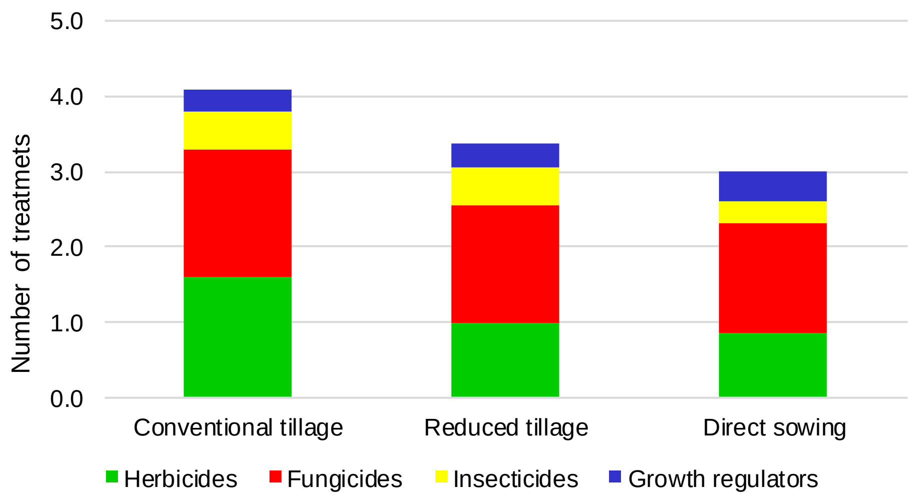

Figure 2. Number of plant protection treatments in winter wheat according to the soil tillage systems (averages for the years 2015-2017).

The largest consumption of active substances was in the reduced tillage (2.16 kg/ha) (Figure 3). Slightly lower amounts of active substances were used in the conventional tillage (2.04 kg/ha) and markedly lower in the direct sowing (1.43 kg/ha). Among the soil tillage systems, herbicides had the largest share of plant protection products used (ranging from 36.1% in the direct sowing to 64.8% in the conventional tillage), followed by fungicides (ranging from 29.3% in the reduced tillage to 39.8% in the direct sowing). In addition to this, protection of winter wheat in the conventional tillage was characterized by smaller use of growth regulators than in other soil tillage systems. The Central Statistical Office of Poland (CSO, 2019a) reported lower average consumption of active substances for winter wheat grown in the country, amounted to 1.32 kg per 1 ha. In the studies of Jankowiak *et al.* (2012), an increase in the consumption of plant protection products was related to area structure of farms. The obtained results indicated more intensive crop protection in terms of the consumption of plant protection products in the reduced tillage. As it was observed in the study this system is more frequently used by larger farms which are furnished with appropriate machinery equipment and run intensive crop production (Townsend *et al.*, 2016).

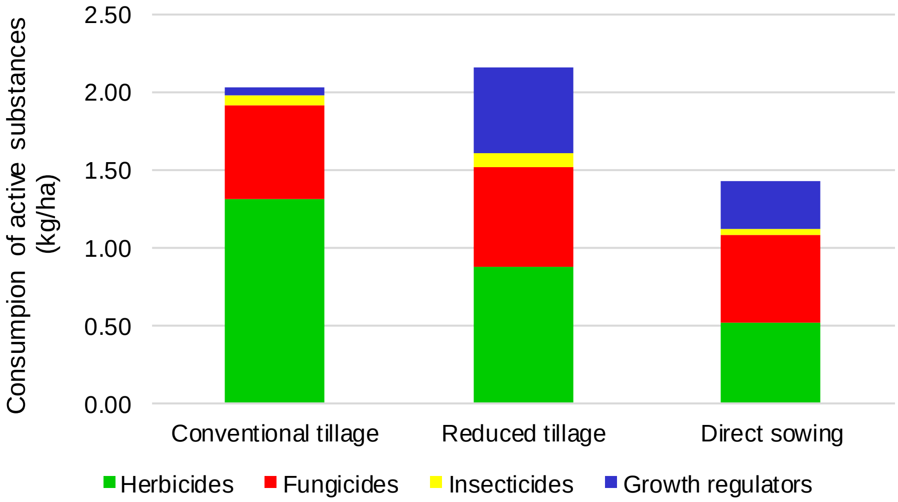

Figure 3. Consumption of active substances in winter wheat according to the soil tillage systems (averages for the years 2015-2017).

The higher costs of plant protection products were in the reduced tillage and in the conventional tillage (Table 1). The direct sowing achieved the lowest cost. The total costs resulted mainly from the use of herbicides and fungicides. On average, the cost of plant protection products for winter wheat in the selected farms in Lublin Voivodeship amounted to 386 PLN/ha (Bojarszczuk and Podleśny, 2017). Smagacz (2012) noted higher overall costs of winter wheat protection in the direct sowing (836 PLN/ha) in comparison with the conventional tillage and the reduced tillage (in both cases amounted to 769 PLN/ha). In the study of Gaworski *et al.* (2013) the costs of plant protection products in winter triticale production in the traditional tillage was 162 PLN/ha and in the direct sowing 216 PLN/ha. In England, costs of winter wheat protection were higher in farms never plough (Townsend *et al*., 2016)

Table 1. Cost of plant protection products used in winter wheat in different soil tillage systems, in PLN/ha (averages for the years 2015-2017).

Type of plant protection products	Soil tillage system		
	conventional	reduced	direct sowing
Herbicides	137.90	113.90	99.10
Fungicides	172.90	217.00	145.90
Insecticides	8.30	14.20	7.50
Plant growth regulators	34.00	10.20	20.40
Total	353.20	355.30	272.90

The soil tillage systems examined differed in respect to the potential toxicity of chemical protection. The results presented in Figure 4 show that the most negative score of the potential toxicity index, indicating the largest use of plant protection products with high toxicity to the environment, had the reduced tillage (-68.1 points), followed by the conventional tillage (-55.5 points). In turn, the least harmful impact of chemical plant protection on the environment was found in the direct sowing as evidenced by the lowest score of the index (-39.5 points). The relative contribution of particular components to the total value of the index was similar between the analyzed soil tillage systems. The greatest environmental risk was driven by volatilisation, followed by surface water contamination and leaching. Risk bioaccumulation of the substances in the tissues of living organisms was of minor importance. In earlier study, the average value of the multi-criteria index of the impact of plant protection on the environment for cereals in conventional tillage amounted to 62.4 (Holka, 2017). Bieńkowski (2011) obtained an average value of the index in farms specializing in field crops equal to -39.4 points. In this study, volatilisation was also found to be the main contributor to the multi-criteria index profile of potential toxicity of chemical protection.

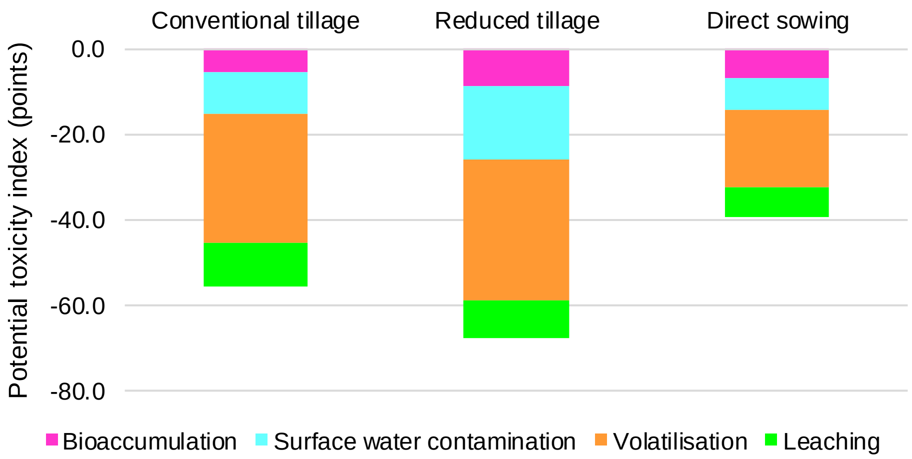

Figure 4. Potential toxicity index and its components calculated for the chemical protection of winter wheat in the analyzed soil tillage systems (averages for the years 2015-2017).

Conclusions

Winter wheat in the reduced tillage system was associated with the highest intensity of plant protection products used, and at the same time it had the most negative impact on the environment. Environmental impact of plant protection was expressed by the multicomponent index of potential toxicity attributable to basic physico-chemical properties of active substances. Practicing direct sowing in wheat cultivation turned out to be most advantageous with respect to number of spray application, environmental impact and cost of chemical protection.

Abstract

Propolis (bee glue) is a mixture of various amounts of wax and resin that honey bees collect from leaf buds or tree barks and bushes. Usually these are poplar trees, ash tree, apple, birch, chestnut, etc. Bees disinfect and protect their hive against unwanted external influences, such as fungi, microorganisms, smaller animals (mice, worms, ants), but they also protect hives against cold, moisture and flows. Propolis is a complex content that result from mixing of natural plant derived and bee released elements and compounds. The proportion of the various materials found in the propolis that related to its place and time of collection but, in general, raw propolis is estimated to have a composition of around 50% of vegetable resins, 30% of wax, 10% essential oils, 5% pollen, and 5% of various organic compounds. Propolis is lipophilic in nature, rigid, fragile and brittle material when cold; but when temperature rises, it becomes soft, pasty, gummy and adhesive property and be sticky. It is used in the treatment of infections, and prevents throat inflammation, paradentosis, etc. The aim of this study was to investigate the antibacterial effects of two alcoholic solutions of propolis originating from Greece and from Republic of Srpska and their effect on clinical isolates of *Staphylococcus pseudintermedius* (isolates from the nose, skin and ear of the dogs and rabbits) and to determine the type of action.The results of work confirmed the higher antibacterial activity of alcoholic solution of propolis originating from the Republic of Srpska with an inhibition zone of 10.66 mm to 23.33 mm, and the range of action for propolis solution originating from Greece was from 10.00 mm to 19.00 mm. Alcoholic propolis solution originating from Republica of Srpska showed greater bactericidal activity, while the propolis originated from Greece have stronger bacteriostatic activity.

Keywords: *propolis, antibacterial properties*

Introduction

Propolis is a mixture of different amounts of beeswax and resins that obtained by the honeybee from different natural plants, especially from flowes and leaf buds. The color of propolis varied from yellow to be more darker brown according to the origin of the resins. Fresh propolis extracted from the hive is a soft, sticky mass and curing at room temperature. The flavor, color and chemical properties depend on the type of plants that are in the bee's radius. Propolis has a pleasant smell of plant buds, honey, wax and vanilla, bitter taste, sticky on the touch and if it is kept longer receives a dark color (Pušnik, 2016). The meaning of the word propolis, according to some interpretations, comes from the Greek: "pro" mean, in front of and "polis" mean city. There is an opinion that the name derives from the Greek and Latin words "propolis" which means to smudge or to smooth out. A honey bee collects propolis and carries it back to the nest on her hind legs. By cutting and chewing the resin and with bee saliva they affection the composition of propolis. Bees use propolis alone or with beeswax in the construction and adaptation of their nests, which ensures purity and sterility, protection against pests and external factors. The dead bees and pests are covered with propolis and thus preventing their decomposition, thereby eliminating the source of potential infection of the bee's society (Toreti, 2013; Kuropatnicki *et al*,. 2013; Pušnik, 2016;).The ancient Egyptians used it as a medium for mummification of pharaohs (Bankova et al., 2000). Bee Propolis has a long history of medicinal use, dating back to 350 B.C., the time of Aristotle and he also mentions propolis in his work "Historia animalium" ("Animal speech") as naturally medies for treating skin lesions, wounds and infections (Toreti, 2013), while the ancient Greeks blended propolis with vegetable oils and made perfumes (Bogdanov and Bankova, 2012). Propolis is used by ancient Inca civilization, against inflammatory processes and to treating a fever (Bogdanov and Bankova, 2012). The ancient Romans used propolis for wound dressings and according to some data dating from that time, propolis had a higher price than honey (Toreti, 2013). Between the 17th and 20th centuries, propolis began to be used intensively in Europe because of his antibacterial properties (Monti *et al.*, 1983). In the 20th century and in the beginning of this century, the use of propolis in the pharmaceutical, food and cosmetic industry is growing, and accordingly it grows interest in examining the chemical composition and biological properties of propolis. Propolis has a complex chemical composition that has not yet been fully tested. It contains about 50% vegetable resins, 30% wax, 10% essential oils, 5% pollen and 5% of various organic compounds. It contains flavonoids, organic acids, polyphenols, terpenes, esters, polysaccharides, minerals, vitamins, aldehydes, coumarins and potentially present foreign substances (Pietta *et al.* 2002; Rusak, 2008; Bankova *et al*. 2008; Bogdanov and Bankova 2012 Graikou *et al.* 2016). The type and amount of biologically active compounds in propolis depends on the chemical composition of the plant resin, which is directly related to the climatic and phytogeographical characteristics of the regions of origin, and therefore propolis from different climatic zones are different from each other (Marcucci, 1995). Propolis exhibits a wide range of biological properties, and antibacterial activity is the most important feature, as confirmed by a large number of studies (Bankova *et al*., 1995; Zwolan and Merest, 2000; Havsteen, 2002; Bankova, 2009; Bogdanov, 2012; Kročko *et al.*, 2012;;). Antibacterial (bactericidal and bacteriostatic) propolis activity has been studied on a large number of bacterial species (*Streptococcus haemolyticus*, *Staphylococcus aureus*, *Salmonella typhi*, *Salmonella paratyphi*, *Bacillus anthracis*, *Escherichia coli*, *Helicobacter pylori*, *Pseudomonas aeruginosa*, etc.). Propolis has good effects on fungi: *Candida albicans*, *Candida tropicalis*, *Candida crusei*, *Torulogis glaerata*, *Aspergilus* spp., *Cryptococcus neoformans*, and others. The strongest antibacterial effect is on *Enterococcus* spp., *Staphylococcus aureus*, *Klebsiella pneumonia*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Streptococcus faecalis*, and others (Park *et al.*, 2005; Mavri *et al*., 2012; *Osés et al*., 2016, Saeed *et al.*, 2016, Graicou *et al*., 2016,). Propolis stops the development of a influenza and herpes virus (Adenovirus, Coronavirus, Herpes Symplex, Influenza A and B virus, Rota Virus, etc.) (Schnitzler *et al*., 2010). Propolis has a great advantage over synthetic drugs because it does not lead to bacterial resistance (Mladenov and Radosavović, 1998; Banskota *et al*., 2001; David et al., 2012; Gressler *et al*., 2012), is not toxic, does not damage the normal intestinal flora, increases the antibacterial effect of ciprofloxacin, penicillin, amoxicillin, ampicillin, cefalexin and tetracycline (Oxyxil *et al.*, 2005; Orsi *et al.* 2012,). Sometimes, propolis is more effective than commercially available drugs (Krell, 1996). Propolis possesses good antibacterial, antiviral, antimicrobial, antioxidant, anti-cancerogenic, immunomodulatory, hepatoprotective, cardioprotective and antiallergic properties (Galvao *et al.*, 2007; Sforcin, 2007;; Fischer and Vidor, 2007; Bankova, 2009 Bogdanov, 2012; Toretti, 2013; Pušnik, 2016; Saeed *et al.*, 2016;).

Staphylococcus pseudintermedius is a normal resident of the skin and mucosa and can be isolated from the nose, mouth, pharynx, forehead, hips and anus of healthy dogs and cats. *Staphylococcus pseudintermedius* is the main cause of skin and ear infections, postoperative wounds in dogs and cats and other tissues (van Duijkeren, 2011). *Staphylococcus*

pseudintermedius is a Gram-positive bacterium called *Staphylococcus intermedius* for the first time described by Hajek in 1976. as a coagulase-positive staphylococci.
S. pseudintermedius has been described from dogs, cats, horses and parrots using the molecular method, and it has been proposed that isolates from dogs, if no molecular methods for identification of such isolates are available, are attributed to this species (Bond and Loeffler, 2012). It is presumed that most of the isolates that were formerly referred as *S. intermedius* are most likely belonging to the species *S. pseudintermedius*, at least in terms of isolates originating from dogs. It is also likely that infections in people who were in contact with dogs were caused by *S. pseudintermedius*. There is an increasing number of cases showing serious invasive infections with *S. pseudintermedius* in humans such as bacteraemia (Talan *et al*. 1989; Goldstein, 1992; Lee, 1994), pneumonia, sinusitis (Gerstad *et al*., 1999), otitis externa (Kempker *et al.*, 2009), nail infection (Tanner *et a*l., 2000), mastoiditis (Pottumarthy et al., 2004), brain abnormalities (Kikuchi *et al.*, 2004), skin absorption (Atalay *et a*l., 2005), bacteremia complicated with septic arthritis (Kelesidis and Tsiodras, 2010).
The aim of this work is to explore the antibacterial characteristic of two samples of propolis originating from Greece and Republic of Srpska and there influence on eleven isolates of *Staphylococcus pseudintermedius* and also to determine the type of action.

Materials and methods

Material

In this study we used two samples of 20% ethanolic solution of propolis from different origin (Greece and Republic of Srpska).

Test cultures

For testing the antibacterial activity of propolis we used bacterial cultures of *Staphylococcus pseudintermedius* (eleven isolates) isolated from a various clinical materials (6 samples from the ear swabs, 4 skin swabs and 1 nose swab) from 10 dogs and 1 rabbit. The cultures were seeded in a nutrient broth and incubated at 37 ºC for 18 h. Petri plates with the appropriate substrate (Müeller-Hinton agar) were seeded with 0.1 ml of bacterial suspension in concentration of 10^5cfu/ml.

Methods

To examine the effects of propolis on selected bacterial cultures, we used agar diffusion method on sterile solid-nutrient medium (Müeller-Hinton agar). Metallic cylinders of 9 mm diameter were placed on the surface of a solid nutrient medium where's a certain pure bacterial culture was previously sown. 100 µl of propolis was placed in the cylinders with the micropipette. As a control, 100 µl of 96% alcohol was put in the one cylinder. The plates were incubated for 24 hours at a temperature of 37 °C. For each bacterial culture, three repetitions were made and the average value for each bacterial culture was calculated.
We also determined the type of action of propolis. To see if propolis has bactericidal or bacteriostatic effect, a small amount of agar was taken from the inhibition zone and added to the nutrient broth. Incubation was carried out at 37ºC for 24 h. After incubation presence of dark blur in broth tell us about bacteriostatic effect, or if, the broth remained clear, about bactericidal effect.

Results and discussion

Products based on propolis come on the market in different shapes, but in our market is the most common alcoholic solution of propolis concentration of 20% and more.
Antibacterial properties of two samples of propolis alcoholic solution originating from Greece and Republic of Srpska were tested on eleven isolates of *Staphylococcus pseudintermedius*

from skin swabs (4 isolates), ear swabs (6 isolates) and nose swab (1 isolate) of 10 dogs and 1 rabbit, and the results are shown in Table 1.

Table 1. Antibacterial activity of alcoholic solutions of propolis on *Staphylococcus pseudintermedius*

Staphylococcus pseudintermedius	Inhibition zone in mm	
	20% ethanol solution of propolis (R. Srpska)	20% ethanol solution of propolis (Greece)
1	18.33	13.33
2	10.66	10.00
3	15.66	**0.00**
4	23.33	19,00
5	18.33	**0.00**
6	12.66	11.66
7	12.00	16.66
8	12.00	**0.00**
9	15.00	10.66
10	**0.00**	10.00
11	**0.00**	16.66

1, 2, 3, - dog skin swabs, 4 - rabbit skin swabs, 5, 6, 7, 8, 9, 10 - ear swabs, 11 - nose swab

As can be seen from the results, a solution of propolis originating from the Republic of Srpska showed greater antibacterial activity on most tested bacterial isolates compared to the Greek propolis solution. Inhibition zones for the propolis solution originating from Republic of Srpska ranged from 10.66 mm to 23.33 mm, while the range of action for the propolis solution originating from Greece was from 10.00 mm to 19.00 mm.

The alcoholic solution of propolis originating from the Republic of Srpska did not appear to be inhibitory for two isolates (one ear swab and one nose swab) while the alcoholic solution of Greek propolis acted inhibitively on both these isolates with inhibition zones of 10.00 mm and 16.66 mm. The alcoholic solution of Greek propolis did not appear to inhibit the isolation of *Staphylococcus pseudintermedius* isolated from the skin swab and two isolates from the ear. Different biogeological factors influence on the different chemical composition of the plant material available to the bees for the production of propolis, and propolis from different climatic zones are different one from another. Despite the differences in the chemical composition of different types of propolis, propolis exhibits a strong antibacterial effect, and this is supported by a large number of publications (Bogdanov, 2012).

The differences in the antibacterial activity of alcoholic tincture propolis from Greece and the Republic of Srpska are in line with the results published in the literature and are probably dependent on the geographical area from which the bees collected honey (Stepanović *et al.*, 2003, Adewumi *et al.*, 2016). Phenolic acids and flavonoids significantly contribute to the antimicrobial activity of propolis (Pepelnik *et al.*, 2004; Mercan *et al.*, 2006., Cabral *et al.*, 2009; Junior *et al.*, 2012., Toreti, 2013., Neves *et al.*, 2016;;). Also, the propolis activity is influenced by the way of conservation, freshness, content of ingredients and method of application (Haynes *et al.*, 2011., Tasleem *et al.*, 2011., Wolska *et al.*, 2016.). The results of this study have shown that both propolis exhibited good antibacterial activity against the tested Gram-positive isolates of *Staphylococcus pseudintermedius*, which is in agreement with the results of other researchers (Stepanović *et al.*, 2003., Bogdano, 2012,). To see whether propolis has a bactericidal or bacteriostatic effect from the inhibition zone, a small piece of agar is taken and added to the nutrient broth. The obtained results are shown in Figure 2.

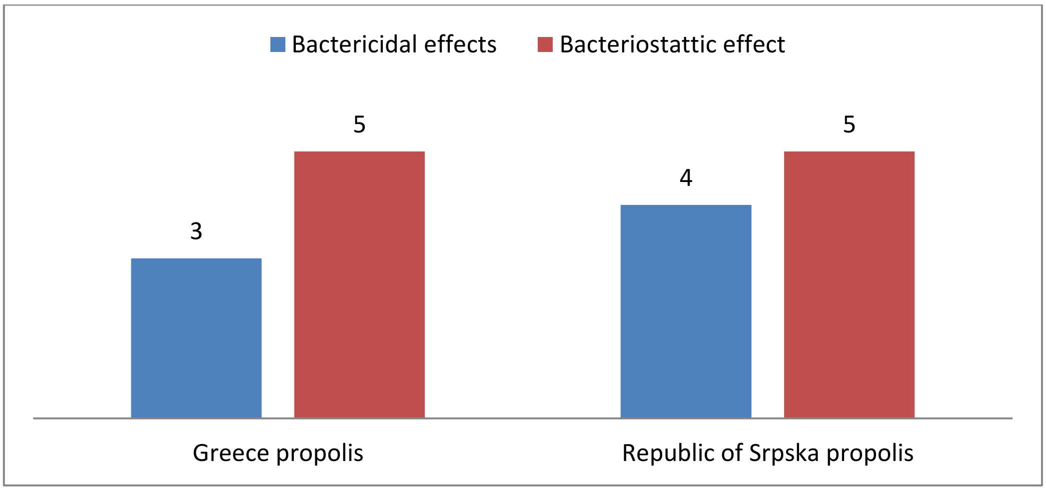

Figure 2. Bacteriostatic and bactericidal effect of propolis

As can be seen from the attached chart, both alcoholic solutions of propolis exhibited a greater bacteriostatic activity on the examined bacteria.

An alcoholic solution of propolis originating from the Republic of Srpska has exhibited greater bactericidal activity compared to Greek propolis.

The results of this work confirm the bactericidal and bacteriostatic effect of alcoholic tincture of propolis, which is in line with research conducted by other researchers (Havsteen, 1983.; Bonvehi *et al.*, 1994., Oksuz *et al.*, 2005., Salas *et al.*, 2014 ;).

Conclusions

The results of the work showed that the propolis solution originated from Republic of Srpska had inhibitory effect on clinical isolates of *Staphylococcus pseudintermedius* with inhibition zones of 10.66 mm to 23.33 mm, while the extent of action for propolis solution originating in Greece was from 10.00 mm to 19.00 mm. Propolis solution originated in Greece acted bacteriostatic with 63.63% and propolis from the Republic of Srpska in 54.54% of the isolates.

Bactericidal activity in 27.27% of isolates showed a propolis solution originating in Republica of Srpska, and a propolis solution from Greece at 18.18% of the isolates. Based on the obtained results, the use of propolis as a natural antibacterial medicament against *Staphylococcus pseudintermedius* can be recommended. The use of propolis in pharmaceutical, cosmetic, nutritional and other purposes determines his diverse chemical composition, as well as experimental scientific research. There is very little research about use of propolis for medical purposes, which provide scientifically-based results, and we must continue this resarch in the future.

Abstract

A large number of organisms like pathogens and herbivores are related to different tree species. They could be often found together on the same plant host. The elevated CO_2 levels can also influence the changes in plant metabolism, which can influence the plant-herbivore relations caused by the pathogens. This paper presents the results of influence of biotic stress, caused by inoculation of Turkey oak (*Qercus cerris*) seedlings with root pathogen (*Phytophthora plurivora*), on the performance of the gypsy moth (*Lymantria dispar*) larvae in elevated CO_2 conditions in extreme scenario which predicts concentration of up to 1000 ppm in the future. Influence of inoculation of seedlings with a root pathogen on the performance of gypsy moth larvae was examined by analysis of covariance (ANCOVA) with plant status (exposure to inoculation, with or without biotic treatment) and environmental conditions (ambient or elevated CO_2 level) as independent variable, and growth rate (GR) and relative growth rate (RGR) as dependent variables. Plant height and larval weight before treatments were used as covariates. Fisher's least significant difference test was used to examine the differences in mean values of individual treatments. ANCOVA showed a statistically significant influence of CO_2 concentration on both parameters, GR and RGR of the larvae. Inoculation with the root pathogen and covariates (larval weight and plant height) as a source of variation, individually, did not influence the performance of the larvae statistically significantly. Interaction between the biotic and environmental conditions had a significant influence on the RGR, but not on the GR.

Keywords: *gypsy moth, root pathogen, Turkey oak, elevated CO_2, tree-trophic interactions*

Introduction

Forests are structurally and functionally complex biotopes rich with species (Messier *et al.*, 2013). More than 25% of all herbivorous arthropods live in tree crowns (Strong *et al.*,1984). Increase in CO_2 level directly influences the trees physiological processes (Traw *et al.*, 1996). The response to this, especially in the content of nitrogen in the leaf tissue, varies from species to species (Peterson *et al.*, 1999). That is why herbivorous organisms face the significantly altered chemical composition of the plant organs that ultimately affects their growth and development (Hättenschwiler and Schafellner, 2004) due to the changes in the plants resistance to pathogens and insects (Henn and Schopf, 2001).

Increased CO_2 concentration directly influences the photosynthesis process, when, with the aid of sunlight and water, plants transform the surplus CO_2 to oxygen and carbohydrates which constitute the plant tissues (Lindroth *et. al.* 1993), while increasing the total forest productivity (Eamus and Jarvis, 1989). By doubling the CO_2 concentration, the plants increase the photosynthetic and water use efficiency by 30-50% (Running and Nemani, 1991). However, the nitrogen content in the leaves which are exposed to increased concentration of

CO_2 decreases, while the tannin content in the same leaves increases (Traw *et al.*, 1996). Since the beginning of the industrial revolution the CO_2 concentration has risen by 30 ppm by 1958, and from 1958 to 2014 by 90 ppm. The total amount increased from 280 to 400 ppm (Besermenji, 2007). Compared to the reference period from 1961 to 1990 an increase in temperature between 1.5 and 4.8 °C is expected by the end of the 21st century (Doljak and Petrović, 2015). It is predicted that the CO_2 concentration will be around 700 ppm by the end of the 21st century (Popović *et al*., 2009).
Previous studies on the influence of elevated CO_2 content in the atmosphere on different forest tree species, and indirectly on the tree pests, were conducted with CO_2 concentrations between 500 and 700 ppm. These concentrations correspond with the most probable scenarios of the increasing of concentration of this gas by the end of the 21st century (van Vuuren *et al*., 2011). However, pessimistic scenarios which predict an increase in CO_2 levels up to 900-1000 ppm in the atmosphere by the end of 21st century were not studied so far. One of the aims of this research was to determine the indirect influence of the root pathogen and increased CO_2 content on herbivorous organism. For this purpose, two-year old Turkey oak (*Quercus cerris* L.) seedlings, gypsy moth (*Lymantria dispar* L.) larvae, and a root pathogen (*Phytophthora plurivora* T. Jung & T. I. Burgess) were subjected to the experiment in this study.

Material and methods

Plant material: Fourty Two-year old Turkey oak (*Q. cerris*) seedlings grown the previous year from acorns that were collected in the vicinity of Belgrade were used for the experiment. The seedlings were grown on peat and perlite substrate (70:30 ratio), in PVC bags of 750 cm^3.
Inoculum: Inoculum was prepared according to Jung *et al*. (1996), where 500 cm^3 of fine vermiculite and 40 cm^3 of millet seeds were measured in one-liter Erlenmeyer flasks. Then, 350 ml of liquid V8 substrate was added to the mixture. The V8 substrate was prepared with 200 ml/l of V8 juice (Biotta, Swiss), 3 g/l of CaCO3 and 800 ml/l of distilled water (Jung *et al*., 1996). After mixing, the mixture was sterilized in an autoclave for 20 minutes at 120°C. Fresh, 3-5 days old *P. plurivora* cultures were taken from the collection and developed on V8-agar media (200 ml/l of V8 juice, 20 g/l of agar (Torlak, Serbia), 3 g/l of CaCO3 and 800 ml/l of distilled water. After inoculation with pieces of fresh *P. plurivora* colonies, the Erlenmeyer flasks were closed with a sterile plug made out of wadding and aluminum foil. Incubation was at room temperature in the dark for 4-6 weeks, until the inoculation. Before the inoculation itself, the inoculum was washed in sterile distilled water, so that the nutrients and sugar from the substrate that could be a carrier of bacterial contaminants, were removed.
Inoculation: The inoculation was conducted by adding of ca. 40 cm^3 of inoculum to the plants rhizosphere, following methodology of standardized soil infestation test (Jung *et al*., 1996). After that the plants were immediately flooded for a period of 72 hours.
Insect material: Gypsy moth egg masses were collected in an oak forest in the vicinity of Bor. They were kept in a freezer at a temperature of 4°C until the spring 2018. Before the beginning of the experiment they were moved to temperature of 25°C in order to induce hatching. After hatching, the larvae were fed with artificial food in petri dishes (120 x 15 mm) at a temperature of 23°C, Rh 75% and light regime 15:9 (day: night) until molting to the fourth larval stage.
Experiment design: For testing the influence of elevated CO_2 and inoculation with a root pathogen on gypsy moth larvae which were intermediated with Turkey oak seedlings, four experimental groups were formed (ten larvae on ten plants per group): LCA (gypsy moth larvae that consumed the leaves of Turkey oak seedlings exposed to ambient CO_2 concentration), PLA (gypsy moth larvae that consumed the leaves of Turkey oak seedlings which were inoculated with a root pathogen in conditions of ambient CO_2 concentration), LCE (gypsy moth larvae that consumed the leaves of Turkey oak seedlings that were exposed

to elevated CO_2 levels) and PLE (gypsy moth larvae that consumed the leaves of Turkey oak seedlings that were inoculated with a root pathogen in conditions of elevated CO_2 levels).
Statistical analysis: Influence of inoculation with *P. plurivora* on the performance of gypsy moth larvae was examined by analysis of covariance (ANCOVA) with plant status (exposure to inoculation, or without biological treatment) and environmental conditions (ambient or elevated CO_2 level) as independent variable, and growth rate (GR) and relative growth rate (RGR) as dependent variables. Plant height and larval weight before treatments were used as covariates. Fisher's least significant difference test was used to examine the differences in mean values of individual treatments.

Results and discussion

Results of the research on influence of inoculation with *P. plurivora* and elevated CO_2 level on the performance of the gypsy moth larvae are presented in the Table 1, and Graphs 1, 2 and 3. Results of the analysis of covariance (ANCOVA) showed a statistically significant influence of CO_2 concentration on both parameters, growth rate (GR) and relative growth rate (RGR) of the gypsy moth larvae. *Phytophthora plurivora* and covariates (larval weight and plant height) did not influence the performance of the gypsy moth larvae statistically significantly. Interaction between the biotic and environmental conditions had a significant influence on the RGR (Table 1).

Table 1. Results of the analysis of covariance of the examined influence of inoculation with *P. plurivora* and environmental conditions (ambient and elevated CO_2 level) on the performance of the gypsy moth larvae

Source of variation	GR				RGR		
	d.f.	MS	F	P	MS	F	P
P. plurivora	1	2.12	0.02	0.9008	23.19	0.00	0.9766
CO_2	1	**7236.71**	**53.94**	**0.0000**	**1642196.24**	**61.82**	**0.0000**
P. plurivora * CO_2	1	326.80	2.44	0.1284	**157925.12**	**5.94**	**0.0205**
Larval weight	1	74.79	0.56	0.4607	94658.88	3.56	0.0682

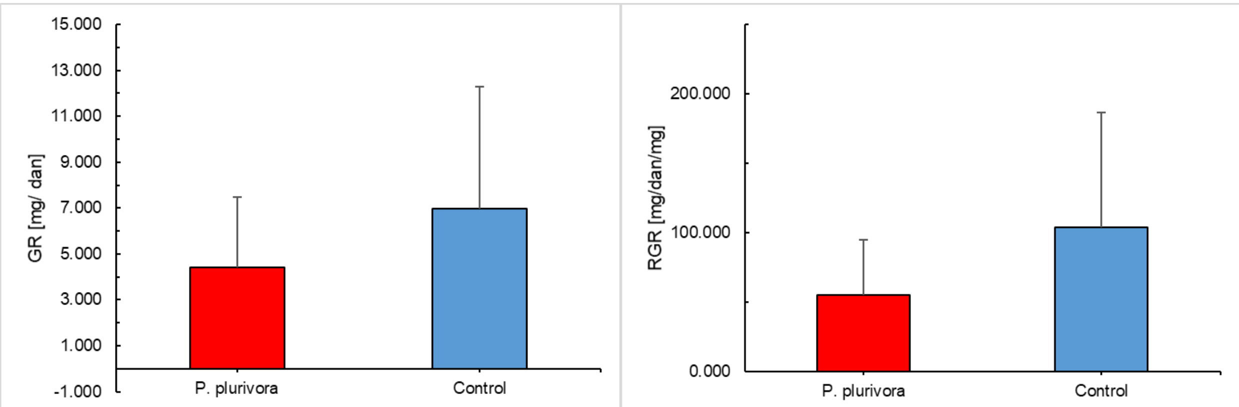
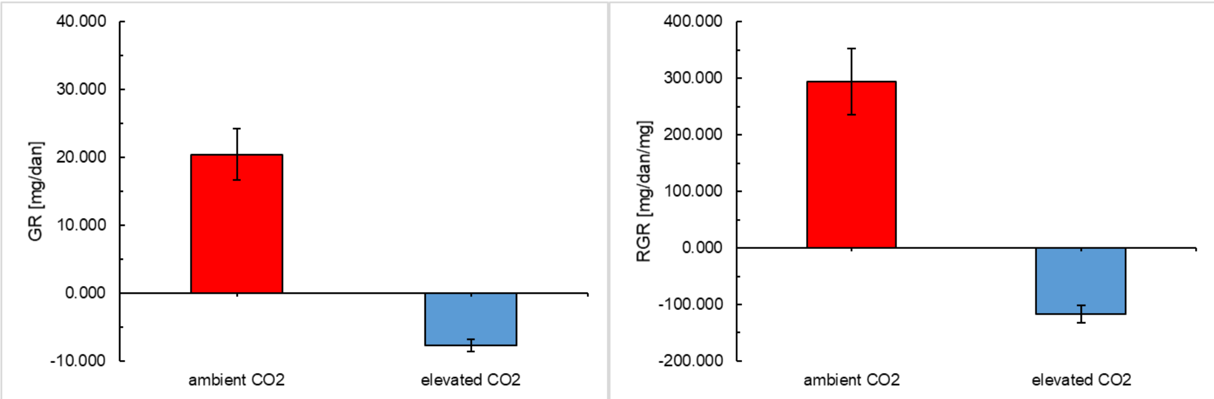
*Bold values indicates a statistically significant difference



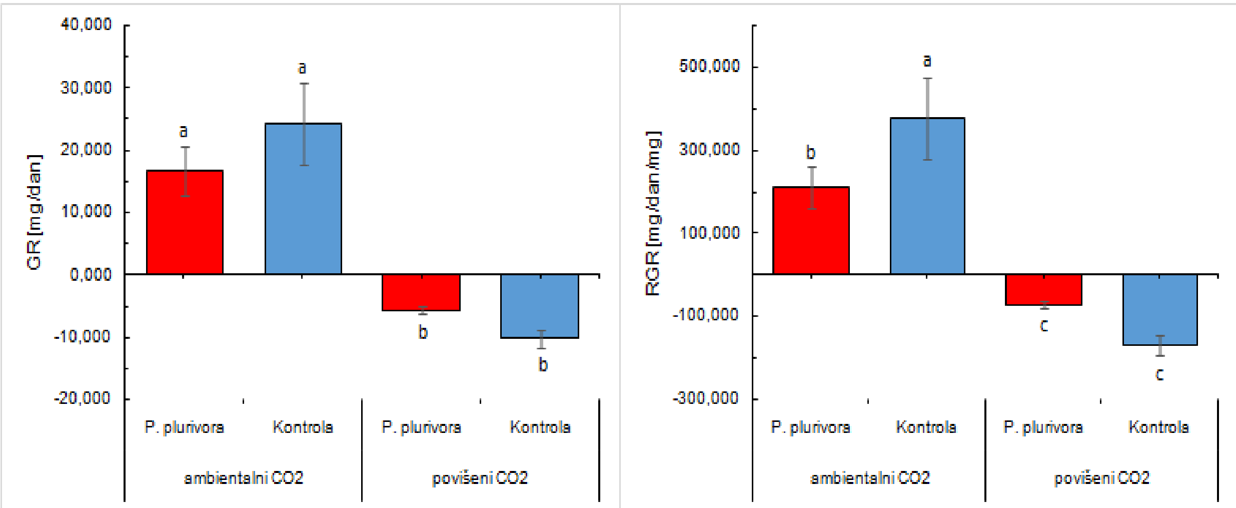
Graph 1. Influence of inoculation with *P. plurivora* on (a) growth rate (GR) and (b) relative growth rate (RGR) of the gypsy moth larvae

GR and RGR of the larvae of the LCA and LCE group compared to the PLA and PLE groups was 37% and 47% higher, respectively, but those differences were not statistically significant (Table 1, Graph 1).



Graph 2. Influence of CO_2 concentration on (a) growth rate (GR) and (b) relative growth rate (RGR) of the gypsy moth larvae

Influence of CO_2 on the performance of the gypsy moth larvae was statistically significant for both GR and the RGR (Table 1, Graph 2a, b). Larvae of the LCA and PLA groups gained 20 mg day^{-1} on average, while those of the LCE and PLE groups lost 7 mg day^{-1} on average (Graph 2a). Larvae of the LCA and PLA groups had a positive RGR of 294 mg day^{-1} mg^{-1}, and those of the LCE and PLE groups had a negative RGR of -116 mg day^{-1} mg^{-1} (Graph 2b).



Graph 3. Influence of CO_2 concentration and inoculation with *P. plurivora* on (a) growth rate (GR) and (b) relative growth rate (RGR) of the gypsy moth larvae

Larvae of the LCA group compared to those of the PLA group had a 31% greater weight. The GR of the larvae of the PLE group was 45% greater that of those from the LCE group (Graph 3a). The larvae of the LCA group had a 44% higher RGR than the larvae of the PLA group, while the RGR of the larvae of the PLE group had a 57% higher than of those in the LCE group (Graph 3b).

Inoculation of the Turkey oak seedlings with a root pathogen *P. plurivora* caused a negative effect on the growth of the gypsy moth larvae in this experiment, while Milanović, *et al.* (2015) noted a positive influence on the growth of the gypsy moth larvae which consumed the leaves of red oak (*Quercus rubra* L.) that were taken from the trees naturally infected with the same pathogen. These findings point out that the relations between a pathogen and an herbivore depends on the plant which mediates them. Also, these differences might be explained with the influence of the exposure length to the inoculum. Namely, in this experiment we used artificial inoculation and short-term exposure of the Turkey oak roots to the *P. plurivora*, and additional experiments with longer soil infestation tests are required to clarify the differences in these findings. Besides the influence of a root pathogen, the intermediary influence of CO_2 level on the gypsy moth larvae was also examined in this study. Numerous studies investigated the influence of CO_2 on diet and development of insects on different tree species (Traw *et al.*, 1996; Henn and Schopf, 2001; Hättenschwiler and Schafellner, 2004; Wang *et al.*, 2009). Hättenschwiler and Schafellner (2004) conducted a research on the diet of the gypsy moth larvae on adult trees in natural stands with elevated CO_2 levels (530 μ mol mol^{-1}). RGR of the larvae which consumed the leaves of the sessile oak (*Quercus petraea* (Mattuschka) Liebl.) exposed to elevated CO_2 levels was 30% lower that the RGR of the larvae which consumed the leaves of the trees exposed to ambient CO_2 level (370 μ mol mol^{-1}). Also, Wang *et al.* (2009) determined that on Mongolian oak (*Quercus mongolica* Fisch.) and birch (*Betula platyphylla* Sukaczev), at elevated CO_2 level, the GR of the gypsy moth larvae was 44.4% lower and the RGR 4.8%, respectively. The results of our experiment are even more drastic in terms of the reduction of GR and RGR in conditions of elevated CO_2 concentration because the recorded negative values, viz., the larval weight did not grow, but they actually lost weight. However, RGR of the larvae which consumed the laves of common hornbeam (*Carpinus betulus* L.) exposed to elevated CO_2 level increased by 29% compared to the RGR of the larvae which consumed the leaves of the control trees at normal CO_2 level. The RGR of the larvae that consumed the leaves of beech (*Fagus moesiaca* L.) did not show any significant decrease or increase at elevated CO_2 conditions (Hättenschwiler and Schafellner, 2004). By comparing these results, we can see that the larval development depends more on the host plant than on the CO_2 concentration (Hättenschwiler and Schafellner, 2004). Based on the above, we can conclude that the indirect influence of increased CO_2 concentration on gypsy moth larvae depends on the mediator tree species. This claim is backed up by the results of Traw *et al*. (1996) who monitored the feeding of gypsy moth larvae on yellow birch (*Betula allegheniensis* Britt.) and gray birch (*Betula populifolia* Marsh.) in the conditions of normal (350 ppm) and elevated (700 ppm) CO_2 levels. Their results indicate that the elevated CO_2 content does affect the gypsy moth larvae feeding on the leaves of gray birch, while when feeding on the leaves of yellow birch, the mass of the females decreases.

Conclusion

Based on the results of our research we can conclude that:

- In the conditions of increased CO2 concentration, inoculation with the root pathogen positively influences the growth of the gypsy moth larvae.
- In the conditions of ambient CO2 concentration, inoculation with the root pathogen negatively influences the growth of the gypsy moth larvae
- The increased CO_2 concentration does not only change the relations between the herbivores and their host plants, but also the relations between different groups of organisms which share the same host plant.

Abstract

We studied different aspects of application of foliar non-standard fertilizers based on amino acids, phytohormones and plant extracts. The trials were carried out at the level of the seedlings, individual plants grown in semi-controled conditions and plants grown in the field. Various energetic and thermodynamic parameters were analyzed, then the chemical composition (mineral elements, different sugars, secondary metabolites, etc.), as well as parameters of plant growth and their yield, in order to better assess the impact of these fertilizers on crops. We found that on maize seedlings it works by changing the content of various elements, then the polyphenol profiles, as well as thermodynamic parameters, where this effect does not only depend on the dosage of the fertilizers, but also on the corn genotype. We also found that the fertilizers affect the energetic and thermodynamic parameters of individual maize plants, as well as the parameters of plant growth. The most significant and most diverse results were obtained by analyzing the yield and components of the yield of many different crops (crop, fruit, vegetable), as well as their chemical composition (mineral elements, different sugars, secondary metabolites, etc.) in terms of improving nutritive quality. It was noticed that these fertilizers greatly affect the content of microelements, starch and crude proteins in maize and barley, sugar and polyphenol content in various fruit trees, as well as in soybeans, in which we note that in certain agroecological situations these fertilizers have led to spectacular magnification yields of different crops, but there were also situations when they did not have any positive effect on crop yields. Overall, the early treatment of cultivated plants with non-standard fertilizers greatly affects the vigor of seedlings of these plants, which is of great importance for crop yield. These fertilizers also significantly affect the quality of crop yield in terms of improved chemical composition of edible parts of these plants.

Keywords: *Amino acids, brassinosteroid (BRs) phytohormones, plant extracts, plant protection, resistance of plants to stress, biofortification*

Introduction

Unlike "classical" fertilizers, which are used as agro-technical measures to supply plants with certain elements, their treatment of non-standard fertilizers is primarily based on the intensification of plant metabolism, either due to their treatment with specific metabolites (eg, amino acids), either phytotohormones, or plants extracts, containing all these substances. This acceleration of plant metabolism occurs due to increased synthesis of protective substances, more intensive adoption of some important nutrients or due to the presence of additional signal substances outside. This path affects not only the yield of crops in quantitative terms, but, more importantly, their reaction to specific agroecological situations of abiotic, biotic and xenobiotic stress, as well as the change in some qualitative yield parameters in terms of increasing the nutritional value of economically usable parts of plants. Thus, more effects are achieved, which do not necessarily have to be related only to crop mineral nutrition, but also to their increased resistance to stressful situations, and also to the possibility of bio-conditioning of crops in a kind of organic food production. Unlike our previous release, which relates only to corn and fertilizer based on brasinosteroid phytohormones (Waisi *et al*., 2015), we give a broader overview of crops and types of applied non-standard fertilizers.

Materials and Methods

Plant growth and yield parameters are described in our previous work (Waisi *et al.*, 2015). The thermodynamic parameters are defined in usual manner (Sun, 2002), and their calculus is described in our previous works (Waisi *et al*., 2017a, 2018). Total polyphenols, starch, sugars, crude proteins, oils are described as in our previous work (Waisi et al., 2015), where a more detailed description of the methods of quantification of total polyphenols, proteins and polyphenolic fractions and antioxidative plant tissue capacity is given as in another our work (Đurović et al., 2019), while the description of the quantification of certain sugars was given in an PhD thesis (Waisi, 2016). The quantification of the elements was performed using the AAS method (Waisi *et al*., 2015, with more detailed in Waisi *et al*., 2017b).

Results and discussions

In our announcement (Nikolić and Waisi, 2012), we examined the results from micro-trials, wich where set up in 2011 in two apple orchards located at northern part of Serbia. Plots were treated with combinations of half of the usual dose of mancozeb and tebuconazole fungicides as a controla, and also same treatments combined with brassinosteroid (BRs) based preparation and also with non-standard fertilizers based on amino acids and plant extracts. First, we evaluated the usual parameter of yield of fruits, and the apples were sampled for determination of content of reducing sugars in extracts of fruit pulp. Also we assesed efficacy of these procedures to plant protection od apple leaves and fruits from notorious phytopatogenic fungus *Venturia inaequalis* (Stevanović *et al*., 2012). In Obrenovac trial evaluated yield/ ha of BRs treated apples is same as in control plots, with comparable pomological and fruit quality parameters of apple. In Šid trial evaluated yield/ ha of BRs treated apples for almost a quarter more then apple yield from control plots (treated by half and full doses of fungicides) and other treatments, also with comparable pomological and fruit quality parameters of apple fruits (data not shown). From plant protection view, our procedures is also satisfy with 78,71% and 77,69% protection efficacy of BRs+half fungicide doses treatment in leaves and fruits (against 84,17% and 87,90% efficacy from full fungicide doses treatment) at Obrenovac, which is satisfactory result. In *Šid locality* we got similar results, whith also satisfactory results (not shown). Our results are very similar to findings by other researchers (Khripach *et al*., 2000).

Also, we examined influence of non-standard fertilizers on yield and yield components in soybean and barley. During 2012 sezone 3 soybean genotypes (ZP-015, "Nena", and "Laura" with low content of Kunitz-trypsin inhibitor protein) was treated with a non-standard fertilizers, as type of biofortification. By this approach we found that it is in lesser extent affected by alterations in P_{phy} (content of phytic phosphorus), as important factor which restrain availability of mineral nutrients. Only at the Zn level, this dependence is significant, where lowering in P_{phy} increase parallel Zn concentration in grains. Moreover, the influence of β-carotene is significant for availability of mineral nutrients, but more important is that its increase is linked with parallel Fe increase, mainly in grains with higher weight, as part of better yielding potential. It is significant to underline that ratio between P_{phy}, β-carotene and mineral nutrients could be altered in some degree by application of foliar fertilizers with potentially higher availability of minerals, but it also depends on soybean variety. 24-epibrassinolide (24-EBL) based preparation and the plant extract ("Zircon") were efficient for decrease of mentioned ratio for ZP-015 and "Nena" grains, as well as some plant extracts ("Zlatno inje" and "Zircon") were efficient for "Laura". Also, in soybean is very significant correlation between 1,000 grain weight (as important yield component) and grain content of β-carotene and Zn (Dragičević *et al*., 2016b). At a beginning of seasons 2013 and 2014 we sown hull-less barley (*Hordeum vulgare* L. var. *nudum*; cv. "Apolon"), after that in the spring of the years, we treated the crop with BRs based preparation, and with other non-standard fertilizers (based mainly on plant extracts and other bioregulators). After harvesting in the summer we assessed yield (at 14% grain moisture content; kg ha^{-1}) and determined by standard methods different chemical ingredients from barley grains. Obtained results (Dragičević *et al*., 2016a) indicate that year affects barley grain yield and its chemical composition, with the highest impact obtained for Si under harsh climate conditions. Applied treatments was the most effective for grain yield and increase of grain quality mainly across reduction of P_{phy}/β-carotene ratio and increase of GSH content, thus increasing potential bioavailability of the mineral elements. What is more, stress present in high precipitation amount (in 2014) could be mitigated by application of *an* fertilizers by increasing potential bioavailability of P, Mg, Ca and Fe. Generally, BRs preparation influenced content of P_i, Zn and Fe, and other fertilizers mainly affected potential availability of some other mineral elements (Ca, Mn, Si and GSH).

From previous field trials carried out on one fruit and two field crops we indicated that *beetwen* other non-standard fertilizers, preparation based on BRs affects not so much yield, as to yield quality or chemical composition (Nikolić and Waisi, 2012; Dragičević *et al*., 2016a, 2016b) and protection to the crops in stress conditions (Stevanović *et al*., 2012).

In our paper (Đurović *et al*. 2019) the influence of different non-standard fertilizers on the content of polyphenolic acids and proteins in soybean seed was monitored. It is also followed the antioxidative capacity of soybean seed (as important soybean nutritional feature) by various methods: Total phenol content (TPC; not shown), free radical scavenging activity by 2,2-Diphenyl-1-picrylhydrazyl (DPPH) radikal assay, ferric reducing ability of plasma (FRAP) assay as a reducing power of soybean extract (Figure 1), and the Briggs-Rauscher (BR) reaction method (Figure 2). All examined plant-extract-based products expressed significant changes in the total phenolic contents and antioxidant activities of the soybean flour extracts. An exception was the treatment with "Cropmax", which only caused a decrease in TPC and antioxidant activities determined by the DPPH and FRAP methods. All other treatments showed a positive influence on the TPC, DPPH and FRAP methods, which is in accordance with several studies (Danilčenko *et al*., 2017; Verkleij, 2012) that showed a positive influence of biofertilizers (based on plant extracts) on the yield, growth and antioxidant activities of different plant species. The results of the post-hoc Tukey test showed that all treatments significantly effected a change in TPC as compared to the control sample. A statistically significant difference in antioxidant activity was not found between the samples treated with "Ekofus" and "Vegard", while all treatments in relation to the control sample exhibited statistically significant differences in antioxidant activity as measured by both DPPH and the FRAP methods. Inhibitory effects after the addition of aqueous extracts of soy flour to active Briggs-Rauscher (BR) mixture were reported (Cervellati *et al*., 2000). However, to the best of our knowledge, this is the first time that soybean treated with products based on plant extracts during vegetation were analyzed in the oscillatory Briggs-Rauscher reaction. It is well-known that the BR reaction method provides a "larger antioxidant picture" and can also show a synergistic effect (Milos and Makota, 2012).

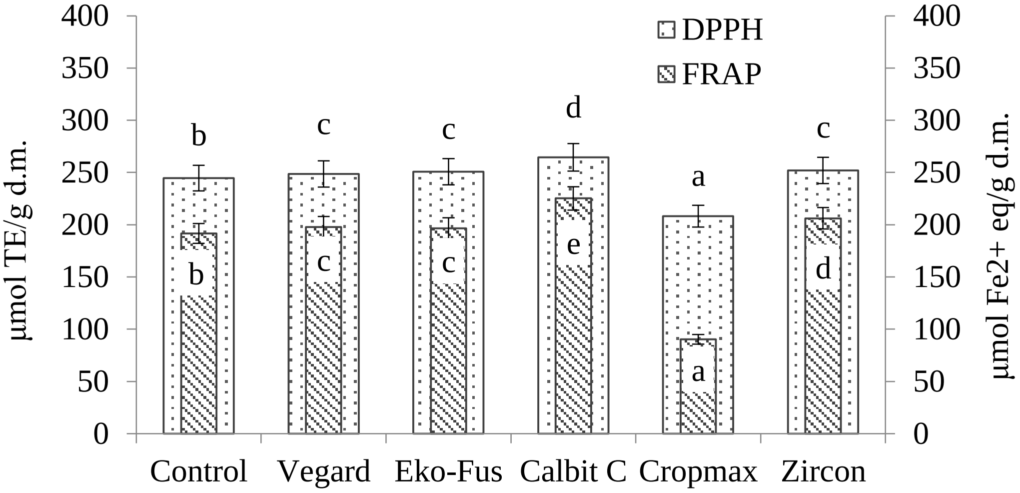

Figure 1. Antioxidant activity by 2,2-Diphenyl-1-picrylhydrazyl (DPPH) and ferric reducing ability of plasma (FRAP) assay in soybean seeds treated with plant extract products. The values followed by the same letters are not significantly different at the 0.05 level

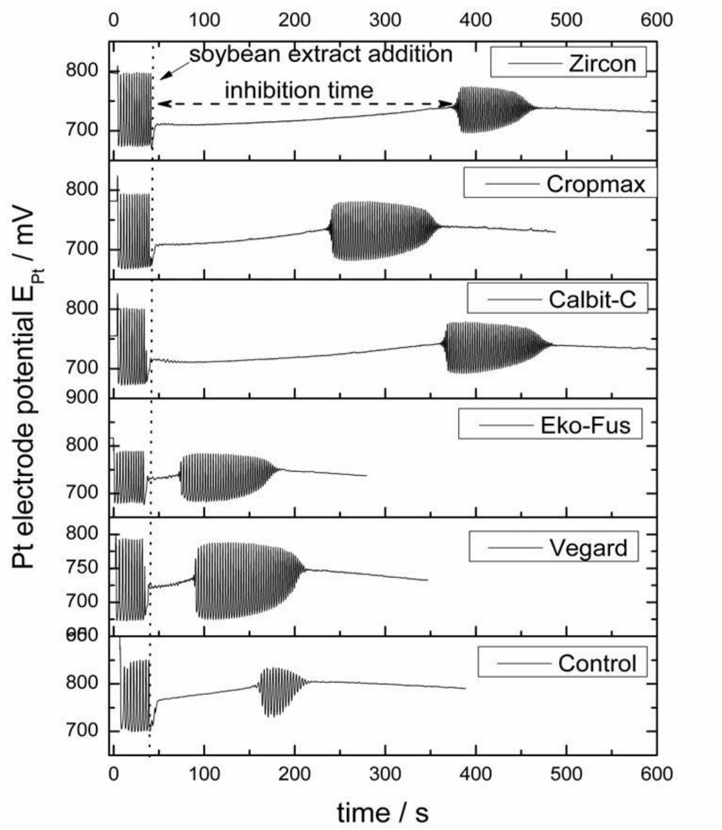

Figure 2. The Briggs-Rauscher oscillograms obtained with particular soybean extract addition (100 µl) after 30 s from oscillatory reaction beginning. The initial concentrations of reactants for BR reaction were $[CH_2(COOH)_2]_0$ = 0.0789 mol/dm^3, $[MnSO_4]_0$ = 0.00752 mol/dm^3, $[HClO_4]_0$ = 0.0300 mol/dm^3, $[KIO_3]_0$ = 0.0752 mol/dm^3 and $[H_2O_2]_0$ = 1.2690 mol/dm^3.

Therefore, the results obtained by the BR reaction method demonstrated the synergistic effect (of phenolic compounds and proteins) in soybean treated with "Cropmax", as well as a more favorable outcome of soybean treatment with "Calbit-C" and "Zircon". This indicated that not only phenolic compounds participated in the inhibition of the oscillatory regime, but also other molecular species (such as proteins and some ions), which influenced the BR reaction, possibly by building and/or stabilizing macromolecular structures in plant cells.
Also we tested (Waisi *et al*., 2017) a brassinosteroid (BRs) phytohormone based fertilizer and their influence on plant growth and microelements accumulation in seedlings of two maize genotypes. It was found that BRs influencing both germination and growth of maize hybrids ZP 704 and ZP 434 at their lower concentrations. Hybrids divergently reacted to exogenous treatment by brassinosteroids. Lower BRs concentrations stimulated seed germination and growth of seedlings, but high concentrations inhibited these processes. Considering that germination percentage, whole plant mass and their *innitial* height as a vigour parameters of plants, seedlings treated with various concentrations of brassinosteroids will probablly have better chance for growth and field establishment. It was found that BRs is affecting redistribution of elements in young plants. Elements could be linked with initial growth and it was assumed that in the case of hybrid ZP 704, poorer emergence of shoots is influenced with lower Zn concentration, since it is known that the Zn and plant growth are correlated. In case of the lowest concentration of brassinosteroid (BRs) phytohormone is obvious blocking distribution of Cu, and these could mean that maize plants could achieve optimum of growth in polluted soils. Low values of ratio of photosynthetic pigments for both hybrids are confirming photosynthetic inactivity. Results are implicating from our findings that maize treated with BRs could be grown at soil polluted with heavy metals due to its ability to remove or block accumulation of toxic elements, especially in shoot.

Conclusions

Overall, the early treatment of cultivated plants with non-standard fertilizers greatly affects the vigor of seedlings of these plants, which is of great importance for crop yield. These fertilizers also significantly affect the quality of crop yield in terms of improved chemical composition of edible parts of these plants.

COMPARISON OF THE BIOACTIVITY OF PROPOLIS EXTRACTED BY OLIVE OIL PRODUCED BY DIFFERENT PRODUCTION PROCESSES

Sibel SİLİCİ*

Abstract

Virgin olive oil is obtained from the fruits of the olive tree (*Olea europea*) by mechanical or other physical means, under conditions that do not cause any changes to the oil. Important factors in the production of good quality olive oil are the harvesting period, maturity of the fruit, the mode of harvesting (hand picking, nets, other means), storage of olives before processing, leaf removal, mode of crushing and kneading, and the system of extraction. Some oils, such as virgin olive oil, are used without further treatment, but most are refined in some measure before use. The refining processes remove undesirable materials, but may also remove valuable minor components which are antioxidants and vitamins such as carotenes and tocopherols. In this study, propolis was extracted with virgin, refined and riviera olive oils in different condensations. Then, the total phenolic, antioxidant and antiradical activities of these extracts were measured. Total phenolic content of the extracts ranged from 462.03-1780.49 mgGAE/100g, antioxidant activity 9.27-27.39 mgAAE/g and antiradical activity 57.52-83.32%. According to the results, the highest activity was observed in virgin olive oil extract.

Key words: Propolis, olive oil extract, total phenolic content, antioxidant activity

Introduction

Propolis is a bee product with high resin content which is used as a building material and provides hygiene in the hive by adding wax and bee secretions to the resin collected from the poplar tree buds. Although the chemical composition of propolis is highly dependent on its geographical and plant origins, crude propolis is mainly composed of resin (50%), wax (30%), essential oils (10%), pollen (5%) and other organic compounds (5%). Phenolic compounds, esters, flavonoids, terpenes, beta-steroids, aromatic aldehydes and alcohols are important organic compounds found in propolis (Gomez-Caravaca et al. 2006).

Since propolis is not used in the food and pharmaceutical sector in its raw form, it is usually extracted with ethyl alcohol, propylene glycol and glycerol. However, due to the restriction of the use of alcohol for religious reasons, alcohol intolerance and children, researchers have sought to find new solvents. One of these solvents is olive oil. In olive oil, more than 200 different chemical compounds have been identified, including sterols, carotenoids, triterpenic alcohols and phenolic compounds. Phenolic compounds are also the main antioxidants found in extra virgin olive oil containing both hydrophilic and lipophilic phenols. The main phenolic subclasses found in olive oil are phenolic alcohols, phenolic acids, flavonoids and ligands (Bendini et al. 2007; Servili et al. 2009). To date, many reports have shown that phenolics found in extra virgin olive oil show strong antioxidant properties and can prevent oxidative stress in brain tissue (Beauchamp et al., 2005; Visioli et al., 2002; Petroni et al. 1995). Some epidemiological studies have shown that the consumption of olive oil has an effect on diseases such as cardiovascular diseases, cancer and rheumatoid arthritis (Guasch-Ferre et al., 2014; Pelucchi et al. 2010; Berbert et al., 2005).

In this study, total phenolic content of propolis olive oil extracts prepared by using different production methods with olive oil (cold press, rivyera, refined) and different concentration of propolis samples were determined by Folin Ciocalteu method and antiradical activity by DPPH method and antioxidant content were determined by phosphomolibdenum test.

Material and methods

Propolis sample

Propolis samples were obtained in 2016 by hand collected from the beekeepers in the region where the poplar trees are common in Bünyan district of Kayseri. In the extraction of propolis with olive oil, cold pressed, refined and rivera olive oils were prepared in 10, 20, 30 and 40% concentrations.

Preparation of Propolis Extraction

10, 20, 30 and 40 grams of propolis were weighed to be 100 ml v/w with olive oil obtained by different production methods.

Determination of total phenolic content

Total phenolic content in the propolis was determined by Folin-Ciocalteu method and applied spectrophotometrically (Singleton and Rossi, 1965). The propolis samples were weighed to 1 g, prepared with 4 mL (diluted 4-fold in a 1: 4 ratio) methanol (Merck KGaA, Darmstadt, Germany) and thoroughly dissolved by vortexing. 1 (Sigma Aldrich, Darmstadt Germany). The concentration of the samples was taken as 200,000 ppm stock. Propolis samples were prepared in 5 replicates. From a 40 stokL stock propolis sample, 2400 µL distilled water, 200 µL undiluted Folin-Ciocalteu (Sigma Aldrich, Darmstadt Germany) reagent, 600 µL Sodium carbonate (20% Na2CO3 Merck Millipore KGaA, Darmstadt, Germany) solution and finally 760 distL distilled water was added to the experiment was established. For two controls, 40 yerineL of methanol was placed in place of the sample and incubated at room temperature and in the dark for 2 hours. The absorbance of the resulting mixtures was then read on the spectrometer (Varian Cary, United State) against corn at a wavelength of 765 nm, and the total phenolic content was given in mg gallic acid equivalent (GAE) / 100 g propolis.

Determination of Total Antioxidant Capacity

Antioxidant capacity of propolis samples were determined by phosphomolybdenum method (Prieto et al., 1999). One g of the propolis sample was weighed and vortexed by addition of 9 mL of methanol to allow complete dissolution. 1 (Sigma Aldrich, Darmstadt Germany). 2.1290 g of sodium phosphate (Merck Millipore KGaA, Darmstadt, Germany) was weighed in a beaker and dissolved in some amount of purified water, 0.9887 g of ammonium molybdate (Merck Millipore KGaA, Darmstadt, Germany) was weighed in a separate beaker and dissolved in a quantity of purified water, weighed in 11.7696 g of sulfuric acid . Sodium phosphate and ammonium molybdate were dissolved in a measuring tape with the aid of distilled water, and the weighed sulfuric acid was slowly added. It was then made up to 200 ml with distilled water and made ready for use.

400 µL of the sample liquid aliquot from the stock sample was mixed with 4 ml of reagent solution (0.6 M sulfuric acid, 28 mM sodium phosphate and 4 mM ammonium molybdate) and placed in a stand in a 95 ° C water bath (Julabo®, Seelbach/Germany) for 90 minutes. The reaction was stopped by cooling in water and the absorbance of the samples was read spectrophotometrically at 695 nm wavelength.

Determination of Antiradical Activity

The free oxygen scavenging activities of propolis extracts were determined using DPPH (2,2 diphenyl-1-picrylhydrazyl) method with some modifications (Gyamfi et al., 1999). The propolis samples were weighed to 1 g, prepared with 4 mL (diluted 4-fold in a 1: 4 ratio) methanol (Merck KGaA, Darmstadt, Germany) and thoroughly dissolved by vortexing. 1 (Sigma Aldrich, Darmstadt Germany). The concentration of the samples was taken as 200,000 ppm stock. Propolis samples were prepared in 5 replicates. Weighed 0.0049 g of DPPH reagent (Sigma Aldrich, Darmstadt, Germany) in a plastic weighing vessel, dissolved with 20 mL of methanol, and finished again with 125 mL of methanol. The concentration of the samples was taken as 200,000 ppm stock. 100 µl of propolis samples and 3900 µl of DPPH reagent were mixed and the mixture was kept at room temperature in the dark for 2 hours and its absorbance was read spectrophotometrically at 517 nm wavelength.

% Values of antiradical activity; % inhibition = [(Abs control-Abs sample) / Abs control) * 100].

Statistical Analysis

The SPSS 11.00 for Windows software package was used for ststistical analyses. Data were given in the form of arithmetical mean values and standard deviations. One-way analysis of variance was performed, and variant groups were determined by means of the Duncan test.

Results and Discussion

The total phenolic content, antioxidant and antiradical activities of propolis extracts obtained with olive oil at different concentrations and different production properties are shown in Table 1. The total phenolic content of propolis extracts obtained in 10-40 % concentration using refined olive oil varied between 462-03-1650.98 mgGAE/100 g. Antioxidant activity was 9.27-22.04 mgAAE/g and antiradical activity ranged between 78.71-81.79 %. In the extracts made using cold pressed olive oil, total phenolic content was determined between 633.76-2064.74 mgGAE/100 g, antioxidant activity 12.74-27.39 mgAAE/g and antiradical activity 69.61- 82.21%. The total phenolic content, antioxidant and antiradical activity of the extracts using other solvent riviera olive oil were determined as 550-51-1780.49 mg GAE/100 g, 10.03-20.61 mgAAE/g and 57.52-81.19 % respectively.

As a result, it was found that cold pressed extra virgin olive oil had the highest values in all concentrations in terms of total phenolic content and antioxidant and antiradical activity.
As a result of the regression analysis;
Total phenolic substance - Antioxidant activity R = 0.943 R^2 = 0.890,
Total phenolic agent - Antiradical Activity R = 0.655 R^2 = 0.428,
Antioxidant activity-Antiradical Activity R = 0.643 R^2 = 0.414 was determined to have a positive correlation between total phenolic content and anitoxidant and antiradical activity. Similarly, a positive correlation was found between antioxidant and antiradical activity.
Although extraction of propolis with alcohol and its derivatives is seen as a simple and effective method, it has a sharp resinous taste and limitations in its use in the cosmetic and pharmaceutical industries. In addition, ophthalmology is not considered appropriate for medical use as in patients with otorhinolaryngology, pediatrics, diabetes and cancer, and people with alcohol intolerance (Kubiliene et al., 2015). In water extraction of propolis, it is reported that phenolic compounds are 10 times lower than ethanolic extraction due to the low water solubility of the active components of propolis (Mello et al., 2010; Matta et al., 2004). For this reason, researchers have started to obtain high activity propolis extract by using non-chemical natural solvents other than ethyl alcohol, propylene glycol and glycerol. Therefore, the dissolution of propolis with vegetable oils and the biological activities of oil-soluble phenolic compounds are of interest. In this research, total phenolic, antioxidant and antiradical activities of propolis extracted with extra virgin olive oil were found to be higher than those obtained by other methods.
Olive oil obtained by chemical extraction can only be used for consumption after refining. A refining process is to purify the extracted oil from any residual solvent and other impurities. Refined olive oil; it lacks vitamins, polyphenols, phytosterol and natural ingredients (Kamm et al. 2001). Extra virgin olive oil is more expensive than other olive oils, but contains the highest level of polyphenols (kalogeropoulos ve Tsimidou, 2014). Due to the removal of free fatty acids, extra virgin olive oil has additional flavor, aroma and light color. Olive oil is mostly composed of triacylglycerols (98-99%). Triacylglycerols (TGA) are various groups of glycerol esters with different fatty acids. The predominant fatty acid found in TGAs with olive oil is monounsaturated oleic acid. The fatty acids that form the remainder of the olive oil TGAs are palmitic acid, linoleic acid, stearic acid and palmitoleic acid. Extra virgin olive oil contains abundant lipophilic or amphiphilic microcomponents, including phytosterols, squalene, tocopherols, phenolic compounds, terpenic acid derivatives (Baskou, 2009;

Luchetti, 2002; Ramirez-Tortosa et al., 1997). Phenolic compounds are formed as phenolic acids or alcohols, oleuropein derivatives, ligands and flavonoids. The content of polyphenols in olive oil ranges from 50 to 1000 mg / kg (Fragaki et al., 2005; Grossi et al., 2014; Luna et al., 2006).

It is a known fact that the total phenolic content of propolis varies depending on the plant source of the propolis, the season, the extraction method of propolis and the solvent used, but has a strong biological activity. Because, considering its use in nature, resin, which is the main substance of propolis, protects the plant bud, propolis created by honey bees by adding saliva and wax protects the honey bees.

Although there are many studies on the total phenolic, antioxidant and antiradical activity of ethanolic and water extract of propolis, there is little research about these activities of olive oil. Kubiliene et al. (2015) water, propylene glycol, alcohol and olive oil used as a solvent in the research propolis + water extract (W1) 5 hours at room temperature, propolis + PEG + water extract (W2) at 70 ° C, propolis + olive oil extract (A1) at room temperature The propolis + PEG + olive oil + water extract (A2) was extracted at 70 ° C and the propolis ethanol extract (EEP) was extracted at room temperature. As a result of this extraction method, the total phenolic content of the extracts were determined to be 1.6, 10.7, 0.5, 9.5 and 12.7, respectively. According to our research results, total phenolic content of propolisin olive oil extract was determined to be between 6.34-20.65 mg/ml GAE. In addition, as the concentration of propolis increased, total phenolic content increased. The differences in the results may be due to the extraction method and the nature of the solvents used. Because the olive oil used in our research was cold-pressed extra virgin olive oil, the duration of extraction with propolis was one week and the extraction temperature was 40 ° C.

Conclusion

In conclusion, it is necessary to select the appropriate extraction method in order to obtain high phenolic content of propolis in olive oil extract. In other words, in the extraction of propolis, besides the factors related to propolis, solvent, extraction time and temperature also gain importance in total phenolic content.

NUTRITIONAL CONTENT OF BEE BREAD (PERGA) FROM NEW DISCOVERED HONEYBEE PRODUCTS

Sibel SİLİCİ*

Erciyes Üniversity, Agriculture Faculty, Department of Agricultural Biotechnology, Kayseri, Turkey
*Corresponding author: sibelsilici@gmail.com

Abstract

The basic nutrient needs of honeybee (*Apis mellifera* L.) are nectar, pollen, and water. While nectar is the source of carbohydrates for honeybees, pollen is a source of protein, lipid and vitamins. The pollen collected by forager honeybees is brought to the hive by putting the honey bee secretions and pressing the pollen basket. Then, with the help of other young bees in the hive, beebread is poured into the honeycomb cells and covered with a small amount of honey and bees wax to prevent spoilage. This mixture is subject to chemical modification by the action of different enzymes, microorganisms, moisture and temperature (35-36 C). This chemically modified pollen is called "bee bread". Bee bread is consumed by adult bees and larvae as fed. The chemical structure of production of bee bread in Turkey was identified in this study. Chemical analyzes were performed according to the methods recommended by AOAC. Accordingly, the ash, protein, carbohydrate, dietary fiber, fat and energy content of bee bread were determined as 8.14g / 100 g, 13.56 g / 100 g (Nx6.25), 30.60 g / 100 g, 18.18 g / 100 g, 21.69 g / 100 g and 408 kcal / 100 g, respectively. There is a need for research on perga, which is rich in nutrients and has bioactive properties.

Key words: *Bee bread, perga, chemical analysis, nutritional content*

Introduction

Living things need nutrients to grow, reproduce and obtain energy. The nutrients of honey bees are nectar and pollen. Honey bee larvae hatching feed on nutrients prepared by young worker bees. These nutrients contain the necessary nutrients for the development of larvae and are rich in protein. A larva needs 4-6 mg of nitrogen to grow. For the development of honey bee larva, amino acids such as cystine, aspartic acid, asparagine, leucine, phenylalanine, arginine must be present in their nutrients. While carbohydrates give energy, vitamins are effective in the development of food glands. Water is necessary for honey bees as well as all living organisms. The content of food in honey bees gains great importance in caste differentiation (Brodschneider and Crailsheim, 2010).

For adult honey bees, honey contains a high percentage of carbohydrates, while the protein content is very low. Pollen is essential for the growth of young worker bees, the development of tissue, muscle and food glands. However, without pollen, it is impossible for colonies to breed offspring. A worker bee needs 3.21 mg of nitrogen to become mature, which is met by 145 mg of pollen. In order to meet protein and amino acid needs, a normal colony collects pollen between 20-60 kg per year. (Brodschneider and Crailsheim, 2010).

Pollen is collected by worker bees older than 21 days who have completed their hive tasks. The season in which the colonies collect pollen most intensively during the year is the spring months and the period in which the offspring activity is highest. Pollen collection activity is provided by the baskets located behind the tibia of the honey bees. The honey bee takes pollen from the flower with its upper jaw and gets it on its tongue with its lower jaw. It is then moistened by vomiting honey and placed in the pollen basket on the hind legs with the help of middle legs. The pollen carried to the hive is discharged to the honeycomb cells with the help of other worker bees in the hive. It is covered with a small amount of honey and wax. Pollen, honey, saliva enzymes and temperature effect in the honeycomb start the chemical process

and the pollen is fermented. This pollen, whose chemical structure is differentiated, is called "bee bread" (Vásquez A, Olofsson, 2009; Anderson et al. 2014).
Bee bread contains about 20 % protein, 24-35 % carbohydrate, 3 % lipid, 3% vitamin and mineral. Bee bread (perga) has a alarga variety of minerals and high quantities of iron, cobalt, phosphorus, calcium, and it is one of the richest natural foods containing selenium. It is also contains all the essential amino acids that the human body cannot bisynthesize suc as phenylalanine, leucine, valine, isoleucine, arginine, histidine, lysine, methionine, threonine, and tryptophan, vitamins such as A, B1, B2, B3, B6, B12, C, PP, E, D, K, H, ensymes such as amylase pigments, phosphatase sucrose, flavonoids and caratenoids, Also it is a nourishing supplementt rich in phyophormones, flavonoids, amino acids, minerals, and other biological compounds with bioavailability at least three times more than pollen (Ceksteryte et al., 2012; Kaplan et al., 2016; Tomas et al., 2017).
In this research, the nutrient content (ash, protein, carbohydrate, dietary fiber, lipid, and energy) of bee bread was determined.

Material and Methods

Bee bread samples
Bee bread was obtained from Nutral Therapy Company in Kayseri, Turkey and was stored at -20 C°.

Chemical analysis
Chemical analysis of bee bread (ash, crude fat and crude protein) was carried out using standard AOAC methods 920.153, 991.36 and 960.52, respectively. Moisture content was measured using a vacuum oven model VO200 (Memmert GmbH+Co. KG, Schwabach, Germany) at 60 °C and weighing until a constant mass. The ash content was measured gravimetrically after incineration at 550 °C and weighing. The total protein content was calculated by multiplying the nitrogen content by nitrogen to protein conversion factor of 6.25. (AOAC, 2000). All analyses were made in triplicate and the results were expressed in g per 100 g of fresh bee bread.
Determination of oil content was carried out using the ISO 659:2009 standard method. The bee bread samples were homogenized using a stainless steel blender (Waring, Atlanta, GA, USA). A mass of 2 g of sample was weighed accurately into a glass beaker and mixed with 100 mL of 4 M HCl. Then the content was heated at 100 °C and stirred for 15 min. After cooling to room temperature the solution was washed three times with 25 mL of distilled water. The sample was filtered through a filter paper, which was dried at 105 °C in an oven for 1 h. The extraction of oil from bee bread samples was carried out with diethyl ether at 50 °C for 3 h by automated Soxhlet extractor (VELP Scientifica, Usmate (MB), Italy).
Statstical Analysis
The SPSS 11.00 for Windows software package was used for ststistical analyses. Data was expressed in mean values of three replicates and expressed as mean ± SD..

Results and Discussion

According to the results of our study, ash, protein, carbohydrate, dietary fiber and fat content of dried bee bread were 8.14, 13.56, 30.60, 18.18, 21.69 g / 100g, respectively. Barene et al. (2015) study, the nutrient content of bee bread; Proteins were found to be 20.30–21.70% Fats 0.67–1.58% carbohydrates 24.40–34.80%. Compared to this research, the reason for the difference in protein and fat values may be due to the use of dried bee bread in our study. Zuluaga et al. (2015) determined that ash content of bee bread obtained from Colombia was 2.19-2.60, lipid content was 1.65-5.50% and protein content was between 19.1-27.3%. In another study, Tomas et al. (2017) determined the amount of ash, protein, carbohydrate, fat

and energy in 17 bee samples collected from Portugal as 2.1-7.7, 14.1-20.9, 63-78, 3.6-16.8% and 397-468 kcal, respectively. In another study from Turkey by Kaplan et al. (2016) the moisture fractions of the samples were between 11.4 and 15.9%, the mass fractions of ash were 1.9 to 2.5%, the fat from 5.9 to 11.5% and protein from 14.8 to 24.3%.
The nutrient content of bee bread samples obtained from different geographic regions is different. Possible reasons for this are; different flora, processing processes, for example, fresh /dried.

Table 1. Nutrient content of bee bread

Nutrients	**Content**
Ash	8.14±0.2 g/100g
Protein	13.56±0.6 g/100g (Nx6.25)
Carbohydrate	30.60 ±1.2 g/100g
Dietary fiber	18.18 ± 0.4 g/100g
Fat	21.69±0.8 g/100 g
Energy	408 ± 1.6 kcal/100 g

An increasing number of researcher appreciate the therapeutic effect not only of honey, but also of other products such as bee polen, bee bread, royal jelly, apilarnil, and bee venom with wide application in apitherapy. Bee bread (perga) is a unique product, which is very important not only for humans, but also for the bees. It is not always easy to get it, and the price is several times higher than the price of honey and bee pollen.
Honeybees pack the components in the cells of the honeycomb, then cover the mixture with bee wax and honey (Barene et al., 2015). Then covered and preserved pollen is subject to lactic fermentation in the environment of beehive. Fermented bee pollen is called the"bee bread"(Fuenmayor et al., 2014; DeGrandi et al. 2013). It is known that, bee bread is characterized by a higher nutritional value than pollen,better digestibility, and richer chemical composition (Habryka,Kruczek, and Drygas, 2016). Moreover, it is better absorbed by the human body than pollen since the nutritional components of bee bread are partially fermented and are more easily assimilated in human organism (Barene et al.,2015). Bee bread contains considerably larger amounts free amino acids. The presence of all the essential amino acids, perga is characterized by better composition than many valuable products obtained based on animal proteins. It contains about 30% protein on average (Degrandi-Hoffman et al.,2016). Roulston and Cane (2000) revealed that, the content of starch in pollen is in the range of 0–22%. Carbohydrates constitute between 24 and 34% (Barene et al.,2015). Perga is more biologically active and easily digestible due tothe high content of easily digestible sugars, fat, vitamin-mineral components, and a higher proportion of free amino acids when compared to pollen (Nagai et al., 2004; Trzybiński, 2005). Bakour et al. (2019) demonstrated that carbohydrates (74.82 ± 0.04 g/100 g bee bread) followed by proteins (19.96 ± 0.08 g/100 g bee bread) were the main macronutrients in bee bread. They were found for ash (3.32 ± 0.08 g/100 g bee bread) and fat (1.90 ± 0.086 g/100 g bee bread), revealing an overall energetic contribution of 396.2 ± 0.4 kcal/100 g bee bread).
Zuluaga et al. (2015) described that the lipid content ranged from 1.65% to 5.50% of bee bread. Andelkovic et al (2012) in Serbian bee bread samples, reported that the lipid content ranged between 4.51% and 4.92%. Moreover, the protein content in bee bread samples from Colombian and Serbia ranged from 27.6% to 29.9%, respectively (Andelkovic et al., 2012; Zuluaga et al., 2015). The differences found between the samples could be due to the floral origin of the bee bread (Urcan et al., 2018).

Conclusion

People are paying more attention to their health in a developing and changing world. Nutritional activities are no longer just a necessity, but have become an activity aimed at preventing or treating diseases. People now understand the importance of natural life and natural nutrition rather than chemicals. Bee products are one of the most important of these natural food groups. Bee bread, which contains protein, vitamins, minerals and carbohydrates, is one of the important nutrients with high nutritional value.

Abstract

Deoxynivalenol (DON) is one of several mycotoxins produced by certain *Fusarium* species that frequently infect wheat, corn, rice, oats, barley and other grains in the field or during storage. DON affects animal and human health causing vomiting, acute temporary nausea, diarrhea, abdominal pain, headache, dizziness and fever. Wheat flour and wheat flour-based products, such is bread take an essential place in Serbian diet which raises exposure level of total population in cases of higher contamination. The objective of this study was to evaluate the presence of DON in wheat flour bread. In this study, a total of 210 samples of wheat flour bread were collected in the period of 2018-2019. All samples were analyzed for DON by enzyme-linked immunosorbent assay. DON was detected in 47 out of 210 wheat flour bread samples (22.38%), at levels ranging from 81 to 214 μg/kg. The maximum contamination level of DON (214 μg/kg) in this study was found in wholemeal bread. These results suggest not very high percentage of contaminated samples. However, the level of contamination was higher in wholemeal bread than in white bread, which raises a risk for consumers of bread made of whole wheat flour.

Key words: Deoxynivalenol, bread, ELISA.

Introduction

Wheat bread is a staple food prepared by baking a dough of flour and water usually leavened with yeast, which is widely consumed around the world (Dewettinck *et al.*, 2008).

Unfortunately, wheat like many other cereals is susceptible to fungal attack and possible mycotoxin contamination, which affects wheat-based products, as well. The presence of mycotoxins is often associated with chronic or acute mycotoxicoses, therefore their occurrence in cereals is of great concern worldwide . Approximately 25% of cereals produced in the world are contaminated with mycotoxins (Charmley *et al.*, 1995).

A great variety of fungi can produce mycotoxins, however several *Fusarium* species are predominant pathogens on cereals in both temperate and semitropical areas and present major concern for all European cereal growing areas (Bottalico, 1998). The percentage of contamination on the worldwide level for some *Fusarium* toxins, such is DON, is considered to be much higher than 25% (Bullermann, 1996).

Deoxinivalenol (DON, vomitoxin) is a natural-occuring mycotoxin, type B-trichothecenes produced mainly by strains of *F. graminearum*, a food-borne fungi widely spread in crops. DON is considered to be one of the most important mycotoxins in wheat and wheat based products. It affects both animal and human health by causing gastro-intestinal problems followed by diarrhea and vomiting (Kushiro, 2008).

Although, occurrence and prevention of DON has been intensively studied, there is a small number of studies conducted in Serbia on retention of DON after harvest and during processing. It is important to know survival rate of mycotoxins during processing in order to evaluate the risk that Fusarium mycotoxins might pose to the consumer. To achieve this it is necessary to study both the occurrence of the mycotoxins in primary agricultural crops such as wheat and the effect of processing and food manufacturing on their concentrations in the retail products (Hazel and Patel, 2004). While considerable data are available to show the frequency and levels of Fusarium mycotoxins, particularly DON, occurring in wheat there is much less information on their transfer to wheat-based products such as bread, cakes, pastries and biscuits at the retail point (Scudamore *et al.,* 2009).

Wheat flour and wheat flour-based products, such are bread, pasta, pastry and cookies represent approximately 26% of Serbian market basket and hold and essential place in Serbian diet (Škrbić *et al.,* 2012).

The objective of this study was examination and determination of the presence of DON in wheat flour bread collected from Serbian producers in order to determine the levels of contamination in different types of wheat flour bread.

Materials and Methods

Reagents and chemicals

RIDASCREEN FAST DON SC (R-Biopharm), a competitive enzyme immunoassay for quantitative analysis of DON in cereals, malt and feed was used according to manufacturer's instruction (RIDASCREEN FAST DON SC Art.No.:R5905). Distilled water was used for the extraction.

Collection of samples

From September 2018 until April 2019, 210 samples of white bread and wholemeal bread were collected from 50 Serbian producers, as a part of the food safety control. Of total number of samples 150 were white bread, and 60 were wholemeal bread. Before analysis, the samples were stored at 4-6 °C and protected from light.

Sample preparation

Collected samples were prepared and analyzed in accredited laboratory for testing food and feed safety Jugoinspekt Beograd. All samples were thoroughly homogenized. Namely, 5 g of each sample of white bread and wholemeal bread was extracted by shaking with 100 ml of distilled water manually for 5 minutes. After shaking sample extracts were filtered through Whatman No.1 filter. 50 μL of the filtrate was used for further analysis according to RIDASCREEN FAST DON SC manual.

Instrumental conditions

The measurement is made photometrically at 450 nm. The absorbance is inversely proportional to the DON concentration in the sample. Multiskan FC microplate reader with absorbance range 0 - 6.000 A was used. Normal reading mode was used with reading speed t = 13 s. Using method was validated (LoD = 75 μg/kg, Recovery = 92%).

Statistical analysis

All obtained data were analyzed using SPSS 15.0 software (SPSS, IBM corporation, USA).

Results and Discussion

The results on occurrence of deoxynivalenol in white wheat flour bread, whole wheat flour bread are given in Table 1.

DON was detected in 18 out of 150 white bread samples (12.00%), at levels ranging from 78 to 176 μg/kg. The average and median values obtained for DON in white bread were 101 and 85 μg/kg, respectively. Of 60 samples of whole meal bread 29 was contaminated by DON (48.33%), at levels ranging from 118 to 214 μg/kg. The average and median values obtained for DON in wholemeal bread were 113 and 94 μg/kg, respectively. The maximum contamination level of DON (214 μg/kg) in this study was found in wholemeal bread. None of the white bread nor wholemeal bread samples exceeded the limit of 500 μg/kg set by Serbian regulative for allowed presence of DON in wheat flour bread („Sl. glasnik RS", br. 22/2018 - Official Gazette of the RS no. 22/2018). The obtained results are in compliance with the level of contamination of bread showed in a study report done by EFSA. (Scientific report of EFSA, 2013). Higher levels of DON found in wholemeal bread are due to the fact that the distribution of DON is not uniform in the milling fractions (Abbas *et al.*, 1985). Abbas *et al.* (1985) found that the highest concentration was in bran, followed by reduction flour and break flour, which proves that the invasion of fungus into the wheat is not uniform, as well. Trigo-Stockli *et al.* (1996) in the similar study, reported that DON levels were highest in the bran (3.4 mg/kg) and lowest in the flour (1.5 mg/kg), as well. This could be due to the fact that after milling most of the concentration remains in outer layers (Tanaka *et al.*, 1986).

Table 1. Occurrence of deoxynivalenol (DON) in white bread and wholemeal bread

Commodity	DON (µg/kg)				
	No. of positives/total	Average value [a]	Median value	max value	Interval of concentration (contaminated samples)
white bread	18/150	124	122	176	81 - 176
wholemeal bread	29/60	169	189	214	88 - 214

a) Arithmetic mean. Values below the detection limit (75 µg/kg) are set to have concentration of half of detection limit

Conclusion

The presence of DON was detected in 47 out of 210 analyzed samples of white bread and wholemeal bread. Higher percent of contaminated samples was detected among wholemeal bread samples (48.33%) than in white bread samples (12.00%). The maximum contamination level of DON (214 µg/kg) in this study was found in wholemeal bread. All of the wheat flour bread samples are in compliance with Serbian regulative („Sl. glasnik RS", br. 22/2018 - Official Gazette of the RS no. 22/2018). These results suggest a high percentage of contaminated samples among wholemeal bread samples, which raises a risk for consumers. These data are also important for the realization of a 'Total Diet study' (TDS). The TDS can be a complementary tool to estimate the population dietary exposure to DON across the entire diet by analyzing main foods prepared 'as consumed'. A provisional tolerable daily intake (TDI) for DON was set in 2002 by the Scientific Committee for Food (SCF) at 1 µg/kg body weight (b.w.) per day.

FUNGAL BIOMASS AND MYCOTOXIN IN KERNELS OF *AVENA* L.

Svetlana ŠLIKOVÁ[1*], Martina HUDCOVICOVÁ[1], Edita GREGOVÁ[1], Peter HOZLÁR[2]

[1]National Agriculture and Food Centre, Research Institute of Plant Production, Piešťany, Slovak Republic

Abstract

The fungal biomass (DNA) of *Fusarium culmorum* Sacc. (FC) and content of mycotoxin deoxynivalenol (DON) were determined in *Avena* spp. kernels. Kernels were harvested from panicles *A. strigosa, A. ludoviciana, A. byzantina, A. fatua, A. sativa* and *A. nuda* after artificial inoculation by fungi. The plants panicles were infected with FC by spray + polyethylene (PE) bag cover 48 h. method during flowering. Quantification of pathogen DNA in samples was carried out by Real-Time PCR method using ABI PRISM® 7000 machine in MicroAmp optical 96-well plates. A commercial competitive enzyme-linked immunosorbent assay (ELISA kit) was used to determine the DON concentration in samples. The lowest content of fungal DNA was found in kernels from *A. byzantina* (0.043 ng kg^{-1}) and the highest content from tested genotypes was found in *A. sativa* (1.725 ng kg^{-1}). A high positive correlation by Pearson ($r = 0.857$; $P = 0.000$) was found between fungal grain infection (FI = % DNA in kernels) and the content of DON. The cultivar PS-201 was the most affected (FI = 4.288%; DON = 37.2 mg kg^{-1}) genotype. In contrast, the *A. byzantina* and one breeding line from *A. nuda* had the lowest FI and accumulated low DON content. The amount of fungal DNA in grain was used as an indicator of the infection degree and the content of DON in kernels showed the level of oat resistance to DON accumulation.

Keywords: *Avena spp., Fusarium culmorum, deoxynivalenol, fungal DNA*

Introduction

Fusarium head blight (FHB) is disease of crop caused by different *Fusarium* species. Infections of spikes lead to yield reductions and contamination of kernels by fusarium mycotoxins. The consumption of *Fusarium*-contaminated cereals and cereal-derived products may cause the poisoning known as mycotoxicosis. Several studies have confirmed that the mycotoxins, present in animal feed, have toxic effects on animals and similar effects can be expected in humans, e.g. cytotoxic effects were detected in human liver cells (Königs *et al.*, 2008).

In the cultivation of oats, the fungus can be attacked by fungi belonging to the genus *Fusarium* spp. and the subsequent accumulation of mycotoxins in the kernels produced by the fungi during infection. Several surveys on the natural occurence of mycotoxins in oat kernels grown in Europe show that oat kernels are most frequently contaminated with fusarium mycotoxins deoxynivalenol (DON), T-2 toxin and HT-2 toxin (Nathanail *et al*., 2015; Hietaniemi *et al*., 2016; Hofgaard *et al*., 2016; Martin *et al*., 2018). In Europe, they are most often responsible for producing DON species *F. culmorum* (FC) and *F. graminearum* (FG) but recently, FG has been spreading Northward in Europe displacing the closely related FC. This shift may be due to changing agricultural practices, climate change and increased maize cropping (Yli–Mattila *et al.* 2013). Increased prevalence of oat samples with above-the-limit DON levels was observed in the sites of the largest European growers of this crop, e.g. in Russia (Gavrilova *et al*., 2016), Norway (Hofgaard *et al*., 2016), Sweden (Fredlund *et al*., 2013) and Finland (Hietaniemi *et al*., 2016).

Searching for resistant genotypes and evaluation of their resistance to fungal pathogens is one of the main goals of plant breeding worldwide as many fungal pathogens produce mycotoxins harmful for people and animals. Evaluation of resistance can be done by modern methods of molecular biology such as real-time PCR for quantification of fungal pathogen DNA in combination with quantification of mycotoxins by ELISA method after artificial inoculation of tested genotypes as genotypes differ also in resistance to mycotoxin accumulation. Quantification of *F. culmorum* DNA using highly specific and sensitive real-time PCR in comparison with quantification of DON using ELISA was successfully done in wheat and barley and significant correlation was found (e.g. Leišová *et al.*, 2006; Hudcovicová *et al.*, 2012). However, this relationship can be influenced by environmental conditions.
The objective was found out infection degree and resistance to DON accumulation of different oat genotypes after artificial inoculation with fungi *Fusarium culmorum* by DNA content and amount of DON.

Material and Methods

Plant material: *Avena strigosa, A. ludoviciana, A. byzantina, A. fatua, A. sativa* (cultivars and breeding lines: Vaclav, Vojtech, Vit, Norik, Dalyup, PS-201) and *Avena nuda* L. (cultivars and breeding lines: Dunajec, Inovec, Važec, Hronec, SV-5, PS-223, PS-215, PS-218, PS-219).
Inoculum production: The fungal colonies of *Fusarium culmorum* was grown on potato dextrose agar (PDA) plates at 25 ºC for twenty-one days in dark. Approximately 1ml conidial suspension of the inoculum (5×10^6 per mL) was applied to each oat panicle.
Greenhouse experiment: The experiment was established with 30 seeds from each genotype of *Avena* spp. These seeds were sown in 3 pots per treatment (5 seeds in one pot). The panicles of *Avena* spp. were sprayed with FC inoculum in three replicates and then were covered with plastic bags for 48 h. In the mature stage, panicles were collected from each *Avena* spp. and kernels were manually separated.
Deoxynivalenol content: A commercial competitive enzyme-linked immunosorbent assay (ELISA kit) was used to determine the DON concentration in oat samples (Ridascreen Fast DON; RBiopharm, Darmstadt, Germany) with limit of detection < 0.2 mg kg^{-1} (mg kg^{-1}) and limit of quantification 0.2 mg kg^{-1} (mg kg^{-1}). The absorbencies (of the wells) were determined photometrically at 450 nm (MRX II. Dynex Technologies. Chantilly. Virginia. USA).
Quantification of pathogen DNA in oat seeds was carried out by real-time PCR method using ABI PRISM® 7000 machine (Applied Biosystems, Foster City, USA) in MicroAmp optical 96-well plates (Applied Biosystems). We used TaqMan TM probe FC92s1 5´FAM 3´MGB and primer pair Fc92s1 specific for *F. culmorum* according to Leišová *et al.* (2006). Reactions were carried out in 25 µl reaction volume consisting of 12.5 µl TaqMan Universal PCR Master Mix (Applied Biosystems), 300 nM each primers, 200 nM TaqMan MGB probe (labelled with FAM fluorescent dye) and 25 ng of DNA in 1 µl. Conditions of PCR were following: 95 ^{o}C for 10 min., 40 cycles: 95 ^{o}C for 15 s, 60 °C for 1 min. As standards for standard curves we used five dilutions of pure *F. culmorum* DNA (1, 10, 100, 1000 and 10 000 pg μl^{-1}) in triplicate in every run. For evaluations of results we used ABI PRISM® 7000 software (Applied Biosystems), in which unknown samples are quantified from measured Ct values by interpolation using the regression equation derived from standard curves.

Results and Discussion

The mean DON level among the selected genotypes ranged from 2.32 to 37.20 mg kg^{-1} (Figure 1). The genotype *A. ludoviciana* showed the highest and *A. byzantina* the lowest mycotoxin levels of all tested genotypes. Our results correspond with the results published by Gagkaeva *et al.* (2017) from an experiment in which sixty-six accessions belonging to *Avena*

spp. were infected by isolates of FC and where *A. byzantina* accumulated the low amount of DON. Among the cultural species *Avena*, *A. nuda* had 54.33 % lower mean DON content (10.66 mg kg^{-1}) than *A. sativa* (23.34 mg kg^{-1}).
Figure 2 shows that *A. byzantina* has the lowest FI (0.04320 %) of all genotypes. The highest mean FI (1.8426 %) was found out in kernels of *A. sativa*. The fungal grain infection of *A. byzantina*, *A. strigosa* and *A. nuda* ranged from 0.04 % to 0.39 % and it was 5.5 times less than FI of *A. fatua*, *A. ludoviciana* and *A. sativa* (mean FI ranged from 1.23051 % to 1.84266 %).

Figure 1. Deoxynivalenol content (mg kg^{-1}) in *Avena* spp. after artificial inoculation with *Fusarium culmorum* Sacc.

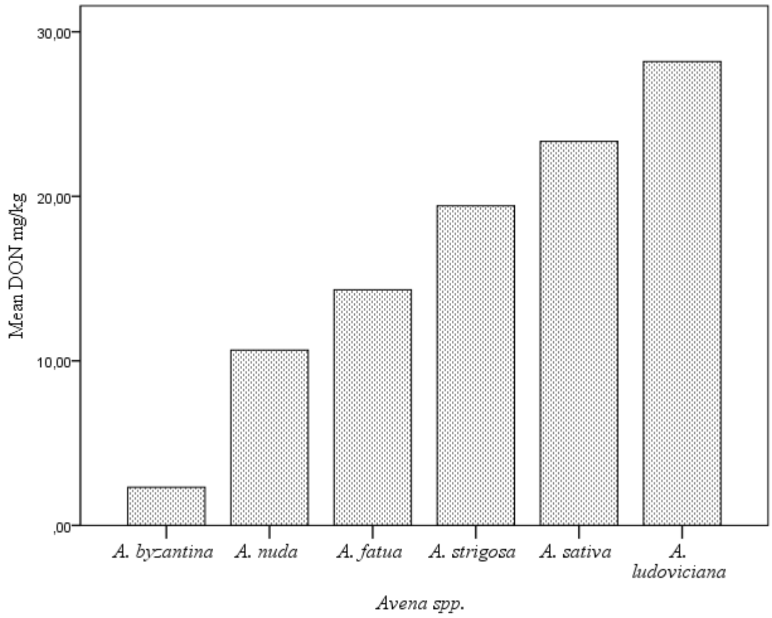

Figure 2. Fungal grain infection (FI = % DNA in kernels) in *Avena* spp. after artificial inoculation with *Fusarium culmorum* Sacc.

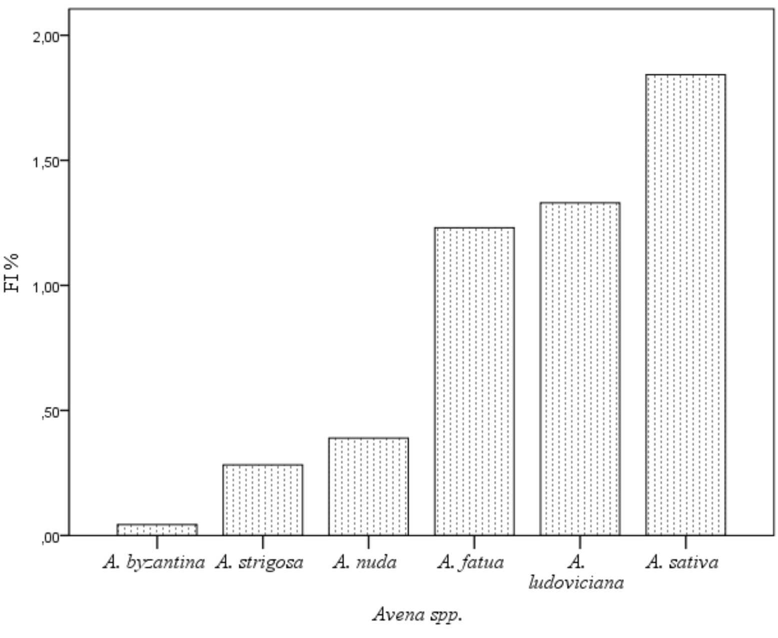


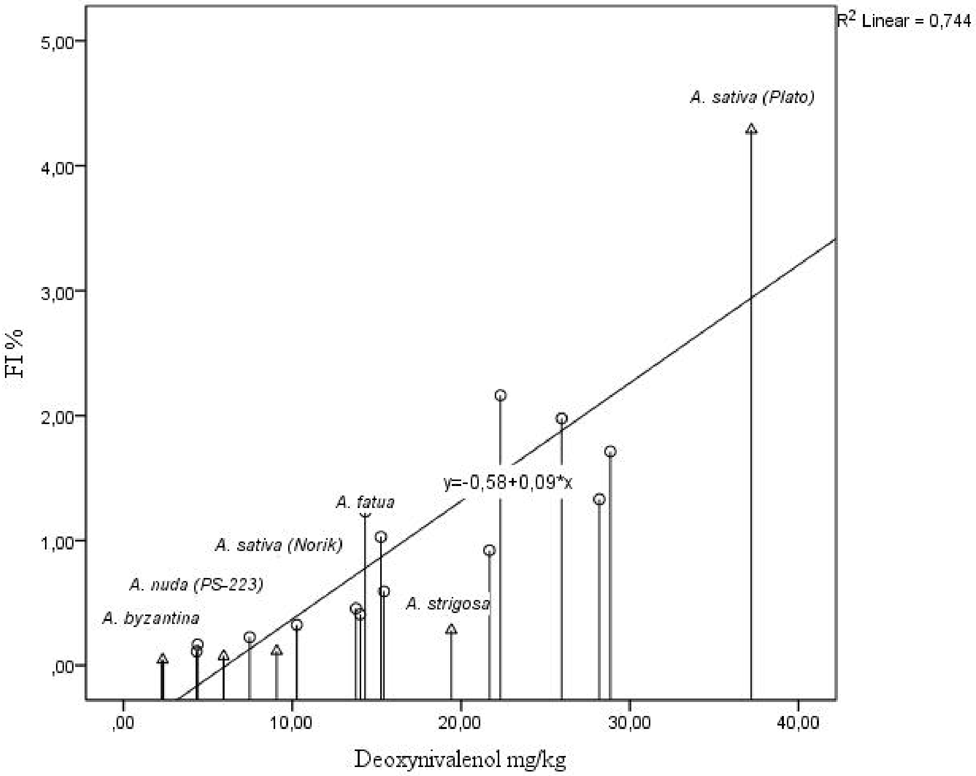
The results in Table 1 show that DON content in kernels of *A. sativa* ranged from 10.27 mg kg^{-1} to 37.20 mg kg^{-1} (Table 1). The lowest DON content was found in kernels of cultivar Norik (Figure 3), and it had the lowest FI from *A. sativa* genotypes. This cultivar cumulated lower mycotoxin DON than some *A. nuda* tested genotypes where DON content ranged from 4.33 mg kg^{-1} to 21.68 mg kg^{-1}. This finding is significant information for breeders because it is known that more DON accumulates in the hulles oat kernels than in the naked oat kernels. It has been found that the most DON is accumulated in the hulls (Šliková *et al.*, 2010), which are analyzed together with the kernels in the hulless oat varieties. Of the genotypes of *A. nuda*, kernels of SV-5 contained the lowest DON.

Table 1. Means of fungal DNA, fungal infection (FI) and deoxynivalenol (DON) contents in kernels of genotypes *Avena* spp. after artificial infection fungi *Fusarium culmorum* Sacc.

Avena spp.	Genotype	*F. culmorum* DNA (ng $1g^{-1}$)	DNA infection percent (FI %)	Mean DON (mg kg^{-1})
A. strigosa	*A. strigosa*	0.408832	0.28244	19.42
A. ludoviciana	*A. ludoviciana*	0.631671	1.33264	28.19
A. byzantina	*A. byzantina*	0.042532	0.04320	2.32
A. fatua	*A. fatua*	1.958003	1.23052	14.32
A. sativa	Vaclav	0.513167	0.59312	15.43
A. sativa	Vojtech	1.260435	2.16124	22.33
A. sativa	Vit	1.585367	1.71132	28.84
A. sativa	PS-201	4.214207	4.28796	37.20
A. sativa	Norik	0.325975	0.32416	10.27
A. sativa	Dalyup	2.453461	1.97780	25.96
A. nuda	Dunajec	0.449139	0.40816	14.02
A. nuda	Inovec	0.641262	0.45596	13.77
A. nuda	Važec	0.884419	0.92012	21.68
A. nuda	Hronec	0.163563	0.22604	7.47
A. nuda	SV-5	0.060386	0.11084	4.33
A. nuda	PS-223	0.093741	0.07260	5.93
A. nuda	PS-215	0.079499	0.11344	9.07
A. nuda	PS-218	0.203138	0.16744	4.39
A. nuda	PS-219	1.469698	1.02920	15.25
Mean			0.91820	15.79
Control		0.006498	0.00560	

A high positive correlation by Pearson (r = 0.862; P = 0.000) was found between the fungal infection and the content of DON (Figure 3). The ideal genotypes with good resistance characteristics should have low average DON content and low FI. From the tested set *A. byzantina* and PS-223 had low FI and DON content. The results suggest that *A. strigosa* is more susceptible to DON accumulation in kernels than other tested genotypes. This genotype has relatively low FI and high DON. On the other hand, we found genotypes such as *A. fatua* with relatively lower DON content and higher FI than other tested genotypes (Figure 3).

Figure 3. The scatter plot from deoxynivalenol (mg kg^{-1}) content and fungal grain infection (FI = %) in *Avena* spp. kernels after artificial infection fungi *Fusarium culmorum* Sacc.



Hautsalo *et al.* (2018) described the current knowledge of oats resistance to Fusarium head blight (FHB) and several resistance related traits. Few studies or knowledge of oat resistance to *Fusarium* have been published so far. Currently, some resistance-related loci are known that allow the selection of oat genotypes with resistance to FHB (He *et al.*, 2013; Bjørnstad *et al*., 2017). Genes that directly affect DON resistance have not yet been described in *Avena* spp, but some wheat genes associated with DON resistance and DON response have been discovered (Walter *et al.*, 2008; Hofstad *et al.*, 2016). Testing genotypes against *Fusarium* showed that within *Avena* spp. it is possible to find genotypes that accumulate low DON after artificial infection. Very important knowledge in breeding oats for resistance to *F. graminearum* and low accumulation of DON was reached in Norway; there were identified lines of *A. sativa* with consistently low DON (and early heading) (Bjørnstad *et al*., 2017).

Conclusions

Kernels were analysed for DON and fugal biomass contents on a set of different genotypes of oats (*Avena* spp.). The lowest DON content and FI were found in kernels *A. byzantina* from the tested set of oat genotypes. There is cultivar Norik (*A. sativa*) and breeding line PS-223 (*A. nuda*) that had the lowest DON content and FI from cultural species, too. The results obtained by the quantification of *Fusarium* in kernels can be helpful for evaluating genotypes for *Fusarium* infection. The evaluation of genotypes for FHB resistance by the quantification of pathogen is more than just using the DON content.

Abstract

Significant pests on ornamental plants in the greenhouses are aphids (Aphididae), such as *Myzus persicae* which cause decreased growth, shriveling of the leaves and transmit plant viruses. The trials were conducted in 2018 by standard OEPP methods at locality Budisava (Vojvodina) in chrysanthemum crop (cultivar Multiflora) in the greenhouse. The pesticide preparations based on dimethoate (400 g a.i./L, SL) were applied at a concentration of 0.1%, bifenthrin 0.05% (100 g a.i./L, EC) and chlorpyrifos + bifenthrin (400 + 20 g a.i./L, EC) at a concentration of 0.1%. Pesticides were foliar applied, using a backpack sprayer with water consumption of 500 L/ha when chrysanthemums were in the flowering stage. The efficiency of the insecticide was calculated by Henderson & Tilton and the significance of differences was determined by ANOVA for a confidence interval of 95%. Before the treatment, the average number of aphids ranged from 133.7 to 161.7. Two days after the application of the insecticides, the number of *M. persicae* was significantly lower in comparison to the control, and the efficacy was 92.8-95.9%, while seven days after the treatment efficacy was 94.5-96.4%. Fifteen days after the application, the efficacy was still high in the range of 93.2-95%. Aphididae populations have shown high sensitivity to these insecticides but this certainly does not exclude the necessity of including them in the monitoring of susceptibility to the most commonly used insecticides, since aphids are capable of developing resistance rapidly.

Key words: *Flowers, greenhouse, Aphididae, insecticides.*

Introduction

The production of ornamental plants represents a valuable potential in agricultural production, landscape architecture, and other similar services. Good climatic conditions, geothermal resources, and a skilled workforce are just some of the preconditions (Glavendekić, 2013). In the Republic of Serbia in 2015, the production of flowers occupied an area of 445 ha, and in 2017 on 1057 ha, but from 2017 the land from the gardens was included in the total used agricultural land (Statistical Yearbook, 2018). The increasing interest in decorative plants in the last two decades has resulted in increased production of these plants in our country as well. Besides increasing production and profitability, it has also led to its modernization, which has caused certain production problems (Balaž *et al*., 2013). First of all there were problems with pests and pathogens. Greenhouses besides creating optimal conditions for plant growth, also create an optimal environment for phytophagous insects, mites and other harmful species. Greenhouses provide immeasurable amounts of plant food as well as a lack of predators, parasitoids and other natural enemies. Harmful insects that have migrated through various openings to greenhouses have all the favorable biotic factors for the rapid growth and development of populations, and as a result, a large number of phytophagous insects gains status as an invasive species on plants grown in greenhouses. Pests occurring in greenhouse are well adapted to living conditions and their populations can only be controlled by integral measures of protection. Their number is constantly increasing by importing the reproductive and planting material of ornamental plants. Aphididae are harmful species that attack a large number of plants used as food but also occur on ornamental plants. They occur in the open field as well as in a protected area. *M. persicae* occurs on ornamental plants such as carnation, chrysanthemum, Christmas star and roses (Petaković and Glavendekić, 2013). It can occur in large populations on young shoots of plants, resulting in a stressful condition, the plant begins to vein and may lose growth. Aphids feed on the host's plant juices but the most harm they cause by transmitting the viruses. Peaches aphids are, as some experts believe, the largest vectors of the viruses in the world. The aim of this study was to determine the degree of chrysanthemum protection in greenhouse conditions against aphids (Aphididae), using preparations based on dimethoate, bifenthrin, and chlorpyrifos + bifenthrin.

Material and methods

The trials were conducted in 2018 by standard OEPP methods (Anonymus, 2004; Anonymus, 2012; Anonymus, 2014) at locality Budisava (Vojvodina Authonomus Province, Serbia) in chrysanthemum crop (cultivar Multiflora) in the greenhouse. The pesticide preparations based on dimethoate (400 g a.i./L, SL) were applied at a concentration of 0.1%, bifenthrin 0.05% (100 g a.i./L, EC) and chlorpyrifos + bifenthrin (400 + 20 g a.i./L, EC) at a concentration of 0.1%. Pesticides were foliary applied, using a backpack sprayer with water consumption of 500 L/ha when chrysanthemums were in the flowering stage.

Experiment in Budisava was set on 18.10.2018. The trials were set in four replicates in a randomized block design. Four assessments were made based on the number of aphids on 10 previously marked shoots per replication: 1) before the treatment, 2) two days after the treatment, 3) eight days after the treatment, 4) 15 days after the treatment.

The efficiency of the insecticides was calculated by Henderson & Tilton (Wentzel, 1963) and the significance of differences was determined by ANOVA for a confidence interval of 95%.

Results and discussion

The results of testing the efficacy of insecticides based on dimethoate, bifenthrin, and chlorpyrifos + bifenthrin in greenhouse production conditions for controlling *M. persicae* are shown in Tables 1-2. Based on the abundance estimate just before the trial was set up (Table 1), the average abundance of *M. persicae* by variants ranged from 133.7 to 161.7.

Table 1. Average number of green peach aphids (*M. persicae*) and insecticide efficacy (Budisava, 2018.)

Insecticides (%)	Before treatment		two days after the treatment		
	$\bar{x}$	±Sd	$\bar{x}$	±Sd	E%
dimethoate (0.1)	151.2 a	20.8	10.2 b	4.62	94.3
bifenthrin (0.05)	137.2 a	25.3	11.5 b	2.61	92.8
chlorpyrifos + bifenthrin (0.1)	161.7 a	38.7	7.75 b	2.50	95.9
control	133.7 a	24.9	157.5 a	11.3	
LSD 5%	42.11		10.14		

$\bar{x}$ – average number; ±Sd - standard deviation; E %- efficacy

Two days after application of dimethoate, bifenthrin, and chlorpyrifos + bifenthrin preparations, the abundances of *M. persicae* was significantly lower than the control. The efficacy of the tested preparations ranged from 92.8 to 95.9% and they are at the same level of significance. The number of Aphids, eight days after the treatment, was at a significantly lower level compared to the control. The efficacy of the tested preparations was 94.5-96.4%. The number of green peach aphids 15 days from the application of the insecticides is significantly lower than the control. The preparation efficiency was still high and ranged from 93.2 to -95.0% (Table 2).

Table 2. Average number of green peach aphids (*M. persicae*) and insecticide efficacy (Budisava, 2018.)

Insecticides (%)	eight days after the treatment			15 days after the treatment		
	$\bar{x}$	±Sd	E %	$\bar{x}$	±Sd	E%
dimethoate (0.1)	9.50 b	2.64	95.6	15.2 b	4.02	93.2
bifenthrin (0.05)	6.75 b	1.71	96.4	10.5 b	5.92	95.0
chlorpyrifos + bifenthrin (0.1)	12.5 b	1.29	94.5	13.7 b	4.03	94.3
control	189.5 a	32.2		199.5 a	8.35	
LSD 5%	26.04			9.39		

$\bar{x}$ – average number; ±Sd - standard deviation; E %- efficacy

In *M. persicae,* two ways of developing resistance are most commonly present: increased detoxification of insecticides and change of site sensitivity. This is the reason why resistance can be developed by a large number of insecticides with different mode of action. Biochemical methods for determining resistance have shown that the apparently reduced sensitivity of green peach is developed to the most commonly used insecticide groups, ie. that resistance has been developed to a certain extent, but that the studied populations of *M. persicae* in Serbia do not yet belong to the category of extremely resistant Aphids (Vučetić *et al*., 2007). As a result of intense exposure to the insecticides, *M. persicae* has developed resistance to numerous insecticides including neonicotinoids (imidacloprid), organophosphates (chlorpyrifos), carbamates (carbaryl and thiodicarb) and synthetic pyrethroids (deltamethrin) in many countries worldwide (Bass *et al*., 2014; Puinean *et al*., 2013; Slater *et al*., 2012).

In order to evaluate the resistance of *M. persicae* populations to seven insecticides, Tang *et al*. (2017) examined the sensitivity of 11 populations collected from eight provinces in China. Toxicity analysis showed that *M. persicae* populations developed several levels of resistance to each tested insecticide. Population from field conditions has developed high levels of resistance to beta-cypermethrin and cypermethrin, while resistance to bifenthrin remains low. According to bifenthrin, 7 of the 11 studied populations of *M. persicae* showed resistance (12-38 times).

Conclusions

The studied population of *M. persicae* in chrysanthemum under greenhouse conditions showed high sensitivity to insecticides based on dimethoate, bifenthrin and chlorpyrifos + bifenthrin. However, since Aphids belong to the group of insects that are able to develop resistance relatively quickly, these insecticides should not be used alternatively with other preparations from the chemical groups of organophosphates and pyrethroids.

Abstract

The fruit characteristic such as nutrition, favour and firmness deteriorated during the process of storage and lead to the decay of the fruit. Lemon is one of the most important citrus fruit and is cultivated in many countries including Iran. The effects of chitosan-clay nano-composite coating on the quality properties of lemon fruit during storage were investigated. Chitosan- clay solution was prepared by composition 1% clay, 2% chitosan. The lemon fruit were dipped into the chitosan-clay composition and then dried at environment temperature. Experiments were carried out at four storage times with coated and uncoated samples. The physical, chemical and mechanical properties of lemon fruit were measured during the storage. The results showed that the pH of lemon fruit juice increased significantly ($p<0.05$) for coated and uncoated samples. Coated samples had the lower TSS (Total Soluble Solid) and higher TA (Titratable Acid) rather than uncoated samples. The inner strength of coated samples was higher because of the higher firmness and peel shear force and also the lower punch force. As a result, the coated fruits had more resistance to the applied force than the uncoated fruits. Coating was more effective in maintaining lemon firmness at prolonged storage. Thus, the coated samples had the most resistance to fungal disease. Finally, it should be indicated that resistance to fungal diseases, interior tissue strength and quality properties of fruit were increased by using the nano composite coating. Consequently, it reduced the percentage of weight loss and maintained the fruit quality longer.

Keywords: *Citrus, Lemon, Mechanical properties, Nano composite*

Introduction

Among the citrus, lemon is the third most important Citrus species after orange and mandarin (Porat *et al*., 2000), and is a subtropical fruit of high commercial value on the international fruit market. It has a split skin and very juicy which can easily suffered by green mold and skin shrinkage. It is extremely sensitive during the storage (Chien *et al*., 2007). Similar to deciduous fruit, lemon fruits are not held in the cold storage and must be harvested with delay from the tree. There are several exceptions to this statement such as reduction of physical disorders, humidity control environment, usage of coating material, disturb carbon dioxide and employing ethylene in cold storage which increase the shelf life (Miller, 1980).

One effective strategy for maintaining product quality properties and keep it fresh is using nanotechnology. It has many applications in agriculture science including: recycling of waste from agricultural products and maintain product quality and properties during food processing and storage process. Nano-coating and nano-composites is a way to increase the shelf life of fruits and vegetables (Henriette, 2009). Nanotechnology has many applications in relation to maintenance of food and particularly their packaging and in some cases nano achievements are applied in practice (Chaudhry *et al*., 2008 and Chen *et al*., 2006).

Consumers interest in nutrition and food safety and also to environment stimulated the in the field of edible coatings. Renewable sources of forming the coating layers are quite available (Baldwin, 2007). The main reason for applying coatings on fruits is the loss of fruit juice in the post-harvest stages. Juice loss usually occurs in the vapor phase. Water vapor permeability describes the movement of water vapor inside layer covered in different temperatures and moistures. (Hugh and Krochta, 1994).

In recent years, many layers and edible coating of food items like candies, fruits and fresh vegetables and processed meats are commonly used (Baldwin, 2007). Chitosan-clay coating has been considered in recent years. Chitosan is a polysaccharide that is non-toxic and is biodegradable (Warayuth *et al*., 2010). It is derived from chitin and is known as anti fungicide. It is edible coating and has significant inhibitory properties in microbes, fungi and pathogenic factors growth (Muzzarelli *et al*., 1990). Nano-composition of chitosan and clay can be obtained by method of clay-particle nano disturb in chitosan solution. Advantages of these compounds are the delay in the loss of moisture; reduce in evaporation and breathing rate, changes in material tissue properties (Muzzarelli *et al*., 1990; Warayuth *et al.*, 2010). Chitosan film has been used to coating of crops such as strawberries, mandarin and cherry (Fornes *et al*., 2005; Martınez-Romero *et al*., 2006; Ribeiro *et al*., 2007). Nowadays studies are focused on the expansion of technology to improve food quality and its durability.

Therefore the aim of this research was to investigate the effects of chitosan-clay nanocomposite coating during the different storage period on the physical, chemical, and mechanical properties of lemon fruit.

Material and Methods

The mature Lemon fruit (140) used in this experiment was provided randomly from citrus orchard in Qaemshar, Mazandaran, Iran. The samples were brought to the laboratory immediately after harvesting. Chitosan- clay solution was prepared by composition 1% clay, 2% chitosan and 25 cc acetic acid then dispersed in 1L of distilled water (Casariego *et al.*, 2009). Chitosan and clay were bought from Aldrich LTD.

Fruit were washed with tap water, dried in room temperature and dipped into the chitosan-clay composition by hand. The surface of coated fruit was dried at environment temperature for 12 h then fruit were stored at about 8^{o}C and 75-80% relative humidity for 63 days. Experiments were carried out at four storage times, 0, 21, 42 and 63 days, with coated and uncoated samples.

The physical, chemical and mechanical properties of lemon fruit were measured during storage. The measurements were done in Citrus Research Central of Sari Agricultural Sciences and Natural Resources University.

The chemical parameters such as titratable acid (TA), total soluble solid (TSS) and pH of fruit juice were measured. Total soluble solid is quality index and TSS were measured with digital refract meter (ATAGO- Palette) in range 0- 20%.

Mechanical test comprised of fruit compression, peel shear and punch test. All tests were performed by Instron machine (Hounsfield Co., England, Model 4400), 60 mm/min speed and 250 KN load cell.

The experiment is performed randomly by factorial design 2*4 (2 coatings and 4 storage times) and 3 replicate. Data analysis and figure drawing was done by SPPS and Excel soft respectively. Differences were regarded as significant when the p-values were less than 0.05.

Results and Discussion

The pH values of juice fruit is illustrated in Table 1. It was increased in the coated and uncoated treatments during the storage which is consistent with the results of Martin-Diana *et al.*, 2009). The pH amount only was significant ($p<0.05$) within the first 3 weeks of storage but it turned to not significant at remained storage period for two treatments. The results showed that the pH of coated samples generally were higher than the uncoated samples. It shows that the coating of lemon fruits could be able to increases the pH of lemon juice.

As it is known, fungal attack the citrus when the pH juice is low. Also the pH of juices has been associated to microbial spoilage (Del Caro *et al*., 2004; Cortes *et al.*, 2008). Thus, by increasing fruit resistant, the quality will be maintained at high level.

Table 1: The amount of pH, TSS and TA for coated and uncoated samples in during storage

During Storage(day)	Coated (Chitosan- Clay) Samples			Uncoated Samples		
	TA	**TSS**	**pH**	**TA**	**TSS**	**pH**
0	2.97^{a}	8.83^{a}	5.88^{a}	2.97^{a}	8.83^{a}	5.88^{a}
21	2.77^{ab}	8.97^{a}	6.33^{b}	2.63^{a}	10.97^{a}	6.33^{b}
42	2.69^{ab}	10.20^{b}	6.37^{b}	2.21^{a}	10.93^{a}	6.37^{b}
63	2.5^{b}	10.67^{b}	6.32^{b}	2.33^{a}	11.07^{a}	6.32^{b}

* the same letter in the table for any column shows that the means had no significant difference ($p<0.05$)

Total Soluble Solid (TSS) measurement

According to Table 1, the TSS of coated samples significantly ($p<0.05$) increased but no significant difference in Brix^{o} were detected for uncoated samples over the storage period. The Brix^{o} values were about 8.83 to 11.07 in the uncoated fruit. It was higher in coated fruit samples (8.83-10.67). Baldwin *et al.* (1995) reported that coated fruits had slightly lower Brix^{o} than uncoated fruit. So lemon fruits with chitosan- clay coating have lower respiration and moisture losses. Therefore, coated treatment by using of chitosan- clay had protected fruit.

Total Acidity (TA) measurement

The TA of the lemon juice significantly ($p<0.05$) decreased by chitosan- clay coating in during storage. The reduction of TA had no significant difference ($p>0.05$) for uncoated samples (Table 1). According to the data, the TA rates for coated samples were higher than uncoated samples. The TA of fruit juice were reduced over the storage time which confirmed by El-Zeftawi (1976). So the coated samples had lower TA than uncoated samples due to higher TSS.

Mechanical Properties

Firmness was measured as a percentage of deformation. According to the data presented in Table 2, the coating application did not decrease firmness values of lemon fruit. For prolonged storage the differences found between the coated and uncoated lemon samples and it decreased for uncoated. The decrease in firmness of fruits is in agreement with the results which reported by Singh and Reddy (2006) for oranges.

Table 2: The amount of firmness, puncture and cutting force for coated and uncoated samples during the storage

During Storage(day)	Coated (Chitosan- Clay) Samples			Uncoated Samples		
	Shear Force	Puncture Force	firmness Force	Shear Force	Puncture Force	firmness Force
0	84.01^{a}	27.64^{a}	260.13^{a}	84.01^{a}	27.64^{a}	260.13^{a}
21	72.67^{a}	21.59^{b}	258.92^{a}	70.18^{ab}	26.79^{a}	215.23^{a}
42	71.22^{a}	21.75^{b}	256.75^{a}	55.81^{bc}	25.61^{a}	169.20^{a}
63	70.73^{a}	20.88^{b}	254.38^{a}	36.47^{c}	25.34^{a}	165.18^{a}

* the same letter in the table for any column shows that the mean amount had no significant difference ($p>0.05$)

The firmness force for the coated lemons (260.13 to 254.358 N) was generally higher than uncoated samples (260.13 to 165.18 N) during storage, but there was no significant difference ($p>0.05$) in firmness of all samples. This might be because of a metabolic delay. Consequently, fruit softening was also delayed, at coated fruit (Singh and Reddy, 2006). When storage was prolonged, coatings were more effective in maintaining lemon firmness. So the coated fruits were more resistant to the applied force than uncoated fruits.
The puncture force decreased from 27.64 to 25.34 N and 27.64 to 20.88 N for uncoated and coated fruits, respectively (Table 2). No significant changes ($p>0.05$) observed in puncture force for uncoated fruits, but puncture force changed significant ($p>0.05$) within the first 3 weeks of storage for coated samples. The puncture force of lemon fruit in the chitosan- clay coating was lower than uncoated samples. The similar trends were also explained by Singh and Reddy (2006).
The peel shear force significantly ($p<0.05$) decreased in coated samples (Table 2). The amount of peel shear force for uncoated sample was significantly ($p<0.05$) lower than coated samples (Table 2). Intercellular spaces result in less cell wall material per volume of tissue and less contact area between cells. Both factors could cause the tissue to be less resistant to shear stress (Harker, *et al.*, 1997). Therefore non coating sample has lowest stiffness because of less contact area between cells.

Conclusions

Investigation of lemon quality properties showed that coated samples have the higher pH and TA and lower TSS rather than uncoated samples. Thus coated samples have the most resistance to fungal disease and have the lower percentage of weight loss. Also studying, mechanical properties showed that inner strength of coated samples was high because of the higher compression; peel shear force and having the lower punch force. Lemon coating did not reduce the firmness loss and more effective in maintaining lemon firmness at prolonged storage. So the coated fruits have more resistance to the applied force than uncoated fruits. Chitosan has been demonstrated to be able to inhibit the growth of some fungi. Finally, it should be concluded that the coating by chitosan-clay proposed in this paper not only promotes fruit moisture retention while maintaining fruit quality.

Abstract

Actinobacteria are filamentous bacteria, commonly found in nature and especially in the soil, and are the most prolific of all microorganisms as producers of bioactive molecules. They are responsible for 70% of natural antibiotics known in the world, 55% of which are produced by actinobacteria belonging to the genus *Streptomyces*. However, with the appearance of resistant pathogenic strains, several antibiotics have become little or no effective. One of the research strategies adopted for rare genera isolation, producers of new antibiotics, is the exploitation of particular ecosystems in order to isolate rare strains. In this investigation, we studied the antibacterial and antifungal activities of six actinobacterial strains, already isolated from the semi-arid rhizospheric soil of eastern Algeria. Different rhizospheres were explored. Among the six isolates, four belonged to the genus *Streptomyces* and two were assigned to the rare genus *Nocardiopsis*. In fact, the six strains were tested for their antifungal activity against seven phytopathogenic fungi. The six isolates were then tested against phytopathogenic bacteria. The results showed that among the six actinobacteria, five strains (Lac1, Lac3, Vic8, Pru14 and Pru16) inhibited all phytopathogenic fungi. Only isolate Pin10 was unable to inhibit *M. nivale*. The six antagonistic strains showed more or less important antibacterial activities. Thus, *S. griseus* Lac1 exhibited the best inhibitory activity. This study confirmed not only the antimicrobial activity of *Streptomyces* strains, but also revealed interesting antibacterial and antifungal activities of the two rare strains belonging to the genus *Nocardiopsis*.

Key words: *Antimicrobial activity, Streptomyces, Nocardiopsis*.

Introduction

Excessive use of chemical fungicides can lead to environmental pollution and the emergence of pathogens resistant to specific fungicides. Plant protection products are responsible for various health problems in humans and animals (Gerhardson, 2002). Phytopathogenic antagonist microorganisms have been discovered and some of them are already used as biological control agents against plant diseases (Prapagdee *et al*., 2008). Actinobacteria are well known for their metabolic capacities, especially *Streptomyces* spp. which produces thousands of antibiotics (Berdy, 2015). They appear to be good candidates for biological control (El-Tarabily and Sivasithamparam, 2006). Actinobacteria are Gram-positive, most are saprophytes (Khamna *et al*., 2009) and are abundant in the rhizosphere (Sardi, 1992). This environment has been considered as a rich source for the isolation of biocontrol agents and plant growth promoters (PGPR) (Jiménez-Esquilin and Roane, 2005; Yilmaz *et al*., 2008).
The aim of this study was to assess the *in vitro* antagonism of six strains of rhizospheric actinobacteria (*Streptomyces* and *Nocardiopsis*) against phytopathogenic fungi *Verticillium dahliae*, *Fusarium culmorum*, *Drechslera teres*, *Microdochium nivale*, *Bipolaris sorokiniana*, *Botritys fabae* and *Fusarium oxysporum*. These strains have also been tested against plant pathogenic bacteria (*Erwinia carotovora* and *Agrobacterium tumefaciens*).

Materials and methods

Antibacterial activity

The method used was the modified technique of Anibou *et al* (2008). The agar cylinders were cut from well sporulated actinobacteria cultures. They were placed on the Petri dishes already inoculated, in mass by the bacterial strains (10^8 cells/ml). The cultures were first incubated for 18 hours at 4°C to allow the diffusion of bioactive substances and then incubated at 30°C. Antimicrobial activity was assessed by measuring the inhibition zone (mm) after 48 hours of incubation. The phytopathogenic bacteria tested were isolated from fruit trees (apple and raspberry) and vegetable crops (potato) in Quebec: *Agrobacterium tumefaciens*, *Erwinia. carotovora* subsp. *carotovora* 824, *E. carotovora* subsp. *amylovora* 1111, *E. carotovora* subsp. *amylovora* 998, *E. carotovora* subsp. *amylovor*a 1024 and *E. carotovora* subsp. *atroseptica* 750.

Antifungal activity

Actinobacteria are streaked, on PDA medium in the center of the Petri dish (145 mm diameter), into a 6 mm large central streak. These cultures are incubated at 28°C for 8 days. Two discs (7 mm diameter) of the 8-day-old fungi culture are placed on each side of the actinobacteria streak. The distance between the fungal discs and the edge of the Petri dish was 15 mm. For each fungal strain, a control treatment was performed, with two discs placed on the PDA medium without actinobacteria. All dishes were incubated at 28°C for 5 days. Every day the diameter of the fungal colony was measured for all treatments including the control (Soares *et al.*, 2006).

Statistical analysis

The data were analyzed with repeated measures analysis of variance (ANOVA) followed by the least significant difference (LSD) test using SAS 9.1 statistical software (SAS Institute Inc., Cary, NC) (Ryan and Kinkel, 1997; Alves-Santos et al., 2002).

Results and discussion

Antibacterial activity

The results of the antagonism test against phytopathogenic bacteria, belonging to the genus *Erwinia* (*E. carotovora* subsp. *amylovora* 1111, *E. carotovora* subsp. *amylovora* 998 and *E. carotovora* subsp. *amylovora* 1024) revealed an inhibitory activity of two strains Lac1 and Pru14. By comparison of the inhibition zones, those obtained with strain Lac1 (32 to 34 mm) are more important than those obtained with strain Pru14 (17 to 20 mm). *E. carotovora* subsp. *carotovora* subsp. 824 and *E. carotovora* subsp. *atroseptica* 750 were found to be resistant. Lac1, Vic8 and Pru14 strains exhibited antibacterial activity against *Agrobacterium tumefaciens*, the diameters of the inhibition zones are 21, 18 and 21 mm, respectively (Table 1, Figure 1).

Table 1. Antimicrobial activity against phytopathogenic bacteria.

Phytopathogenic bacteria	**Actinobacterial strain**[1]		
	Lac1	**Vic8**	**Pru14**
E. carotovora subsp. *carotovora* 824	n.i.[2]	n.i.	n.i.

E. carotovora subsp. *amylovora* 998	32	n.i.	17
E. carotovora subsp. *amylovora* 1024	34	n.i.	20
Agrobecterium tumefaciens	35	18	21

[1] No inhibition zone was obtained with strains Lac3, Pru16 and Pin10; [2]: n.i.: no inhibition.

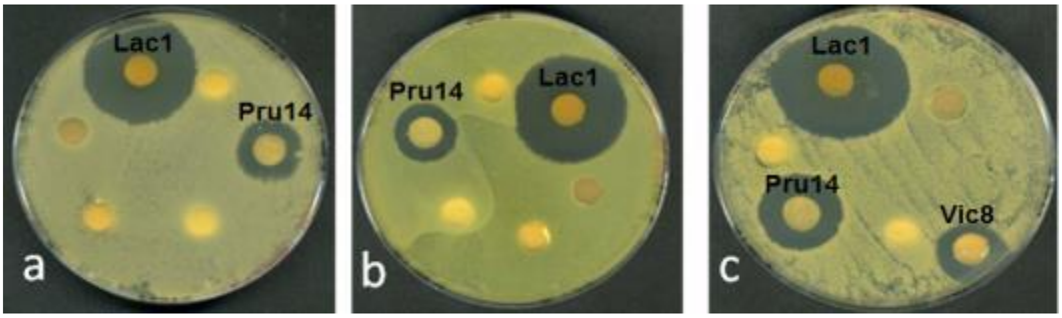

Figure 1. Result of antibacterial activity, (a) *E. carotovora amylovora* 1111; (b) *E. carotovora amylovora* 998; (c) *Agrobecterium tumefaciens*

Antifungal activity

The results of the antagonism test are presented in Figures 2 and 3. Among the six antagonistic actinobacteria strains, five of them (Lac1, Lac3, Vic8, Pru14 and Pru16) inhibited all phytopathogenic fungi. Only Pin10 strain was unable to inhibit the growth of *M. nivale*. Lac1 was found to be the most effective in the control of mycelial growth of *D. teres*, *M. nivale*, B. *sorokiniana* and *B. fabae* with a growth inhibition of 59.72%, 72.19%, 65.09% and 52.33%, respectively. The strain Pru14 was effective in reducing the mycelial growth of *F. culmorum* (60.15%), while Pru16 was the best antagonistic strain for the control of *V. dahliae* and *F. oxysporum* with growth reductions of 50.81% and 62.77%, respectively. Lac1 and Pru16 strains showed the highest antagonistic activity.

Actinobacteria are characterized by their metabolic activities, and PGPR bacteria often showed biocontrol properties. It has been reported that nearly 5% of rhizobacteria can

increase the growth of plants and protect them against pathogens such as bacteria and fungi. Actinobacteria are well known to produce secondary metabolites and extra-cellular enzymes with interesting antibiosis (Khamna *et al.,* 2010). Thus, several studies have examined theirs *in vitro* antibiosis activity against phytopathogenic bacteria (de Oliveira *et al.,* 2010).
In the present investigation, six actinobacterial strains were evaluated against phytopathogenic bacteria and fungi. These strains were obtained from rhizospheric soils, at first selected for their PGPR traits (acide 3-indole acétique, sidérophores and phosphate solubilization) (Aouar *et al.,* 2019). Antifungal activity was detected in five strains that inhibited all fungi. Among the active strains, one strain belonging to a rare genus (*Nocardiopsis*) could produce interesting antifungal molecules. *In vitro* assays performed against phytopathogenic bacteria revealed different antibiosis abilities among the six actinobacteria tested as potential biocontrol agents. While *E. carotovora* subsp. *carotovora* 824 and *E. carotovora* subsp. *atroseptica* 750 appeared resistant to all actinobacteria, Lac1 showed the most significant inhibitory activity. This strain belongs to *Streptomyces griseus* species from which several antibiotic compounds with antagonistic activities against Gram-positive (streptomycin, novobiocin and griseoviridin) and Gram-negative bacteria (griseorhodin) have been isolated.
Many studies have focused on the exploration of antimicrobial activity of actinobacteria. The results of Oskay *et al* (2004) indicated that 34% of the 50 actinobacteria isolates were active against at least one tested microorganism; *A. tumefaciens*, *E. carotovora* subsp. *amylovora*, *Pseudomonas viridiflova*, *Clavibacter michiganensis* subsp. *michiganensis*, *B. subtilis, K. pneumoniae*, *Enterococcus feacalis*, *S. aureus*, *E. coli* and *Sarcina lutea*. The study by Yilmaz *et al* (2008), involving 55 actinobacteria strains, isolated from different rhizospheres, showed the antimicrobial activity of 22 strains. This activity is more pronounced on Gram-positive bacteria than on Gram-negative bacteria. In addition, about 18% of actinomycetes showed antifungal activity.

Conclusion

This study highlighted the antifungal and antibacterial potential of six strains of rhizospheric actinobacteria belonging to two genera *Streptomyces* and *Nocardiopsis*, previously selected for their PGPR traits. Thus, except the Pin10, the other strains inhibited all the phytopathogenic fungi. The Lac1 strain has the best antifungal activity. In addition, the Lac1, Pru14 and Vic8 strains have inhibited the growth of phytopathogenic bacteria. Among these strains, Lac1 exhibited the most significant antibacterial and antifungal activity. Among active strains, one was affiliated with the *Nocardiopsis* genus. Members of the *Nocardiopsis* genus could be promising candidates leading to the development of interesting biocontrol products.

Abstract

Sunflower seed hybridization proceeded in two directions: towards an increase in oil content (oily sunflower hybrid seed) and an increase in protein content (non-oily or confectionary sunflower hybrid seed). Sunflower oil hybrids are used for oil production, while non-oily seeds are primarily used as a source of protein, however they contain significant amounts of oil (about 30%) and are a potential raw material for oil production.

The oxidative stability of three different cold-pressed oils obtained by confectionary sunflower hybrid seed was studied by monitoring the content of oxidation products. Samples were tempered at 63±2°C for a period of 8 days and the peroxide (PV) and anisidine value (*p*-AnV) as well as the content of the conjugated dienes and trienes in the initial samples and after 4th and 8th day of the exposure to the test were determined. The best oxidative stability in the initial sample had the oil of hybrid NS-H-6304. The PV was 2.20±0.02 mmol kg^{-1}, while the *p*-AnV was 0.47±0.06. The worst oxidation characteristics in the initial sample had NS-H-6971 oil (PV=3.98±0.05 mmol kg^{-1}, *p*-AnV=1.52±0.34). After 8 days, the lowest PV was found in the sample NS-H-6971 (54.70±4.10 mmol kg^{-1}), while the highest value was obtained in the sample NS-H-6488 (72.88±6.07 mmol kg^{-1}). The lowest *p*-AnV after 8 days was 1.60±0.02 (NS-H-6488) while the highest value of 6.56±0.04 was found in the sample NS-H-6791.

Keywords: *Sunflower oil, non-oily hybrids, primary and secondary oxidation products*

Introduction

Non-oily (confectionary) sunflower hybrid seed and oily sunflower hybrid seed have significant difference in chemical composition as well as the appearance of seed. Confectionary hybrid seed has lower oil content (30-35%) and higher protein content (about 40%) (Kaya *et al*. 2008; Hladni *et al*., 2011). Sunflower seed contains small amounts of antinutritive compounds (eg protease inhibitors, cyanogen, lectins, etc.) (Gassmann, 1983; González-Pérez and Arellano, 2009; González-Pérez, 2015). The amino acid composition of sunflower seed protein, with the exception of a small amount of lysine, is in accordance with the requirements of the FAO/WHO for human nutrition (Gassmann, 1983; Raymond *et al*. 1991).

Confectionary sunflower hybrid seed compared with oily sunflower hybrid seed has larger seed with a thicker hull, most commonly colored (black and white). Hull represents 40-45% of the total seed mass, it is poorly attached to the kernel and is easily removed (Jovanović, 2001; Gonzales-Perez and Vereijken 2007).

Oxidative stability of the oil represents the ability of vegetable oils to resist the oxidation process during production, storage and manipulation. It determines the quality and shelf life of the oil. The oxidative stability of the oil is influenced by many factors: fatty acids composition, antioxidants, the content of free fatty acids, mono and diglycerides, conditions of production, storage and manipulation, etc. Some of these factors are influenced by the seed hybrid used to produce oil. The aim of this paper is to examine the oxidative stability of sunflower oils obtained from the latest non-oily sunflower hybrids.

Material and Methods

Material: Hybrid seeds are a secondary filial (F2) generation of confectionary sunflower hybrid seed. Samples NS-H-6791, NS-H-6488 and NS-H-6304 were grown under conditions of small-plot trials in 2017 (Vojvodina, Serbia). Six months after harvesting the seed was cleaned and stored under normal storage conditions and without prior peeling and pressed with a screw press. The oil temperature at the output of the press was 60-70°C. Samples of cold pressed oils were taken after 72 hours of agitation at room temperature for the sedimentation, decantation and oil filtration through plain, wrinkled laboratory filter paper.

Methods: Samples of oil have been exposed in the laboratory conditions at moderate temperatures (63±2°C), in the presence of air, without the presence of light according to the methodology described by Pokorny *et al*. (1985). It was measured in 50 ml of each sample and subjected to test conditions for a period of 8 days. After the 4^{th} and 8^{th} day, the samples were taken and analysed and compared with the initial samples. The content of primary oxidation products is determined on the basis of the peroxide value (PV) (ISO 3960:2017) and specific absorbances at a wavelength of 232 nm, i.e. the content of conjugated dienes (ISO 3656:2011/Amd 1:2017). Based on anisidine value (ISO 6885:2016) and specific absorbances at a wavelength of 270 nm, i.e. the content of conjugated triens (ISO 3656:2013/A1:2017), the content of secondary oxidation products has been determined. The fatty acids composition in oils is determined by the application of gas chromatography - mass spectrometry (GC-MS) (ISO 12966-1:2014, ISO 12966-2:2017) using the HP 5890 gas chromatograph with HP 5971A mass detector ("Hewlett Packard", USA). All determinations were done in three replications, the results are tabulated as the mean value ± standard deviation, and only the mean value for the graphic representation was obtained. Statistical processing of the obtained results and graphical representations were made using Microsoft Excel 2010 (Microsoft, Washington, USA) and Statistica 13.0 (StatSoft, Tulsa, USA)

Results and Discussion

Tested oil samples are obtained from linoleic hybrid seed so the variation in fatty acid composition is minimal (Table 1).

Table 1. Fatty acid composition of the tested samples

Fatty acid (%)	NS-H-6791 % w/w	NS-H-6488 % w/w	NS-H-6304 % w/w
C 14:0	0.05±0.00	0.06±0.01	0.06±0.01
C 16:0	5.91±0.03	6.07±0.28	6.17±0.07
C 16:1	nd	nd	nd

nd – not detected

The highest content of linoleic fatty acid (C18:2) was determined in the NS-H-6791 sample and amounted to 57.65±0.03%. In the same sample the smallest content of oleic acid (C18:1) was also determined, which amounts to 30.04±0.11%. The smallest content of linoleic fatty acids of 55.70±0.34% and the highest content of oleic acid 32.70±0.09% were determined in the sample NS-H-6488. In the sunflower oil samples, the content of linoleic (C18:2) and oleic acid (C18:1) is very strongly correlated according to the literature data (Oštrić-Matijašević and Turkulov, 1980). The NS-H-6791, NS-H-6488 and NS-H-6304 sunflower hybrids examined in cold-pressed sunflower oil also identified a very strong negative correlation (C18:2 = -0.732 × C18:1 + 79.712, R = -0.989) between the content of linoleic and oleic acid.
The highest peroxide value (3.98±0.05 mmol kg^{-1}) and content of conjugated dienes (4.02±0.01) was determined in the initial sample NS-H-6791 while the lowest peroxide value (2.20±0.02 mmol kg^{-1}) was obtained in NS-H-6304 initial sample and the lowest conjugated dienes content (3.15±0.01) was found in the initial NS-H-6488 sample. In the initial sample NS-H-6488 the value of the peroxide number was 2.87±0.03 mmol kg^{-1}, and the content of conjugated dienes was 3.68±0.01 in the NS-H-6304 initial sample. After 4 days of exposure samples at a temperature of 63±2°C, peroxide values ranged from 29.85±1.00 mmol kg^{-1} (NS-H-6791) to 31.13±1.33 mmol kg^{-1} (NS-H-6488). The content of conjugated dienes after 4 days ranged from 9.22±0.02 (NS-H-6304) to 12.94±0.01 (NS-H-6791). After 8 days, the highest peroxide value of 72.88±6.07 mmol kg^{-1} was determined in the sample NS-H-6488 while the lowest value of 54.70±4.10 mmol kg^{-1} was determined in the NS- H-6791 sample. The content of conjugated dienes after 8 days of exposure to the test conditions ranged from 18.81±0.01 (NS-H-6791) to 21.28±0.01 (NS-H-6304).
In the tested samples, a strong linear correlation (R = 0.990-0.994) was obtained between the content of the conjugated dienes and the peroxide value (Figure 1, Table 2).

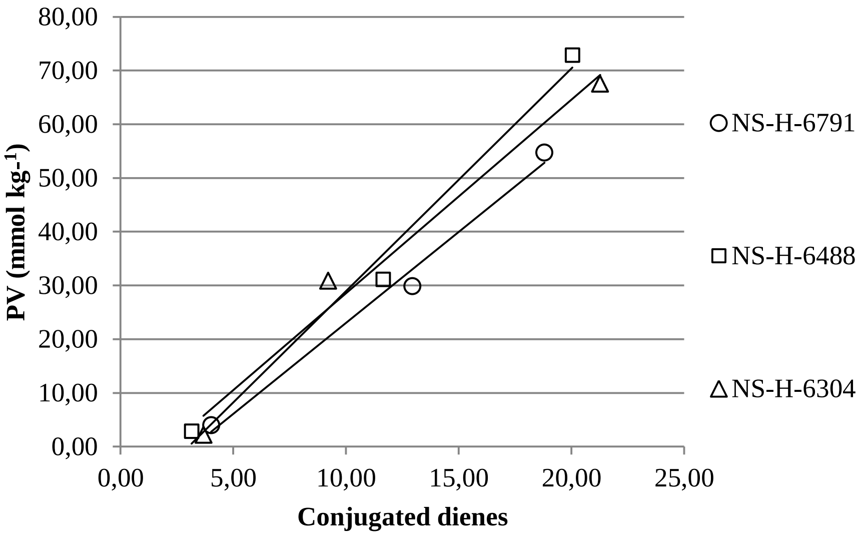

Figure 1. Linear dependence of the peroxide value and content of conjugated dienes

Table 1. Parameters of the linear dependence of the peroxide value and content of conjugated dienes

Sample	PV = a × Conjugated dienes + b			
	a	b	R^2	R
NS-H-6791	3.387	-10.869	0.989	0.994
NS-H-6488	4.141	-12.478	0.987	0.993
NS-H-6304	3.606	-7.5358	0.981	0.990

Romanić *et al*. (2018) examined the dependence of the peroxide value and conjugated dienes in sunflower oil obtained from oil hybrids under the same conditions and obtained high values of coefficients of determination (R^2 = 0.994-0.999).
The highest anisidine value in the initial samples (1.52±0.34) was determined in the sample NS-H-6791. After 8 days exposure of the sample to a moderate temperature, the anisidine value of 6.56±0.04 was determined. The lowest anisidine value in the initial samples was determined in the sample NS-H-6304 and was 0.47±0.06. After 8 days of the test the anisidine value was 2.44±0.64. The highest content of conjugated trienes in the initial samples (0.54±0.00) was determined in the NS-H-6791 sample, in which after 8 days was determined the maximum value of conjugated trienes content (1.22±0.01). The lowest value of conjugated triene content was determined in the NS-H-6488 initial sample and amounted to 0.37±0.01. In the same sample, the minimum content of conjugated trienes of 0.54 ± 0.01 was found after 8 days of the test.
Between the peroxide values and conjugated trienes content in the tested samples was found a significant and strong linear correlation with correlation coefficients between 0.405 and 0.806, as shown in Figure 2 and Table 3.

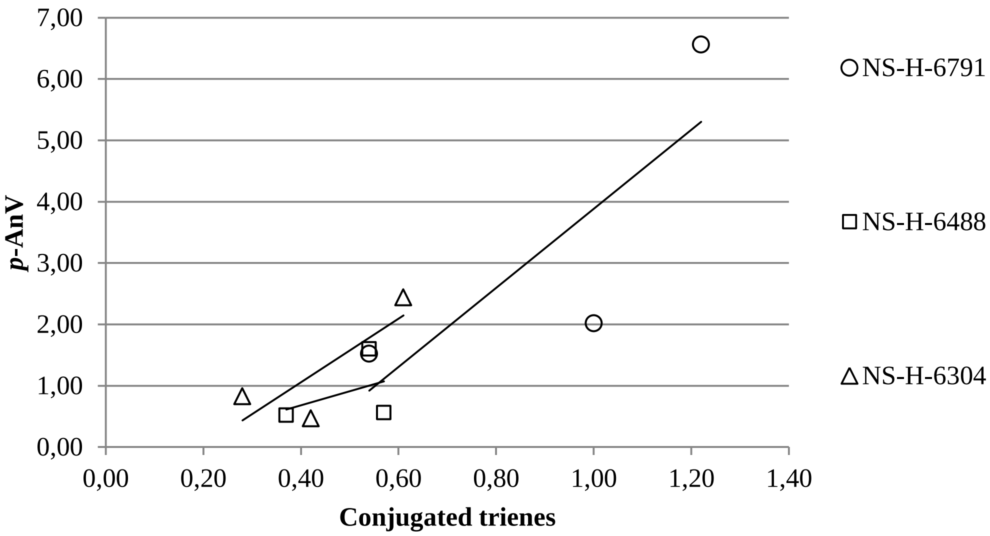

Figure 2. Linear dependence of anisidine values and content of conjugated trienes

Table 3. Parameters of the linear dependence of the anisidine values and content of conjugated trienes

Sample	*p*-AnV = a × Conjugated trienes + b			
	a	b	R^2	R
NS-H-6791	6.445	-2.529	0.649	0.806
NS-H-6488	2.298	-0.240	0.164	0.405
NS-H-6304	5.196	-1.022	0.673	0.820

Romanić *et al*. (2018) examined the dependence of the anisidine number and conjugated trienes on sunflower oil obtained from oil hybrids under the same conditions and obtained similar values of coefficients of determination (R^2 = 0.164-0.717).
Based on the peroxide and anisidine values, as well as the content of conjugated dienes and trienes in the initial samples, and after 4 and 8 days of the test, clustering was performed using

the *Ward's method* and the differences between the samples were expressed as Euclidean distance values (Figure 3).

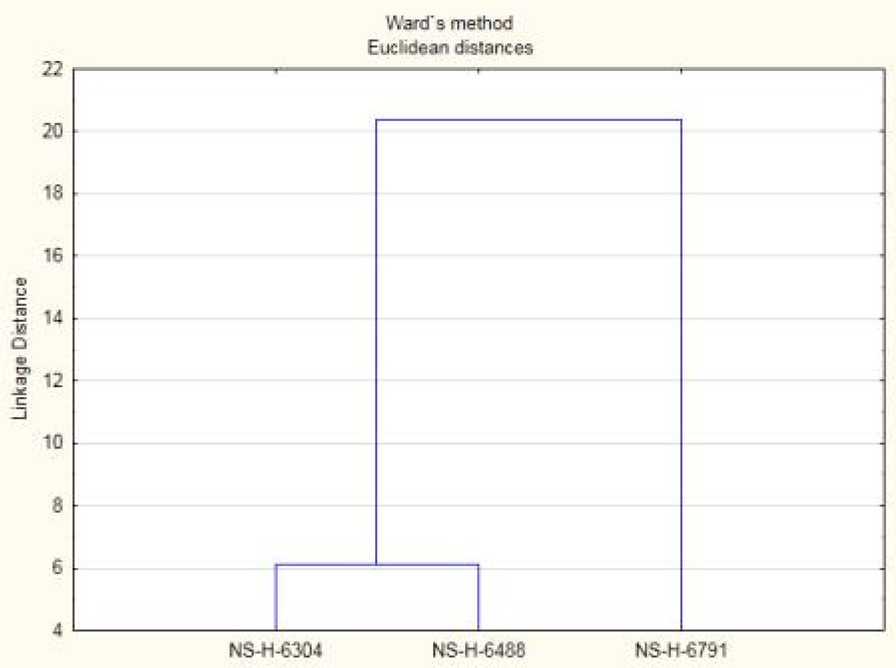

Figure 3. Hierarchial dendogram analysis of oxidation products of tested samples

The NS-H-6304 and NS-H-6488 samples are less different by oxidative stability than the NS-H-6791 sample. The largest difference was found between samples NS-H-6488 and NS-H-6791 and was 19.1 (expressed as Euclidean distance). A somewhat lower difference was found between samples NS-H-6304 and NS-H-6791 and was 14.5, while the smallest Euclidean distance was found, as mentioned, between samples NS-H-6304 and NS-H-6488 and amounted to only 6.1.

Conclusions

Based on cluster analysis, it is concluded that the NS-H-6791 sample varies considerably by oxidative stability compared to the other two samples. The highest peroxide value in the initial sample was found in this sample and also the lowest peroxide value after 8 days of exposure to the test. The peroxide value in this sample increased 13.74 times, while for samples NS-H-6488 and NS-H-6304 it increased 25.39 and 30.71 times, respectively. The NS-H-6791 anisidine value increased 4.32 times during test exposure, while for samples NS-H-6488 and NS-H-6304 this increase was 3.08 and 5.19 times, respectively.

Aknowlegment

This work is the result of research under the projects TR 31014 and TR 31025, financed by the Ministry of Education, Science and Technological Development of the Republic of Serbia.

Abstract

The present study focused on inhibitory effects of water extracts of flowers, leaves, stems and roots of *Xeranthemum cylindraceum* Sibth. et Sm. on the total germination percentage, germination rate and germination rate index of chickweed (*Stellaria media* [L.] Vill.), common ragweed (*Ambrosia artemisiifolia* L.) and velvetleaf (*Abutilon theophrasti* Medik.). Water extracts were made by soaking 10 g of plant biomass in 100 ml of distilled water on a shaker for 24 h. Batches of 50 (*A. artemisifolia* and *S. media*) or 30 (*A. theophrasti*) seeds were germinated in 0%, 10%, 20% and 50% extract solutions in three replicates. The extract of *X. cylindraceum* flower did not affect the germination percentage of test species but it did affect the germination rate and germination rate index of all three species. The highest concentration of leaf extract significantly reduced chickweed germination percentage, while it had no corresponding inhibitory activity on the other two species. Its 10% concentration even stimulated the germination of *A. theophrasti* seeds. Leaf extracts had inhibitory effects on the germination rate and germination rate index of all three species. Stem extract of *X. cylindraceum* had no effect on any germination parameter of common ragweed seeds. However, it had inhibitory effect on the germination rate and germination rate index of chickweed, and on germination rate of velvetleaf. Root extract acted inhibitory on all three germination parameters of chickweed seeds, and on the germination rate of velvetleaf. It had no inhibitory activity on the seeds of common rageweed. Based on available literature, the present study is the first to show that *Xeranthemum cylindraceum* has allelopathic properties.

Keywords: *alellopathy, Xeranthemum cylindraceum, water extracts, weed seeds, germination inhibition.*

Introduction

Successful cultivation of crop hybrids resistant to diseases and insects, in combination with evolving integrated pest management systems, have enabled reductions in damage caused by fungicides and insecticides, but the use of herbicides has continued to expand worldwide (Bhadoria, 2011). Research into the allelopathic properties of various plants has intensified over the past several decades both for scientific purposes and with the idea of introducing allelochemicals in agricultural production in order to eliminate or at least reduce harmful effects of excessive herbicide use. Based on available literature, allelopathic properties of *Xeranthemum cylindraceum* Sibth. et Sm. (syn. *X. foetidum* Mnch., *Xeroloma foetida* Cass.) have not yet been studied. The plant is widespread in Serbia and frequent on roadsides, in arable fields, vineyards, sunny grasslands and on rocky terrain (Gajić, 1975).
The present study focused on testing the inhibitory effects of water extracts of flowers, leaves, stems and roots of *X. cylindraceum* on total germination, germination rate and germination rate index of chickweed (*Stellaria media* [L.] Vill.), common ragweed (*Ambrosia artemisiifolia* L.) and velvetleaf (*Abutilon theophrasti* Medik.) seeds.

Material and Methods

X. cylindraceum plants were sampled in the vicinity of Krušedol Monastery, Mt. Fruška Gora in northern Serbia in July 2017. They were dried before flowers, leaves, stems and roots were partitioned. Water extracts were made by soaking 10 g plant biomass in 100 ml of distilled water on a shaker for 24 h.

Seeds of the test plants were sampled in Belgrade's Zemun outskirts (Serbia) over the 2017 season, depending on their respective maturation periods. *A. artemisifolia* and *A. theophrasti* seeds were sterilized for 10 min in 10% water solution of bleach (industrial sodium hypochlorite, minimum concentration 40 g active chlorine/l) and stratified for four weeks at 4±2°C, and for 10 min at 65±5°C, respectively. *S. media* seeds were neither sterilized nor stratified. Batches of 50 (*A. artemisifolia* and *S. media*) or 30 (*A. theophrasti*) seeds were germinated in 0%, 10%, 20% and 50% extract solutions in three replicates. The seeds were germinated in the dark, and illuminated for 5-10 min during counting sessions at 1-3 days intervals. Chickweed seeds were germinated at 18±1 °C, and seeds of the other two species at 28±1 °C.

Germination properties were assessed based on: total germination (TG), germination rate (GR) and germination rate index (GRI). Total germination (TG) is the percentage of germinated seeds at the end of experiment. Germination rate (GR) is the sum of the quotients of germinated seed number since previous counting session and number of days since the beginning of experiment. It is calculated using a modified equation by Maguire (1962): $\mathbf{GR=\sum(Gi/ti)}$, where **Gi** is the number of seeds germinated since the last counting session on day **i**, and **ti** is the number of days since the beginning of experiment until day **i**. Germination rate index (**GRI**) is the product of **GR** and the quotient of germinated seed number by the end of experiment (**G**) and total seed number (**N**): $\mathbf{GRI=GR(G/N)}$.

Statistical analyses were performed using the STAT-GRAPHICS software, version 4.2 (STSC Inc. and Statistical Graphics Corporation, 1985-1989, USA). The percentage data were *arcsin* transformed before statistical analysis. The data were subjected to one-way analysis of variance (ANOVA). Differences between means were evaluated by Fisher's LSD test calculated at the confidence level of $P \leq 0.05$. The results of statistical analysis are marked with appropriate letters in the figures, and samples marked with the same letters have no significant statistical difference.

Results and Discussion

The effects of water extracts of different *X. cylindraceum* organs on germination dynamic of chickweed (*Stellaria media*) seeds were most evident in leaf extracts (Figure 1b). Their concentrations of 20% and 50% delayed germination start by a day, and the raching of germination plateau by two and one day, respectively. All concentrations of *X. cylindraceum* water extracts delayed the germination of chickweed seeds, compared to their germination in distilled water, but only the highest concentration (50%) delayed the reaching of germination plateau by a day (Figure 1a). Germination start was not delayed by stem extracts, while seeds germinating under 50% concentration reached germination plateau two days later than control seeds (Figure 1c). Only the highest concentration of root extract delayed the start of germination of chickweed seeds (Figure 1d).

Common ragweed (*Ambrosia artemisiifolia*) seeds generally showed no change in germination dynamic, except at the highest concentration (50%) of *X. cylindraceum* water extract, which delayed germination plateau by two days (Figure 2). The analysis of germination parameters suggest similar conclusions as only the highest concentrations of flower and leaf water extracts affected the GR and GRI (Table 2).

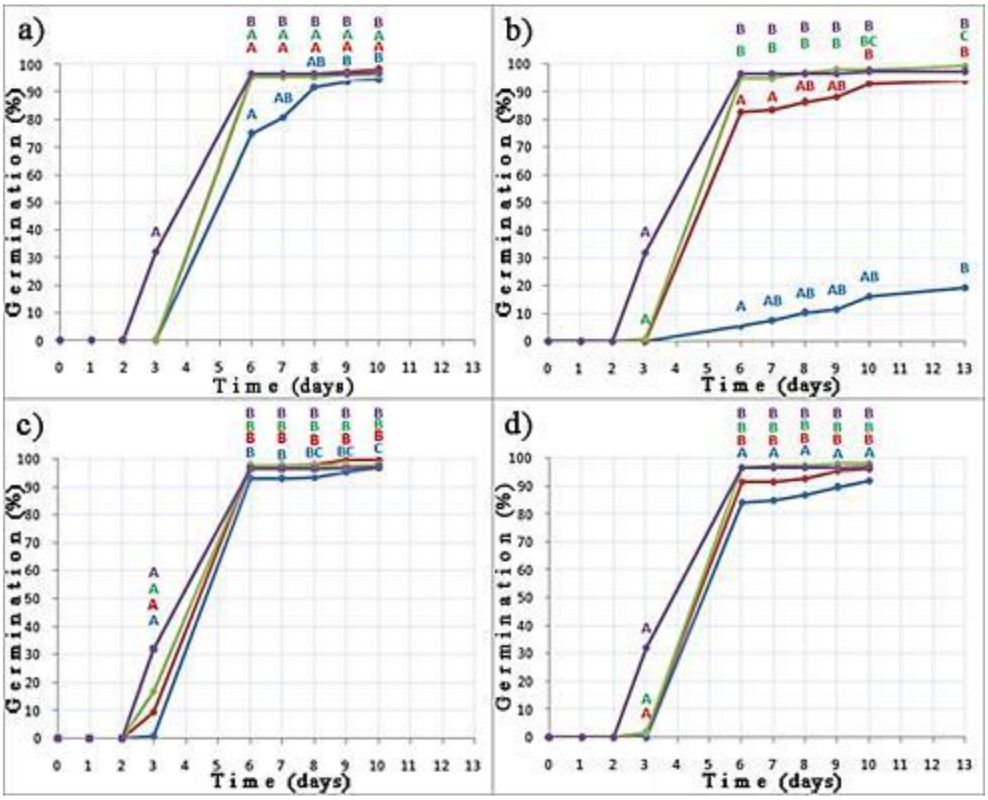

Figure 1. Dynamic of germination of *Stellaria media* seeds in different concentrations of *Xeranthemum cylindraceum* flower (a), leaf (b), stem (c) and root (d) water extracts. Different colours are used to distinguish different concentrations: purple – 0% (control), green - 10%, red - 20%, blue - 50%. Letters of the same colour show significant difference in the percentage of germinated seeds over time in extracts of corresponding concentrations.

The dynamic of velvetleaf (*Abutilon theophrasti*) seed germination changed only under the influence of leaf extract. Concentrations of 20% and 50% delayed the start of germination by one day, while 10% and 50% concentrations also delayed germination plateau by a day (Figure 3).

The effects of extracts on seed germination of the test species generally varied depending on plant organs used and their extract concentrations, as well as on the plant species whose seeds were tested (Tables 1, 2 and 3). These findings are in agreement with previous reports showing that allelopathic effects tend to differ depending on extract source, extract concentration and target species (Tabrizi and Yarnia, 2011; Pirzad *et al*., 2012; Suwitchayanon and Noguchi, 2014.; Zhang *et al*., 2018).

Leaf extracts of *X. cylindraceum* demonstrated the strongest effect on seed germination of the test species in this experiment. Leaf extracts had inhibitory effects on the GR and GRI of all three species (Tables 1, 2, 3). The highest concentration of leaf extract significantly reduced the TG of chickweed seeds, while it had no corresponding inhibitory activity on the other two species (10% concentration of leaf extract even had a stimulating activity on the TG of *Abutilon theophrasti* (Table 3)). Many studies have revealed stronger inhibitory activity of leaf extracts on seed germination or early root or shoot development and shoot growth, compared to extracts of other plant organs (Chung and Miller, 1995b; Naderi and Bijanzadeh, 2012; Suwitchayanon and Noguchi, 2014; Zhang *et al*., 2018).

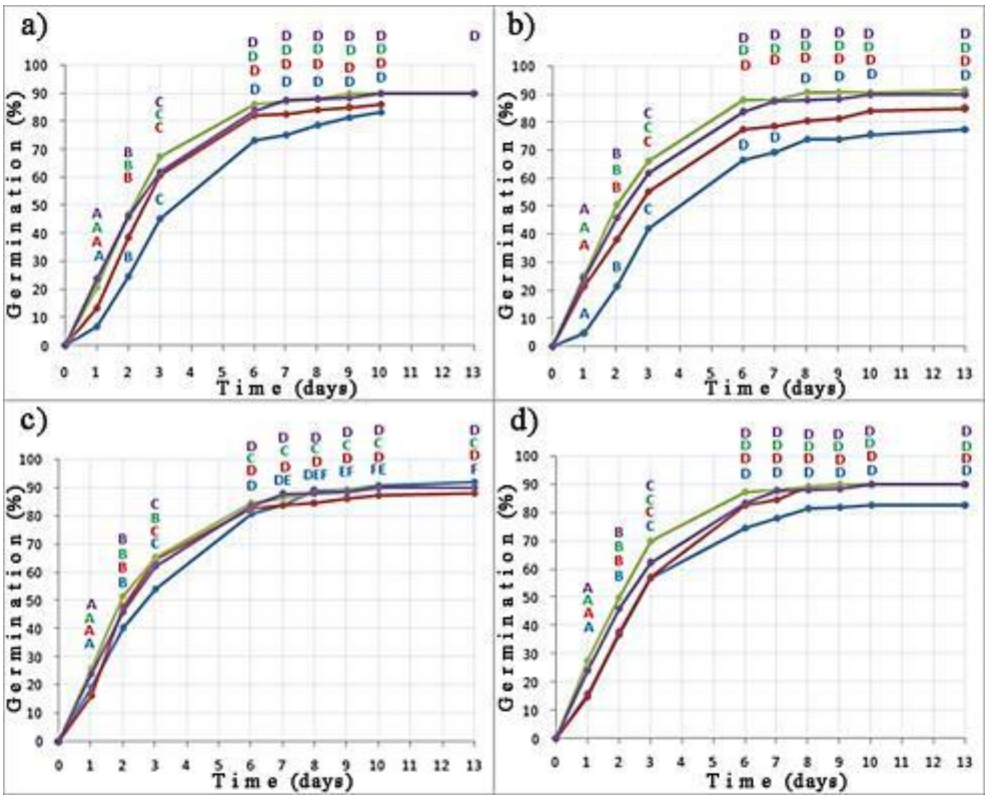

Figure 2. Dinamic of germination of *Ambrosia artemisiifolia* seeds in different concentrations *Xeranthemum cylindraceum* flower (a), leaf (b), stem (c) and root (d) water extracts. See Figure 1 for markings.

The extracts of *X. cylindraceum* flower did not affect the TG of test species but did affect the GR and GRI of all three species. Studies of allelopathic activity of plant organs probably focus the least attention to the flower, which usually has no distinct activity, compared to the other plant organs. However, other examples have also been reported. Chon (2004) showed the highest inhibition of alfalfa (*Medicago sativa*) seedling growth in extracts of flowers and leaves, followed by stems and roots of common thistle (*Cirsium pendulum* Fisch.).

Of all parts of sorghum (*Sorghum bicolor*), its stem extracts have shown the highest allelopatic effect on mung bean (*Vigna radiata*) seedling growth (Moosavi et al., 2011). On the other hand, Chung and Miller (1995a) ranked autotoxic effects of water extracts of alfalfa plant parts as: leaf (greatest), seed, root, flower and stem (least). The stem extract of *X. cylindraceum* in our present study had no effect on any germination parameter of common ragweed seeds. However, it had an inhibitory effect on GR and GRI of chickweed, and on GR of velvetleaf.

Root extract of *X. cylindraceum* acted inhibitory on all three germination parameters of chickweed seeds, and on the GR of velvetleaf. It had no inhibitory activity on common rageweed seeds.

The results of this experiment infer that *X. cylindraceum* owns allelopathic properties. The species is known to contain cyanogenic glicosides (Nahrstedt and Schwind, 1992), which have allelopathic activity (Fateh *et al.*, 2012). Recent studies have targeted the chemical composition of *X. cylindraceum* plant parts sampled in Serbia (Dekić *et al*., 2015; Gavrilović *et al*., 2018). The detection and identification of lactonitrile indicated the presence of cyanogenic glycosides in *X. cylindraceum* (Dekić *et al*., 2015).

Conclusions

The effects of water extracts of flower, leaf, stem and root of *X. cylindraceum* on the germination of chickweed (*Stellaria media*), common ragweed (*Ambrosia artemisiifolia*) and velvetleaf (*Abutilon theophrasti*) seeds were tested. Based on available literature, this was the first study on allelopathic properties of *X. cylindraceum.* Leaf extracts perceptibly affected the seed germination dynamic of *S. media* and *A. theophrasti*, but not *A. artemisiifolia*. The other extracts demonstrated considerably weaker effects on seed germination dynamic. Extracts of the examined organs did not show strong inhibitory effect on TG, except leaf extract which exceptionally reduced the percentage of TG of *S media* seeds (below 20%). Flower and leaf extracts reduced GR and GRI in all three weed species. Stem and root extracts did not affect the germination of common ragweed, while they only reduced GR data for *A. theophrasti*. The study for the first time showed that *X. cylindraceum* owns allelopathic properties. It was shown to act inhibitory at variable degrees on the seed germination of all three tested weed species.

Abstract

Biological control potential of *Trichoderma harzianum* in the control of postharvest fungal pathogens of *Pepa* white yam tubers in storage was carried out for two years. Rotted *Ogoja* and *Pepa* white yam tubers were collected from farmers' barns in Zaki-Biam, Benue State, Nigeria. Pathogenicity tests conducted on healthy *Pepa* yam cultivars after fourteen days of inoculation revealed that the tubers were susceptible to *A. flavus*, *F. moniliforme* and *P. expansum*. Treatments comprised either inoculation of yam tubers with *A. flavus*, *F. moniliforme* and *P. expansum* alone or paired with *T. harzianum* as well as a control where the tubers were neither inoculated with antagonist nor with fungi pathogens and were stored for five months between December, 2015 and April 2016 and between December, 2016 and April, 2017. Results got in the first year of storage showed that tubers treated with fungi pathogens alone caused mean percentage rot of between 8.89% (*P. expansum*) and 20.00% (*A. flavus*) while those treated with *T. harzianum* alone produced only 2.22%. In the paired treatments, mean percentage rots were between 4.44% (*P. expansum* × *T. harzianum*) and 6.67% (*A. flavus* × *T. harzianum*). The findings in the second year revealed 13.33% (*P. expansum*), 22.22% (*A. flavus*) and 4.44% (*T. harzianum*) in the alone treatments while paired treatments produced mean rot of between 4.44% (*P. expansum* × *T. harzianum*) and 8.89% (*A. flavus* × *T. harzianum*). The results revealed that *P. expansum* was the most antagonized while *A. flavus* was the least inhibited. The findings revealed that *T. harzianum* (biological control agent) was more effective in inhibiting the growth of *A. flavus*, *F. moniliforme* and *P. expansum* in the first year of storage compared with the second year of storage. The antagonist therefore has biological potentials in controlling fungi pathogens of yam in storage.

Keywords: *Biocontrol, Trichoderma harzianum, Zaki-Biam, Pathogenicity Test, Aspergillus flavus.*

Introduction

Trichoderma harzianum is an antagonistic fungus that is widely recognized as an effective biocontrol agent for a range of important airborne and soil borne plant pathogens (Papavizas, 1985; Harman *et al.*, 2004; Mokhtar and Aid 2013). The genus *Trichoderma* is known to be promising members against soil-born plant parasitic fungi. Rot of crop produce have been known to reduce quantity and quality of yam both in the field and in storage (Amusa *et al.*, 2003) and fruits (Amusa *et al.*, 2003).

Studies conducted in different parts of the country have shown that fungal rot is the greatest cause of tuber loss in storage (IITA, 1993; Amusa *et al.*, 2003). These pathogenic organisms associated with yam rot in Nigeria are: *Aspergillus flavus*, *A. niger*, *Botryodiplodia theobromae, Colletotrichum spp, Fusarium oxysporum, F. solani, F. moniliforme, Penicillium purpurogenum, P. digitatum, P. oxalicum, Rhizoctonia sp, Rhizopus nodosus* (Markson *et al.*, 2012; Ogunleye and Ayansola, 2014; Gwa *et al.*, 2015; Gwa and Akombo, 2016; Shiriki *et* *al.,* 2015, Gwa and Abdulkadir, 2017, Gwa and Nwankiti, 2017a). Rot of yam tubers in storage is caused by up to 30 different pathogenic fungi (Ikotun, 1989 and Nahunnaro, 2008). There are different methods of control of these pathogens such as chemical, use of natural plant extracts as well as biological control method. Chemical control is fast but with lots of adverse effects such as killing beneficial micro and macro organisms, risk to humans, pollution of the environment (Yadav, 2010; Lakshmeesha *et al.,* 2013a). The use of plant extracts in controlling these pathogens of crops has proven to be effective (Taiga *et al.,* 2008; Nweke 2015; Gwa and Akombo 2016; Gwa and Nwankiti 2017a). Biological control using fungi belonging to the genus *Trichoderma* such as *T. harzianum*, *T. viride* and the genus *Pseudomonas* such as *P. syringae, P. chlororaphis* as well as *Bacillus subtilis* and *Gliocladium roseum* has been considered very effective as bio- control agents in controlling postharvest and storage rots of yam tubers (Okigbo, 2004; Okigbo and Emeka, 2010; Gwa *et al.,* 2016; Gwa and Nwankiti, 2017b, Gwa and Ekefan, 2017; Gwa and Abdulkadir, 2017). The bio control agents have no phytotoxic effects, target specific, eco-friendly with no pollution problem as well as promote plant growth (Mausam *et al.,* 2007; Harman *et al.,* 2004). The study therefore, focuses on the capabilities of *T. harzianum* as a bio control agent of postharvest rot causing fungal pathogens of yam tubers as alternative to synthetically used fungicides.

Materials and Methods

Source of *T. harzianum*

T. harzianum was collected from yam pathology unit, University of Ibadan, Nigeria. Stock cultures of the isolate were aseptically prepared and maintained on slants of acidified potato dextrose agar (PDA) in McCartney bottles and stored for subsequent studies.

Collection of rotted and healthy yam tubers

Ogoja and Pepa varieties of white yam (*D. rotundata*) tubers showing various degrees of rot symptoms were collected from yam farmers' barns in Zaki-Biam, Benue State, Nigeria which lies between longitudes 9^o $25'$ and 9^o $28'$E, and latitude 7^o $32'$ and 7^0 $35'$N respectively. The yam tubers were packaged in sterile polyethylene bags to avoid wounding before taken and to Advanced Plant Pathology Laboratory, Federal University of Agriculture, Makurdi, Nigeria for subsequent isolation and identification of pathogens two days after collection. The medium used for isolation of the pathogens was Potato Dextrose Agar (PDA).

Isolation and identification of fungi associated with rots of yam tubers

Tubers were washed in running tap water and were cut into approximately 2 x 2mm from the advancing edge of lesion with sterile scalpel. The cut tissues were surface sterilized for 2 minutes in 5 % Sodium hypochlorite solution in order to remove surface contaminants. The pieces were then rinsed in four successive changes of sterile distilled water and dried on sterile filter paper (Gwa and Nwankiti, 2017a). Four pieces of the sterilized tissues were plated out on the solidified potato dextrose agar (PDA). The plates were neatly covered with mastic tapes and incubated at ambient room temperature (30±5°C) for 7 days and growths were observed daily for the development of fungi. Sub-cultures of growing fungi mycelial were identified after 7 days of incubation when pure cultures were fully established (Gwa and Nwankiti, 2017a). The grown pure cultures were used for identification of the fungi with the aid of a compound microscope and identification guide (Navi, *et al.,* 1999; Burgess *et al.*, 2008).

Pathogenicity test of the isolated fungi

B. theobromae, A. flavus, A. niger, F. moniliforme, F. oxysporum, P. purpurogenum P. expansum and *Pestalotia* sp isolated from the rotted yam tubers were inoculated into healthy *Pepa* yam tubers. Healthy yam tubers were washed under running tap water and surfaced sterilized in 5 % Sodium hypochlorite solution for 2 minutes. The tubers were rinsed in four successive changes of sterile distilled water. Cylindrical discs of 5 mm were removed from the tubers using a sterile cork borer. Mycelial discs of each fungus measuring 4 mm in diameter were taken from 5 day-old cultures of each of the fungi and each fungal disc was put into a hole in each of tubers. Same procedure was replicated for the control experiment except that sterile agar discs were used instead of the inoculum obtained from the fungi in the holes created in the tubers (Gwa *et al.,* 2017). Petroleum jelly was used to completely seal the remaining holes to prevent contamination by other pathogenic organisms. The inoculated yam tubers were replicated three times for each of the pathogens and control experiments. A total of 27 tubers of Pepa yam varieties were used in this experiment (three tubers for each of the eight pathogens and three tubers for control). The treatments were completely randomized and incubated for 14 days at ambient room temperature (30±5^{o}C) under sterile condition to allow for growth and establishment of the fungi organisms after which the tubers were examined for infection and disease development by cutting transversely at point of inoculation. Disease symptoms produced by artificial inoculation of the yam tubers with the pathogens after the incubation period were compared with those observed on the naturally infected tubers initially collected from farmers' barns. The fungi were re-isolated from the inoculated diseased yam tubers and cultured on PDA plates. The morphology of each pathogenic fungus was compared with that of the original culture obtained from the naturally infected tubers.

Preparation of fungal spore suspension and culture of *T. harzianum*

Spores suspensions of *A. flavus*, *F. moniliforme* and *P. expansum* and the antagonist; *T. harzianum* were prepared from 5 days old cultures grown on Potato dextrose agar (PDA) plates. Conidia from the surface of agar plate from these fungi were scrapped with a sterile glass rod to dislodge the spores (Nduagu *et al.*, 2008) and were each re-suspended in 1L of sterile distilled water containing 5% Tween 80 (Ismet *et al*., 2012). The spore suspensions obtained were filtered through four folds layer of sterile cheesecloth into a sterile 1000ml Pyrex glass beaker. The suspension concentrations were determined by using an improved Neubauer haemocytometer (model BS 748) and adjusted to 1×10^{6} spores per ml.

Determination of the interaction between rot fungi (*A. flavus, F. moniliforme* and *P. expansum*) and biological antagonist (*T. harzianum*) on healthy *Pepa* white yam tubers

Healthy white yam tubers of Pepa cultivar (*D. rotundata*) were used for storage when applied with different treatments. Treatments comprising *A. flavus, F. moniliforme* and *P. expansum* were each paired with *T. harzianum* separately to determine their effects on rot development in Pepa white yam tubers during storage. The tubers were also inoculated with each of the fungal isolates separately without *T. harzianum* as a bio control agent. Yam tubers without fungal isolates and *T. harzianum* served as the control. *T. harzianum* was paired with the three pathogenic fungi and yam tubers were inoculated separately according to the following inoculation regime (Okigbo and Emeka (2010):

(a) Uninoculated yam tubers (control);
(b) Tubers inoculated with *A. flavus* alone;
(c) Tubers inoculated with *P. expansum* alone;
(d) Tubers inoculated with *F. moniliforme* alone;
(e) Tubers inoculated with *T. harzianum* alone;
(f) Tubers inoculated with *T. harzianum* and *A. flavus* simultaneously;
(g) Tubers inoculated with *T. harzianum* and *P. expansum* simultaneously;
(h) Tubers inoculated with *T. harzianum* and *F. moniliforme* simultaneously;

Three tubers formed a treatment; each of the eight treatments was replicated three times giving a total of nine tubers per treatment. 72 tubers of yams were used in this experiment for the eight different treatments. The suspension for each of the treatments was poured in a hand sprayer and the yam tubers were sprayed accordingly (Sarma 1984; Wilson and Pusey, 1985). The yam tubers were arranged in completely randomized design and stored at ambient room temperature (30 ± 5 ^{0}C) for five months for two years. Record of rotted tubers were kept on periodic basis and cumulative percentage rot during storage of yam tubers that were inoculated with *T. harzianum* and the post harvest pathogens of yams in different combinations were calculated at monthly interval for five months according to the method described by Dapaah, (2013), thus, calculated as follows;

$$Percentage\ rot\ (\%) = \frac{N}{T} \times \frac{100}{1}$$

Where,
% = Percentage rot of tubers
N = Number of rotten tubers at the time of evaluation
T = Total number of tubers stored for the treatment

Data analysis

Data that were collected from the different treatments were subjected to Analysis of variance (ANOVA) using GenStat Discovery Edition 12, Graph Pad Prism 6 for trend graphs and significant means for each measured parameter were separated using Fisher's least significant difference (FLSD) ($P\leq 0.05$) (Cochran and Cox, 1992).

Results and Discussion

Isolation and identification of pathogenic fungi from rotted yam tubers

B. theobromae, A. flavus, A. niger, F. moniliforme, F. oxysporum, P. purpurogenum P. expansum and *Pestalotia* sp. were identified from the rotted Ogoja and Pepa white yam tuber cultivars. These fungi are rot-causing pathogens of *D. rotundata* in different parts of Nigeria (Ogunleye and Ayansola, 2014; Okigbo *et al.,* 2015, Gwa and Akombo, 2016; Gwa and Nwankiti, 2017b). The occurrence of *B. theobromae*, *A. flavus*, *A. niger*, *F. oxysporum* in high numbers in major yam producing areas in Nigeria have been previously demonstrated by Ogunleye and Ayansola (2014), Okigbo *et al.*, (2015) and Shiriki *et al.,* (2015).

Pathogenicity tests carried out on the healthy Pepa white yam tubers produced typical symptoms of the pathogens isolated from the naturally infected tubers and the re-isolation of identical fungi from the artificially inoculated rotted yam tubers fulfils Koch's postulates and establishes the pathogenicity of the yam fungi isolates. The tubers that were treated without mycelial from different fungi (control tubers) did not produce rot suggesting the absence of inoculum in the bored yam tissues. Table 1 shows the result of inoculation of healthy white yam tuber of Pepa with *T. harzianum* and rot-causing fungi alone and in combination for two years. There was no significant difference ($P\leq 0.05$) in mean percentage rot in the treatments for the five months storage period between for the two years. However, *P. expansum* was most antagonized followed by *F. moniliforme* while the least antagonised pathogen was *A. flavus*. The result revealed that *T. harzianum* was more antagonistic in the first year of storage compared with the second year of storage (Table 2). Similar results were obtained by Markson *et al.,* (2012) and Nikolajeva *et al.,* (2012) who showed that *Trichoderma* species are useful in the control of rot fungi of fruits, vegetables and tuber diseases.

Result obtained by Okigbo and Emeka (2010) showed the biological control of rot-inducing fungi of water yam (*D. alata*) using *T. harzianum*, *Pseudomonas syringae* and *P. chlororaphis* which they both revealed that the three antagonists significantly inhibited the growth of *B.*

theobromae and *F. solani* on stored yam tubers. Result obtained by Okigbo (2005) showed the inhibitory potentials of *Bacillus subtilis* in controlling post harvest fungal pathogens of yam tubers in storage

The use of *T. harzianum* in controlling postharvest fungal pathogens of yam tubers in storage for five months is similar to the result obtained by Okigbo and Ikediugwu, (2000) that used a single application of *T. harzianum* and protected yam tubers in storage for up to 6 months. Though *T. harzianum* was able to reduce rot pathogen infections, the effect of the antagonist pairing with *P. expansum* was more potent than the inhibition recorded between the interaction of *T. harzianum* and *F. moniliforme* and *P. expansum*. The difference in antagonistic potency could probably be due to production of antifungal phenolic compounds which function by breaking down the polysaccharides, chitin, and glucans that are responsible for the rigidity of fungal cell walls, thereby destroying cell wall integrity and limiting the growth of these pathogens (Anita *et al*., 2012).

The tubers that were neither treated with pathogenic fungi nor antagonist (control tubers) showed between 8.89 % and 15.56 % rot in the first and second year respectively after five months of storage similar to the result obtained by Ekundayo and Naqvi (1972) who reported losses in yam tubers due to rots pathogens to be between 10 % and 15 % in the first three months of storage. The results however, disagreed with studies conducted by Okigbo and Ikediugwu (2000) who estimated an average of between 20 and 39.5 % of stored tubers lost to rot pathogens. Arinze (2005) and Okigbo *et al*., (2009b) reported that about 50% reduction of the total stored tubers has been reported lost to diseases within the first 6 months of storage in Nigeria. The findings revealed that *T. harzianum* (biological control agent) was more effective in inhibiting the growth of *A. flavus, F. moniliforme* and *P. expansum* in the first year of storage compared with the second year of storage. The difference in the antagonistic potential of *T. harzianum* could probably be due to favourable environmental condition such as adequate moisture or relative humidity which increased the interaction of the rot-causing fungi with the host yam tissues and decreased the potentials of *T. harzianum* in the second year. It has been reported that fungal species occurred more abundantly in the more humid months where the environmental conditions favoured the production of inoculum more than in the drier less humid period (Ekundayo, 1986; Agrios, 2005).

Conclusion

The result has demonstrated that *T. harzianum* has potentials to control *A. flavus, F. moniliforme* and *P. expansum* in post harvest Pepa white yam tubers. It is therefore, concluded that the application of the antagonist will provide better alternative measures in reducing rot of yam tubers in storage compared with the use of synthetically produced fungicides which are in many cases destructive to the ecosystem, expensive, non target specific and toxic to the applicator as well as beneficial organisms.

Abstract

The influence of five different maceration times on extraction of some polyphenols and anti-DPPH radical activity of wine samples were investigated. In focus were: caffeic acid, syringic acid and *p*-coumaric acid. Grape variety Cabernet Sauvignon was harvested in the state of technological maturity. Phytosanitary state: 100% health, sugar in must 23% and total acid in must 6.8 g/l. Alcohol fermentation and maceration was carried out by microvinification method using the pigeagé system. Sulphur dioxide was added as $K_2S_2O_5$ (10g/100 kg crushed grapes), enzymatic preparation Caractére (Car) (Enartis, Italy) with pectolytic, hemicellulase and *ß*-glycosidase activity and wine yeast *Saccharomyces cerevisiae* (BDX, Lallemand, Canada) in the amount of 20g/hl. Liquid parts were separated from the start of fermentation (3, 5, 7, 14, 21 day, respectively), and fermented without contact with pomace (seeds and skin). Control sample obtained first day, without maceration. Determination of the amount of caffeic, syringic and *p*-coumaric acids was performed using Waters Acquity UPLC H-Class with mass detector. It was found that the dynamics of extraction during alcohol fermentation all three phenolic compounds take place exponentially. Maximal amount of extraction for caffeic acid was at 13th day (2.851 mg/l), for syringic acid was at 11th day (1.096 mg/l) and for *p*-coumaric acid at 12th (1.335 mg/l) day of maceration. For anti-DPPH radical activity, the highest potential (5.8%) was found for wine macerated 21day, and lowest (40.66%) was found for wine macerated 3 days. Addition of enzymes and longer maceration leads to better extraction of phenolic compounds and to higher antiradical activity.

Keywords: *Maceration time, Phenolic compounds, Extraction, Antiradical activity.*

Introduction

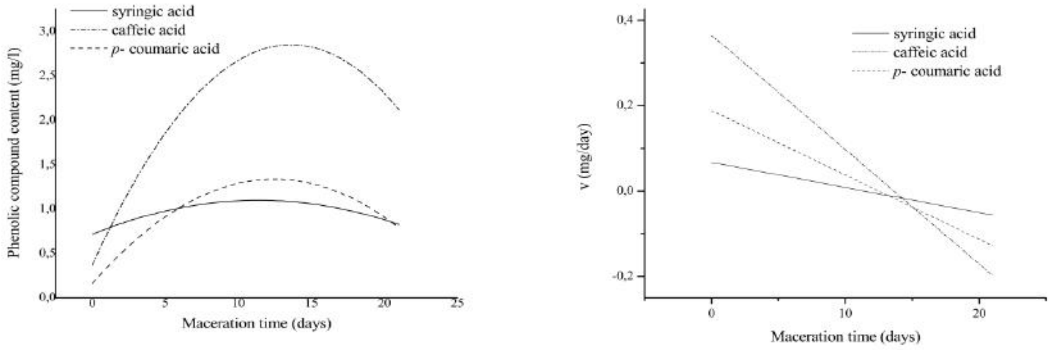
The polyphenolic compounds in wine consist in two classes of components (flavonoids and non-flavonoids) and depend on the grape variety, vineyard location, cultivation system, climate, soil type, vine cultivation practices, harvesting time, production process and ageing (Di Majo et al., 2008). Phenolic compounds come from various parts of grape bunches and are extracted during winemaking and play a very important role in enology because of their contribution to wine sensory properties and antioxidant properties. Grapes and wine contain benzoic and cinnamic acids which belong to group of phenolic acids. Benzoic acids include *p*-hydroxybenzoic acid, protocatechuic acid, vanillic acid, gallic acid, syringic acid, salicylic acid and gentisic acid**.** Cinnamic acids include *p*-coumaric acid, caffeic acid, ferulic acid and sinapic acid. In grapes, they are mainly present as linked glycoside, from which they are released by acid hydrolysis, and esters (gallic and ellagic tannins), from which they are released by alkaline hydrolysis. Free forms are more prevalent, mainly in red wine, due to the hydrolysis of these combinations (Ribereau-Gayon et al., 2006; Sun et al., 2011). During maceration and alcohol fermentation these compounds turn into wine from solid parts of grapes. Among other factors, the optimum pomace contact time needed to achieve the proper level and composition of phenolics in wine depends on the desired wine style and cultivar. The antioxidant compounds present in wine are derived almost exclusively from grapes and have been identified as phenolic acids, flavonols, monomeric catechins and anthocyanidins (Damijanic et al., 2012). There are a lot of winemaking techniques for better extraction phenolic compounds from solid parts of grapes such as increased maceration temperature (thermovinification), cold maceration, must or grape freezing, addition of some enzymatic preparations, prolonged maceration time etc. Addition of pectolytic enzymes improve juice yield and clarification by breaking down the pectins that provide the form structure of the berry (Lopez et al., 2009; Kelebek et al., 2009). The polyphenolic molecules have a functional role because they behave as antioxidants against the free radicals and show a physiologic role as well. In fact, they increase the antioxidant capacity in the human body after red wine consumption (Di Majo et al., 2008). The first objective of this study was to determine the moment during maceration when the maximal amounts of certain phenolic compounds were extracted. The three phenolic compounds i.e., caffeic acid, syringic acid and *p*-coumaric acid were in the focus of the study. Also, the interest of the study was to evaluate the anti-DPPH radical activity of these red wine samples obtained with different maceration time and addition of enzymatic preparations.

Material and Methods

Grape variety Cabernet Sauvignon was harvested in the state of technological maturity at the Oenological station Radmilovac of Faculty of Agriculture, Zemun, Belgrade, Serbia. Phytosanitary state: 100% health, sugar in must 23% and total acid in must 6.8 g/l. Alcohol fermentation with maceration was carried out by microvinification method at temperature of 25°C using the pigeagé system. Sulphur dioxide was added as $K_2S_2O_5$ (10 g/100 kg crushed grapes). Yeast *Saccharomyces cerevisiae* (BDX, Lallemand, Canada) in the amount of 20 g/hl and Enzyme Caractére (pectolytic, hemicellulase and ß-glycosidase activity) (Enartis, Italy) in the amount of 2 g/hl were used. Liquid parts were separated from the start of fermentation (3, 5, 7, 14, 21 day, respectively), and fermented without contact with the solid phase (seeds and skin). After the alcoholic fermentation, the wines were racked for the first time in December 2016. Second racking was done in March 2017 after which the wines were bottled into 750 ml bottles and stored until analysis. In order to detect and quantify the phenolic compounds in wine samples of Cabernet Sauvignon variety, it was necessary to separate them from the accompanying components, concentrate and purify. Solid phase extraction has been experimentally found to be the most suitable. Determination of the amount of caffeic acid, syringic acid and *p*-coumaric acid was performed using the Waters Acquity UPLC H-Class with mass detector (Waters TQ (Tandem Quadrupole, WAT-176001263). All samples were analysed three times. Anti-DPPH radical activity of the wine samples was evaluated as previously described (Blois, 1958). The obtained results were expressed as a reciprocal value I (%) multiplied by 100.

Results and Discussion

It was found that dynamics of the extraction of phenolic compounds during maceration and alcohol fermentation took place exponentially. Maximal extracted amount for caffeic acid was at 13th day (2.851±0.118 mg/l), for syringic acid was at 11th day (1.096±0.088 mg/l) and for *p*-coumaric acid was at 12th (1.335±0.214 mg/l) day of maceration (Figure 1a).



a) **b)**

Figure 1. Extraction dynamics (a) and kinetics (b) of syringic acid, caffeic acid and *p*-coumaric acid during 21 day of maceration.

According to Francesca et al. (2014), that studied these phenolic acids, during prolonged maceration, noticed increasing of its amounts until 20th day and in our research that is a few days earlier. There are many factors that could affect extraction of phenolic compounds such as temperature, yeast, enzymes etc. (Ribereau-Gayon et al., 2006).

One more parameter which can be defined during maceration is extraction rate of certain phenols from pomace to must or wine. For different phenols there are different extraction rates. In our study, the highest extraction rate had caffeic acid (0.02095) than *p*-coumaric acid (0.0151 mg/day) and the lowest had syringic acid (0.005892 mg/day). This depend of temperature, yeast, enzymes etc. (Figure 1b).

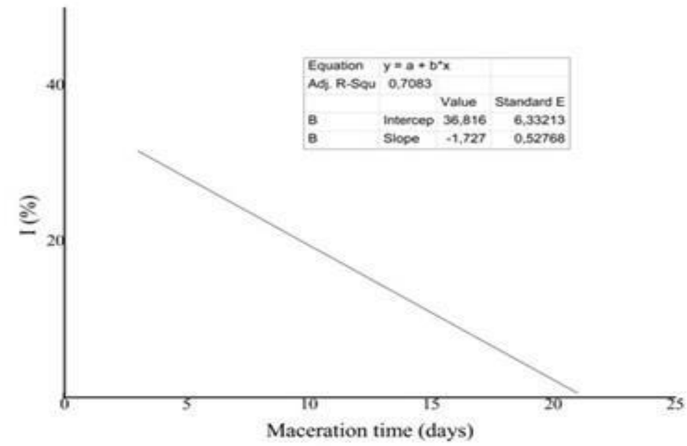


Figure 2. Anti-DPPH radical activity of wine samples during 21 day of maceration with enzyme Caractére.

Antioxidant capacity was measured by radical scavenging assay (DPPH). During prolonged maceration there is an enrichment of phenol content, what consequently improve antioxidant capacity of wine samples. This could explain the significant increase in the antioxidant capacity of Cabernet Sauvignon wine samples during prolonged skin maceration. Higher alcohol level improved the extraction of phenolic compounds leading to better antioxidant capacity of wine. With increasing total phenols content there is increasement of antioxidant properties of wine samples (Ribereau-Gayon et al., 2006). Maceration with this enzyme showed that wine sample macerated 21 day had the highest anti-DPPH radical activity (5.8%) and the lowest was observed for wine macerated 3 days (40.66%) (Figure 2).

Conclusions

In the past many researchers try to find the best way for extraction phenolic compounds from pomace to must or wine. In this study we showed one way for maceration grapes variety Cabernet Sauvignon. It is concluded that prolonged maceration lead to increasement of syringic acid, caffeic acid and *p*-coumaric acid. For this phenolic acids maximal extractions were until 13th day of maceration. The highest extraction rate was evaluated for *p*-coumaric acid. Also, prolonged maceration lead to better anti-DPPH radical activity so that wine sample obtained at 21st day had the highest.

Abstract

Aphid species identification based on host plant and morphological traits is difficult for immature aphids, sometimes even for adult aphids and in other cases for biotypes that have no or very small differences in morphological characters. However, precise identification of aphids is necessary in agriculture because of differences between species and biotypes in virus transmission efficiency or insecticides susceptibility. Fortunately, since the development of molecular techniques, mitochondrial DNA sequences were used for species discrimination and even for intraspecific differentiation between populations. In this study we performed the cytochrome c oxidase subunit I (COI) mitochondrial barcode region on 17 *Aphis gossypii* and 13 *Aphis spiraecola* populations collected from citrus, hibiscus, zucchini, potato and pepper in addition to 03 samples of *Pterochloroides persicae* collected from peach tree. Sequence analysis of the partial mtCOI gene of 709 bp fragment for the three studied species showed the utility of mtCOI as species-distinguishing molecular marker that can be used as reliable species identification of aphid species. In contrast, intraspecific discrimination was not evidenced. The two species of Aphidinae subfamily were identified in a neighbor-joining tree. Mean intraspecific sequence divergence in Aphidinae subfamily was of 6.4%, ranging from 5.8% to 7%. However, the mean interspecific variation between subfamilies (Aphidinae and Lachnidae) was higher than 10% with a range of 9.4% to 10.6%. Intraspecific variations of *A. gossypii* and *A. spiraecola* populations were insignificant with a very low clonal diversity level that varied from 00% to 0.3% and from 00% to 0.9% respectively. This molecular test evidenced that the mtCOI partial gene is a powerful marker to solve the taxonomic ambiguities that the morphological identification cannot decipher.

Key words: *Aphids, Identification, mtCOI, Reliability, Molecular*.

Introduction

The genus *Aphis* is the most species rich genus among Aphididae, with approximately 560 species known in the world (Favret, 2005). Compared to other genera, the species in the genus *Aphis* have remarkable diversity in their host plant utilization (Heie, 1986; Von Dohlen and Teulon, 2003) and display various types of lifecycles; monoecy on woody or herbal plants and heteroecy (Kim *et al.,* 2010). However, due to their rapid radiation, most of the congeneric species are often cryptic in their morphology (Kim *et al.,* 2010). Before molecular tools development for study evolutionary relationships studies, there was little data on the phylogeny of *Aphis* species because of their similar morphologies. Phylogeny within the Aphidini tribe has been partially based on changes in host plant utilization during the evolution of aphids (Komazaki *et al.*, 2010). Morphology and host plant association are significant sources of aphid classification. Heie (1986) asserted that, identification using the morphological characters and host-plant affiliation are more reliable than those based on morphological data alone. However, identification could be restricted by substantial intraspecific variation (Margaritopoulos *et al*., 2000). There are many reports of using mitochondrial DNA to study aphid phylogeny (Stern, 1995, Turcinavicien *et al*., 2006, von Dohlen *et al*., 2006) for species discrimination (Raboudi *et al*., 2005, Valenzuela *et al*., 2007) and even for intraspecific differentiation between aphid populations (Boulding, 1998, Anstead *et al.*, 2002). As a result, they are widely used to solve the taxonomic ambiguities of insect pests. In the light of this, we have decided that it will be very useful to carry out molecular identification work on two economically important aphid species in the study area, *Aphis gossypii* and *A. spiraecola* populations collected on different crops in the Chlef Valley. This study will verify the effectiveness of the partial mitochondrial mtCOI gene as species identification marker and its ability to detect possible intraspecific variations existing within populations of the same species.

Material and methods

Molecular characterization of aphid's populations

In order to assess the reliability of the Mitochondrial Cytochrome Oxidase I (mtCOI) partial gene fragment to identify interspecific and intraspecific variation within the Aphidinae subfamily. A genetic approach was performed on Five (5) *A. gossypii* populations (Ag_{CITR}, Ag_{HIBI}, Ag_{COUR}, Ag_{POMM} and Ag_{POIV}) sampled from citrus (*Citrus sinensis* (Osbeck, 1765): Rutaceae), hibiscus (*Hibiscus syriacus* (L, 1661): Malvaceae), zucchini (*Cucurbita pepo* (L, 1753): Cucurbitaceae), potato (*Solanum tuberosum* (L, 1753): Solanaceae) and pepper (*Capsicum annuun* (L, 1753): Solanaceae) respectively, and five (5) populations of the green citrus aphid *A. spiraecola* collected from the same plant hosts, characterized respectively by As_{CITR}, As_{COUR}, As_{POMM}, As_{HIBI} and As_{POIV}. One (1) population of the giant black bark aphid *Pterochloroides persicae* (Pp) (Hemipetra: Lachninae) sampled from peach trees (*Prunus persica* L. Batsch) was added as out of group to assess genetic variation degree between subfamilies. All aphid samples were stored in 70% ethanol at -20°C. Selected available mtCOI sequences were retrieved from NCBI GenBank and used in this study for intraspecific and interspecific variation of the three studied species.

DNA Extraction and PCR

Aphids stored in 70% ethanol were rinsed twice with RNase and Protease free molecular biology water and then with 100 µl of dellaporta extraction buffer. Five adult apterous aphids were randomly selected from each sample. Total nucleic acids were extracted using the protocol described by Dellaporta *et al* (1983). The Mitochondrial Cytochrome Oxidase I (mtCOI) partial gene fragment (709pb) was amplified using universal barcode primers (LCO1490F) 5̀GGT CAA CAA ATC ATA AAG ATA TTG3̀ and (HCO2198) 5̀TAA ACT TCA GGG TGA CCA AAA AAT CA3̀ (Folmer *et al*, 1994; Zhang and Hewitt, 1997; Cocuzza *et al*, 2008; Komazaki *et al*, 2010; Sharma and Koabayashi, 2013; Zhang *et al*, 2014, Lee *et al*, 2015 and Lokeshwari *et al*, 2015). Synthesized at Integrated DNA technologies IDT, Coraville, Iowa, USA. PCR was performed in a thermocycler (BIORAD C1000©) with the following cycling parameters: five cycle of 94°c for 40s, 45°c for 40s, 72°c for 60s, followed by 35 cycles of 94°c for 40s, 51°c for40s, 72°c for 60s and 72°c for 10mn as final extension. PCR was performed was performed in a 25 µl total reaction volume containing 0.5 µl of each primer, 2.5 of PCR buffer, 0.5 µl of dNTPs, 0.25 µl taq DNA polymerase (Roche diagnostics international LTD). The amplified products were resolved in 1% agarose gel, stained with ethidium bromide (0.6µl/ml). PCR products were submitted to further mtCOI sequencing. Homology tests were carried out using BLAST (https://blast.ncbi.nlm.nih.gov/Blast.cgi), compared with published sequences available in the NCBI, and matched with corresponding region of mitochondrial COI. All the sequences generated in the present study and retrieved sequences corresponding to COI, were aligned with the multiple sequence alignment software CLUSTAL OMEGA at nucleotide level. Phylogenetic tree was generated using neighbor-joining method (NJ) (Saitou et Nei, 1987). The evolutionary distances were computed using the Maximum Composite Likelihood method (Tamura *et al*., 2004). Evolutionary analyses were conducted in MEGA7 (Kumar *et al.*, 2016) .

Results and Discussion

In total, 33 aphids' population were included for COI data set, among them 17 *Aphis gossypii* samples of Ag_{CITR}, Ag_{HIBI}, Ag_{COUR}, Ag_{POMM} and Ag_{POIV}, 13 *Aphis spiraecola* samples characterized by As_{CITR}, As_{COUR}, $As_{POMM,}$ As_{HIBI} and As_{POIV} and three (3) *Pterochloroides persicae* samples found on peach trees. Sequencing of the partial mtCOI gene yielded a 709 bp fragment for *A. gossypii*, *A. spiraecola* and *P persicae* (Fig 1). Comparison of the replicate sequences for the 33 samples showed no mismatch, indicating no sequencing errors. No pseudo-genes were amplified in any of the sequences subjected to analysis, as indicated by the absence of stop codons. A BLAST search for the sequences showed highest hits for the respective species. The sequences obtained were deposited in NCBI-GenBank with accession numbers MH632726 to MH632734.

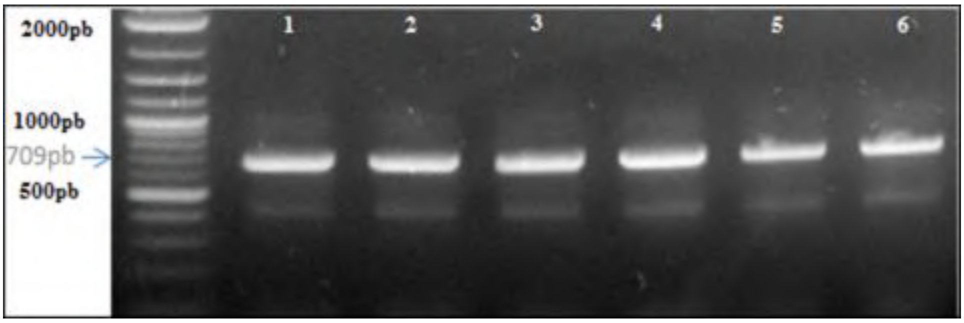

Figure 1. Polymerase chain reaction products (709pb) were amplified using universal primers set: LCO1490F-HCO2198. PCR products were separated in a 1% agarose gel and stained with ethidium bromide.

The partial sequence of the mtCOI (709bp) of *A. gossypii*, *A. spiraecola* and *P. persicae* generated in this study were compared between them. The results of our molecular analysis based on the mtCOI region revealed that in term of species identification the use of mtCOI gene enabled rapid and effective identification between the three species. The two species of Aphidinae subfamily (*A. gossypii* and *A. spiraecola*) were identified in a neighbor-joining tree. Their mean interspecific sequences divergence was 6.4% with a range of 5.8% to 7%. Mean nucleotide sequence variations between subfamilies (Aphidinae and Lachnidae) was significantly high (10%) with a range of 9.4% to 10.6%. The phylogenetic tree was made to compare the studied aphids' population shown in Fig 2 demonstrated that the aphid samples used in this study were divided in three distinct and robust clades. *A. gossypii* populations were clustered together with mtCOI partial gene marker of several *A. gossypii* worldwide populations. In the same way *A. spiraecola* samples collected from hibiscus, citrus, zucchini, pepper and potato were grouped in a single cluster with *A. spiraecola* species from several parts of the world. A third cluster grouped sequences of the studied *Pterochloroides persicae* with other populations collected overseas.

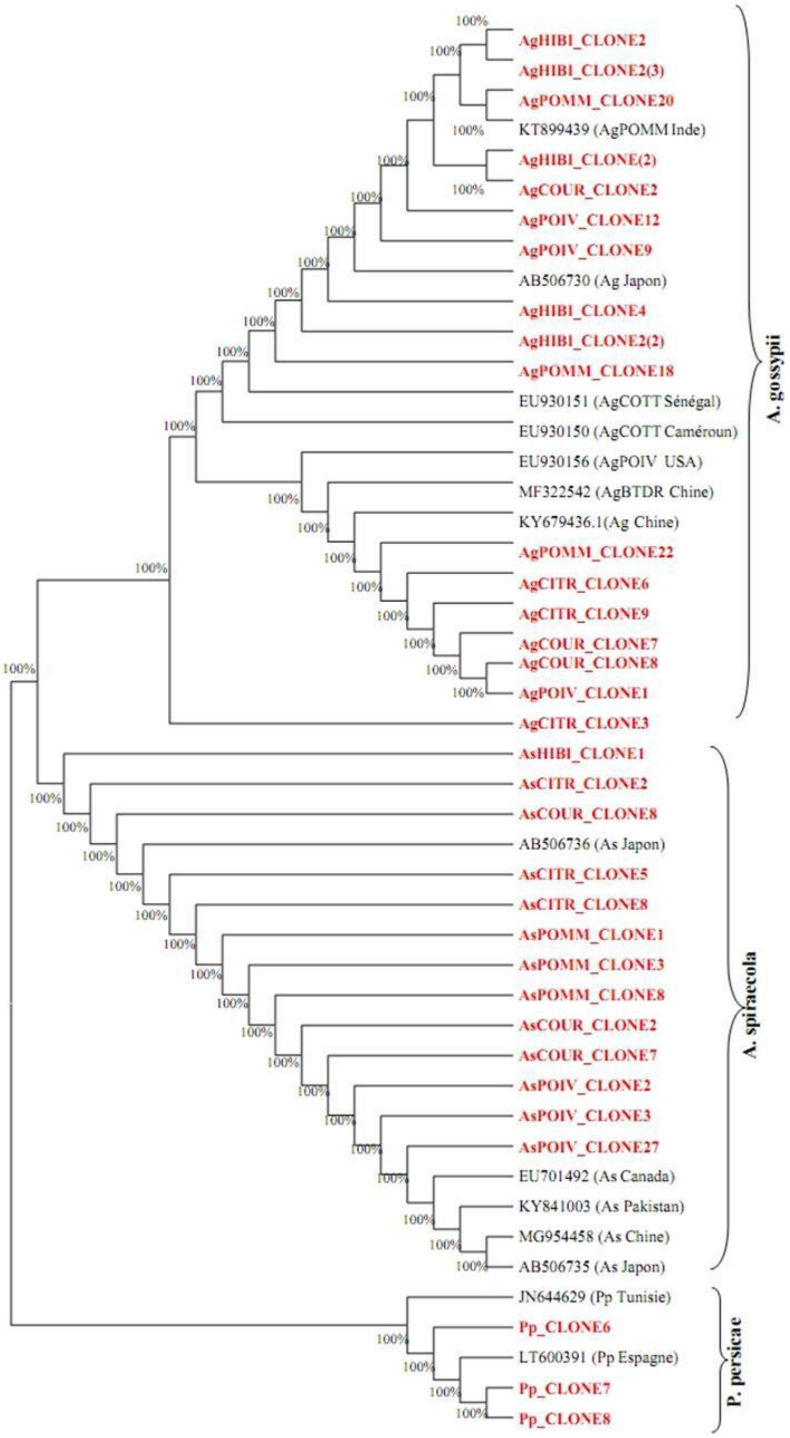

Figure 2. Neighbor-Joining phylogenetic tree depicting evolutionary relationships among various populations of *A gossypii*, *A spiraecola* and P persicae collected at Chlef valley based on analysis of a 709 bp mitochondrial cytochrome c oxidase subunit I – COI DNA fragment.. Evolutionary analyses were conducted in MEGA7

Comparison of the mtCOI sequences from 17 populations of *A. gossypii* collected from five different host plants showed that there were a little nucleotide variation among them, confirming a relatively recent divergence as reported by various researchers (Lee *et al.*, 2015; Lokeshwari *et al.*, 2015; Chen *et al.*, 2013; Komazaki *et al.*, 2010, Carletto *et al.*, 2009). Sequence identity matrix of mtCOI sequences of *A. gossypii* and *A. spiraecola* populations showed a very few nucleotide divergence between the studied population (data not shown).

However intraspecific variations within species was very low, *A gossypii* and *A. spiraecola* populations showed only 00% to 0.3% and 00% to 0.9% of nucleotide variation respectively. We suggest that intraspecific identification requires other molecular tools, either nuclear or mitochondrial markers in addition to biological assays such as host transfer experiments.

Conclusion

In the present study, we have shown the utility of the mitochondrial cytochrome oxidase mtCOI gene as a molecular marker distinguishing different species of aphids. This is the first time in Algeria that this molecular technique has been used for aphid species identification. Although this molecular tool has demonstrated a high reliability for interspecific aphid's identification, it couldn't decipher intraspecific variations between different populations of *A. gossypii* and *A. spiraecola* collected from various host plant. We considered the work as pioneer trial of molecular identification of aphid species. It will help to solve taxonomic ambiguity of *Aphis* genus populations present on crops of the valley leading in one hand to precise determination and thus adequate sustainable management strategy, and in the other hand allows prompt and reliable identification of alien aphis species that can be of great economic importance.

Abstract

Birdsfoot trefoil (*Lotus corniculatus* L.) is a species adapted to field conditions in the most important livestock production region in the all continents and constitutes a very valuable forage species. It has a high ability to utilize nutrients and has very modest demands on the conditions of its growth. The roots of birdsfoot trefoil are associated with bacteria that fix atmospheric nitrogen and, thusly, its populations increase the availability of nitrogen in the soil. This species often forms dense, fibrous root networks that reduce soil erosion. Isolation of the pathogen was done from the leaves and roots. Black leaf spots were observed on birdsfoot trefoil in field plots in Serbia. These spots were circular to irregular. Single lesions often coalesced to form larger lesions and became dark brown. On the roots systems of a large number of plants birdsfoot trefoil symptoms of light to dark brown necrosis and discoloration of conductive tissues were observed. There has not been a systematic research of birdsfoot trefoil mycoflora in Serbia. This research aims to present the results of preliminary research of mycopopulation of 12 different genotypes of birdsfoot trefoil. Total of 480 plant parts have been examined and 7 genera of fungi were isolated: *Alternaria*, *Fusarium*, *Phythophthora*, *Mucor*, *Sclerotinia*, *Bipolaris* and *Rhizoctonia.* Considering the importance of birdsfoot trefoil as a fodder crop in Serbia, the aim of this study was to identify phytopathogenic fungi as casual agents of diseases in birdsfoot trefoil for a clearer perception of problems (the extinction of plants, reducing yields, deterioration of the quality of feed and others) arising as a result of the presence of those fungi.

Key words: *birdsfoot trefoil, fungi, mycoflora.*

Introduction

Birdsfoot trefoil is a widespread plant throughout the world. It originates from Western Europe and North Africa. Birdsfoot trefoil is a very valuable fodder crop that has an important place in our country. It can be cultivated as a single crop or mixed with other crops and used for grazing or for conservation in the form of hay or silage. In addition to being cultivated as a single crop, birdsfoot trefoil has the most important place in grass-leguminous mixtures in the establishment of planted grasslands (Vučković et al., 2010). Birdsfoot trefoil is a plant that thrives on all types of soil, whether sour, lime, sandy, clay or salty. It grows on low quality soils that are not favorable for alfalfa (Vučković et al., 2010).

There are small requirements for soil acidity (Petrović et al., 1996). Birdsfoot trefoil hay contains an average of 18% of crude protein. Birdsfoot trefoil does not cause bloat in ruminant animals (Vučković et al., 2010). The Birdsfoot trefoil is distinguished by its high digestibility and ability to utilize nutrients and very modest requirements considering the conditions of its growth, especially the soil (Petrović et al., 1996). Due to the developed symbiotic bacteria at the root, significant quantities of nitrogen can be fixed annually, which according to some authors exceed 200 kg/ha (Vučković et al., 2010).

Phytopathogenic causative agents of birdsfoot trefoil disease can be present year after year. They are of different intensity and can cause significant losses in yield and the quality of hay. Diseases can limit persistence of *Lotus* spp. in production systems. Several pathogens are involved in a ''diseases complex''. Nevertheless, little is known about diseases and their impacts, both in the world and ours. Fungal pathogens are the most prevalent organisms and according to the plant tissue they can affect, diseases are classified as follows.
The genus *Epicoccum* was reported in Argentina as a seed pathogen in *Lotus* spp. (Sisterna and Lori, 2005). Also, *Epicoccum nigrum* in Argentina was cited as a causative agent of brown leaf spot of birdsfoot trefoil (Colavolpe et al., 2018).
Fusarium wilt (caused by *Fusarium oxysporum* f. sp. *loti*) is a serious disease of birdsfoot trefoil, reducing yield of forage and seed (Miller-Garvin et al., 2011). Similarly, inducers of diseases such as *Rhizoctonia solani*, *Cercospora medicaginis*, *Sclerotinia trifoliorum*, *Stemphylium botryosum*, *Verticillium albo-atrum*, as well as species of genus *Phytium*, *Leptosphaerulina*, *Phoma*, *Fusarium* and *Alternaria*, are significant disease agents in birdsfoot trefoil as a fodder crop, spread in all the areas of its production (Villegas-Fernández and Rubiales, 2011; Sillero et al., 2014, Vasić, 2015, Vasić, 2017). If care is not taken, the disease can cause serious damage to birdsfoot trefoil seedlings.
Considering the importance of birdsfoot trefoil as a fodder crop in Serbia, the aim of this study was to identify phytopathogenic fungi as casual agents of diseases in birdsfoot trefoil for a clearer perception of problems (the extinction of plants, reduction of yields, deterioration of the quality of feed and other) arising as a result of the presence of those fungi.

Material and methods

For the mycopopulations study, samples were collected from the experimental plant genotypes of birdsfoot trefoil (*Lotus corniculatus* L.) originating from Serbia, from the Rasina region (Gaglovo 1 and 2, Globoder 1, 2, 3, 4, 5, 6 and 7), Mačvanski region (Svileuva 1 and 2) and Pomoravski region (Gložane). The samples were collected between Mart and June 2016-2017 at the location of the Institute for forage crops in Globoder. Parts of plants are carefully washed under running water. After washing, the parts of stem and roots are cut to piece of 0.5-1 cm in size. Prepared samples of roots and stems were disinfected with 96% ethanol for 10 seconds and with 1% sodium hypochlorite (NaOCl) for 1 minute and then washed three times in sterile distilled water. They were then dried on sterile filter paper and placed on potato dextrose agar (PDA) with streptomycin. Five pieces of the plant parts (roots and tree) were placed in each Petri dish in four replications. They were kept in a thermostat at 25°C in 12 h light / 12 h night regime. The observations were performed every 3 days, and the majority of mycelium samples were developed up to 14 days. Developed mycelia were screened to a new PDA substrate and, after an initial grow, the peak part of the mycelium was reseeded on PDA again.
Microscopic examination was performed using microscopes Olympus CX31. Morphological identification of fungi to the genus was carried out using a standard key. Calculated by the frequency of isolation in % according to the formula Vrandečić *et al*. (2011):

$$\text{(\%) Isolation frequency} = \frac{\text{Number of segments containing the fungal species}}{\text{Total number of segments used in the isolation}} \times 100$$

Results and discussion

In the study of mycopopulations of birdsfoot trefoil genotypes, total of 480 plant parts were analyzed. Fungi were isolated on all plants from birdsfoot trefoil, and there were clear symptoms on stems in the form of spots and necrotic lesions. Fungi from genus *Alternaria*, *Phythophthora*, *Fusarium* and *Rhizoctonia* were isolated from these plants. Also, in small number of plants, there were necroses with white airy mycelium in the lower third of stems and fungi from the genus *Sclerotinia* and *Bipolaris* were isolated from those plants. Also, saprophytic fungi from the genus *Mucor* were isolated (Table 1).

Table 1. *Frequency of fungal isolation on Lotus corniculatus* L.

Genotypes	***Number of samples***		***Fungi species - stem***	***(%) Isolation frequency***	***Fungi species - root***	***(%) Isolation frequency***
	Plant part - leaf	***Plant part - root***				
Globoder 1	20	20	*Alternaria* sp. *Fusarium* sp. *Phythophthora* sp.	15 10 25	*Rhizoctonia* sp. *Fusarium* sp.	40 35

Globoder 3	20	20	*Phythophthora* sp. *Alternaria* sp. *Mucor* sp.	25 20 40	*Fusarium* sp.	85
Globoder 4	20	20	*Alternaria* sp.	35	*Rhizoctonia* sp.	65
Globoder 5	20	20	*Fusarium* sp. *Rhizoctonia* sp.	25 10	*Fusarium* sp. *Rhizoctonia* sp.	65 20
Globoder 6	20	20	*Phythophthora* sp.	60	*Fusarium* sp. *Rhizoctonia* sp.	10 85
Globoder 7	20	20	*Alternaria* sp. *Mucor* sp.	40 15	*Rhizoctonia* sp.	75
Svileuva 1	20	20	*Rhizoctonia* sp.	35	*Fusarium* sp. *Rhizoctonia* sp.	25 70
Svileuva 2	20	20	*Fusarium* sp.	10	*Fusarium* sp. *Rhizoctonia* sp.	20 65
Gaglovo 1	20	20	*Alternaria* sp.	60	*Fusarium* sp.	75
Gaglovo 2	20	20	*Sclerotinia* sp. *Bipolaris* sp.	30 35	*Fusarium* sp.	85
Gložane	20	20	*Alternaria* sp. *Fusarium* sp.	15 35	*Fusarium* sp.	90

The symptoms of a light to dark brown necrosis on the root system of the plants were observed, and from these plants fungi of the genera *Rhizoctonia* were isolated. Discoloration of the conductive tissues of the root system was observed in a large number of plants, and from these plants, fungus of the genus *Fusarium* was isolated (Table 1).

Isolations were conducted in all the birdsfoot trefoil plants with clearly visible symptoms of the disease.

In these studies, there was a difference in the frequency of isolation of certain genera of phytopathogenic fungi in birdsfoot trefoil genotypes originated from different regions of Serbia. It has been observed that in birdsfoot trefoil genotypes that originated from the Rasina region, fungi of the genera *Alternaria*, *Rhizoctonia* and *Fusarium* were more frequently

isolated. While the genera *Sclerotinia* and *Bipolaris* were isolated in significant percentages on one sample originating in the Rasina district (Table 1). Likewise, genera *Fusarium* and *Fusarium* were more often isolated from genotypes originated from the Pomoravlje region. While in the Mačva region isolated fungi from the genus *Fusarium* and *Alternaria*.
The results indicate that birdsfoot trefoil is vulnerable to the attack of a large number of phytopathogenic fungi that can have a significant impact on reducing its yield and quality.
In all the plants, in which isolations were conducted, there were clearly visible symptoms of the disease present. In these studies, there was difference in frequency of isolation of some genera of phytopathgenic fungi in birdsfoot trefoil genotypes from three regions in Serbia. It was observed that in the genotypes that originated in Serbia, fungi of genus *Rhizoctonia*, *Fusarium*, *Alternaria*, *Phythophthora* and *Sclerotinia* were frequently isolated.
Birdsfoot trefoil are adversely affected by numerous fungal diseases leading to a steady reduction in the cultivated area in many countries. Crown and root diseases considered chronic diseases, causing plant death and losses of 60 to 80%. Typical symptoms are rot and wilt. The main Genus is *Fusarium* (*F. solani*,*F. oxysporum, F. vertillicioides* and *F. equiset*) (Sisterna and Lori, 2005). Stem and foliar diseases onse do not cause directly the plant death. They contribute to the progressive weakness of the plant through the effects on the basic metabolic processes. The reported pathogens are *Phomopsis loti* (blight) *Colletotrichum destructivum* (anthracnose), *Stenphylium loti* (leaf spot) (Vasić et al., 2016, Sisterna and Lori, 2005). Seed diseases they cause decrease in germination and damping off. Fungi genera present in the seed are: *Alternaria, Aspergillus, Bipolaris, Botrytis, Cladosporium, Colletotrichum, Culvaria, Epiccocum, Fusarium, Leptosphaearulina, Penicillium, Phoma, Phomopsis, Stemphylium* and *Verticillium* (Sisterna and Lori, 2005).
The *Fusarium oxysporum* isolates pathogenic to birdsfoot trefoil have a unique host range relative to other pathogenic *Fusarium oxysporum* tested; they cause severe vascular wilt on birdsfoot trefoil but not on alfalfa (*Medicago sativa* L.), red clover (*Trifolium pratense* L.), dry bean (*Phaseolus vulgaris* L.), or soybean [*Glycine max* (L.) Merr.]. *Fusarium oxysporum* f. sp. *loti* is only known to occur in USA (Miller-Garvin et al., 2011). Altier et al. (2000) showed that one cycle of phenotypic selection in the greenhouse using a composite of Uruguayan *Fusarium oxysporum* isolates increased the level of resistance to Fusarium root and crown rot in birdsfoot trefoil adapted to Uruguay. The Uruguayan *Fusarium oxysporum* isolates cause vascular wilt and root necrosis similar to the disease symptoms caused by *Fusarium oxysporum* f. sp. *loti*, but the wilt symptoms develop more slowly. The Uruguayan isolates of *Fusarium oxysporum* are primarily associated with disease development on mature plants, with disease symptoms and plant mortality becoming most severe in the second and third production years. *Fusarium oxysporum* f. sp. *loti* causes considerable plant mortality at the seedling stage Miller-Garvin et al. (2011).
Al-Jaradi et al. (2018) state the fungus of the genus *Alternaria* spp. causing various types of spots and blights on *Vicia faba, Pisum sativum* and *Vigna unguiculata.* Likewise, Coca-Morante and Mamani-Álvarez (2012) detected fungus from the genus *Alternaria* on *Vicia faba* plants in Bolivia. At three sites in Bolivia, *Alternaria* sp. were found during the vegetative growth of the plants. Problems appeared as isolated spots. Colavolpe et al. (2018) in Argenitina for the first time stated *Epicoccum nigrum* as causing a brown leaf spot of birdsfoot trefoil. On infected plants birdsfoot trefoil, yellow spot and black spots were spotted (Sisterna and Lori, 2005).

Conclusion

This paper presents the preliminary results of mycopopulations research in 12 experimental birdsfoot trefoil genotypes. Birdsfoot trefoil is an important forage crop and its importance as livestock feed is growing within our country. This research is the beginning of a more comprehensive study of phytopatogenic fungi on of birdsfoot trefoil. So far, there were no significant researches in this direction in Serbia, so the future researches related to birdsfoot trefoil will go in the direction of selection of genotypes with increased tolerance to fungal diseases.

Abstract

Grapevine cultivar "Prokupac" is officially recognized as Serbian autochthonous variety, It has a long history, tracing to the Middle Ages. This cultivar is used to be the most widespread variety in this part of Balkans and best-rated domestic Serbian wine at international markets. Survey of virus infection incidence in grapevine nurseries, was conducted at 14 location of Rasina district (Republic of Serbia), during 2018. The survey was conducted by Agricultural Service Krusevac, as authorized institution with a professional capacity included into a national phytosanitary system, for implementation of the system of control of prevention of fruit tree and grapevines pathogens (including export and import). It also controls the presence of pathogens in main nurseries. Total number of 17 samples was tested on presence of four viruses using ELISA: *Grapevine fanleaf virus* (GFLV), *Grapevine leafroll-associated viruses 1, 2* and *3* (GLRaV-1, GLRaV-2, GLRaV-3). The presence of GLRaV-1 was confirmed in one tested sample, and the presence of GLRaV-1, GLRaV-2, GLRaV-3 were also confirmed in one tested sample. Conducted investigation indicates deteriorated viral sanitary status of cultivar "Prokupac" and necessity for intensifying the clonal and sanitary selection program.

Key words: *Virus diseases, Prokupac, Autochthonous grapevine cultivar, ELISA*

Introduction

"Prokupac" is an old autochthonous grapevine (*Vitis vinifera L.*) variety originating in Serbia that belongs to *Convar pontica, Convarietas balcanica* (Bešlić et all., 2012). According to the literary data, besides Prokupac and other autochthonous varieties Smederevka, Plovdina and Začinak have been cultivated in this area since Roman Empire (3rd century B.C.) (Jiriček, 1923). In the past it had much greater significance than it does today. It is grown in Serbia, Macedonia and Bulgaria. The great value of this variety is reflected in the fact that it produces a wine of pink or red color. Grapes are also used for blending, but also for the production of lozovača (rakia made from grapes) and vinjak (a brand of brandy). The trend in wine production is changing and is looking for authentic and specific wines of a certain area, where autochthonous varieties play an indispensable role. In the last few years, work on the prevention of genetic resources and clonal selection of this variety has started, with the aim of its preserving and restoring cultivation on farms. A major problem in its spread is the lack of quality planting material, where by viruses play a significant role since they have a very detrimental effect on the growth and development of the vine (Walter and Martelli, 1998), and, among other things, to a considerable extent may affect the reduction of sugar and increase in acids in freshly crushed must (wine juice) (Besse et al., 2009; Borgo and Angelini, 2002), the reduction of photosynthesis (Bertamini et al., 2004) and, in general, the reduction of grape yields, delay in vegetation and ripening, affect the chemical composition and aromatic profile of must, reduced reception of the rootstock and graft stem and poorer rhizogenesis. Their harmfulness is further enhanced by the fact that as obligate biotrophic

parasites, their development and reproduction requires host living cells, and thus cannot be eliminated by conventional chemical methods (Juretic, 2002).
The aim of this study was to determine the health status of the Prokupac variety in terms of infection with economically the most harmful and the most widespread grapevine viruses by using the ELISA method.

Material and Methods

The research included 14 localities in the Rasina District in Serbia. When testing samples were selecting, those with good viticultural characteristics and satisfactory exuberance were selected which did not show any visible signs of viral infections (leaf curl and deformities, purple color on leaf face, etc.). Samples were collected during the 2018 vegetation resting phase. Sampling was carried out on the presence of the following viruses: Grapevine fanleaf virus / GFLV and Grapevine leafroll virus / GLRaV-1,2,3, in native plantations for the production of the stems of vines. For native plantations of the grapevine for the production of the stems in the gantry system, a visual inspection of all the grapevines in the nursery was carried out in accordance with the Rule Book and mandatory sampling of 10% of the native grapevines from which 1% of the collective samples are formed. A group of 10 adjacent vines or from adjacent rows is selected from which every second (to be marked) is sampled and a group pattern is formed. The specimens contain five central parts of the stems 10-15 cm long. The specimens were packed in plastic bags, labeled and refrigerated at 4 ° C until testing and with the official order of the *competent service – Agricultural Service Kruševac* forwarded to an authorized first-stage diagnostic laboratory (Agriculturaal Service Smederevo), according to the procedure described in the Rule Book on crop health inspection and planting material production facilities (Dulić-Marković, 2008).
Commercial ELISA kits were used in their analysis, and all steps of the analyzes were performed in accordance with the test manufacturer's recommendations. Each sample was tested by ELISA for the presence of four viruses:
- Grapevine fanleaf virus, GFLV,
- Grapevine leafroll-associated virus 1, GLRaV-1,
- Grapevine leafroll-associated virus GLRaV-2,
- Grapevine leafroll-associated virus 3, GLRaV-3.

The following antibody double antibody sandwich ELISA, DAS-ELISA for GFLV, GLRaV-1, GLRaV-2, GLRaV-3 was used for virus presence testing. Monoclonal antibodies were used in GLRaV-2, while polyclonal antibodies and serums were used for other viruses.

Results and Discussion

The conducted analyzes determined a low level of infection of the variety "Prokupac" in the area of Rasina District, Republic of Serbia. Of the 14 samples tested, the presence of GLRaV-1 was detected in one sample, while the presence of GLRaV-2, GLRaV-3 and GFLV was not present in the samples tested. It should also be pointed out that monoclonal antibodies were used in the detection of GLRaV-2, so the possibility of this virus is slightly higher than determined by the conducted research. The main vectors of both GLRaV-1 G and LRaV-3 are in the production of vineyards except humans also the use of infected planting material and different varieties of scale insects. Then the possibility that the plantation can be infected by viruses after vines planting cannot be excluded. From mixed infections, the presence of the combination of GLRaV-1 + GLRaV-2 + GLRaV-3 virus in one tested sample was determined.
The determined health status of native grapevines of the autochthonous variety "Prokupac" is similar to the results of the conducted research on other autochthonous varieties in the Rasina District. According to the research results (Miletaković and Jovanović, 2018) related to the

presence of GFLV, GLRaV-1, T GLRaV-2 and GLRaV-3 on a total of 17 samples in the native vineyard of the autochthonous variety "Smederevka", using the ELISA test, the presence of GLRaV-3 was determined in four tested samples (23.53%), while other viruses did not exist in the tested samples or mixed infections. The occurrence of GLRaV-3 was found in the mixed infection in this Study, so it can be concluded that the infection with this virus of the "Prokupac" variety is much smaller than the infection of the "Smederevka" variety. In both Studies, a large percentage of plants was free from all four studied viruses.

Conclusion

The results of this, as well as similar research, indicate the relatively good health of the native vines of our autochthonous varieties grown in nurseries in the Rasina District. In order to eliminate the presence of viruses in native plants of autochthonous vine varieties, a number of measures should be applied which individually cannot provide major effects. In the future, many varieties, including Prokupac, in order to produce certified planting material, it would be necessary to carry out the thermotherapy procedures and meristem culture to produce virus-free plants. Cured plants could show better production characteristics and thus become more interesting to both nurseries and grape and wine producers. All the above mentioned point to the need to intensify the program of clonal and phytosanitary selection for the purpose of production of certified planting material with the aim of preserving and revitalizing this very valuable perspective and autochthonous variety.

Abstract

Phytochemical screening of the crude ethanolic extracts of the aerial part (PA) and the subterranean part (PS) of the plant *Thapsia garganica* L. was carried out by TLC and GC/MS. The results of these phytochemical characterizations showed that the two parts (PA and PS) of the plant contain flavonoids, tannins, saponosides and alkaloids in the form of traces. The study showed that the plant did not contain anthocyanins and leucoanthocyanans. PA and PS are poor in coumarins and iridoids. Gallic tannins are present with significant intensity in both parts of the plant. Phytochemical tests showed the presence of glucosides. The CG-MS gave an idea about the composition of the crude extracts of this plant. Eight compounds were identified for the crude extract of PA and 5 compounds for the crude extract of PS. The major constituents for these extracts were: phytole, hexadecanoic acid, octadecanoic acid, hexadecanoic acid, erucylamide and 13-docosenoic acid amide erucamide. In order to highlight the bioinsecticide potential of the extracts of this plant, toxicity tests were carried out on the 5th instar larvae of the migratory locust by testing 5 doses for PS ranging from 100 to 3000 µg/larvae and 4 doses for AP ranging from 300 to 3000 µg/larvae. The results of the toxicity tests revealed an increase in mortality as a function of time. The ethanol extracts tested hadgood insecticidal activity with a dose-response relationship. The 100% mortality was obtained 4 h after treatment for PS and after 24 h for PA at the highest doses tested.

Key words: *phytochemical screening, biological screening, Thapsia gargarina.*

Introduction

Current methods of curative control against gregarious locusts use liquid insecticidal products whose active ingredients belong to organophosphorus, pyrethroid and carbamate family. These synthetic preparations proved to be both very effective on locust pests but also harmful to human and animal health. Insecticides cause a significant accumulation of active ingredient in the treated ecosystems, and contribute to the development of resistant insects (Barbouche et al., 2001). These environmental and health concerns highlight the need for new strategies to protect crops from insect infestation, that are more "environmentally-friendly" to the environment and human health (Nenaah et al. 2011 and Cespedes et al. 2015).
Many plant secondary metabolites have significant biological activity associated with the presence of alkaloids, iridoids, monoterpenes, sesquiterpene, lactones, di-and tri-terpenes, naphthoquinones, anthroquinones, coumarins, phenylpropanoids, flavonoids, and other types of phenolics.These compoundscan act as insecticidal, ovicidal, ovipositional deterrents, feeding deterrents and growth retardants to pests through acute toxicity, enzyme inhibition, and interference with the consumption and/or utilization of food. In insects. These compounds have different sites of action and different molecular targets when they interact with enzymes and metamorphosis processes (Selin-Rani, 2016 and Cespedes et al., 2006). Recent studies proved that essential oils, alkaloids and extract of some plants like *Calceolaria talcana* and *C.*

*integrifolia*are potent neurotoxic and giving symptoms similar to those produced by organophosphates and carbamates insecticides.
Research focusing on the modes of action of phenolic compounds has shown that their insecticidal and insect growth regulators activities are largely due to their anti-feeding and inhibitory effects on enzymes and metabolism as a whole (Muñoz, 2013 and Isman 2006). The extracts of many plants are a mixture of potentially bioactive substances whitch may act synergisticallyby combiningseveral effects: antifeedants, insect growth regulators, and inhibitors of pupation, emergence, malformations and enzymes (Cespedes et al., 2005 and Cespedes et al., 2015a). These mixtures possess an exceptional activity and can build promising sources of bioactive molecules for botanical insecticides (Cespedes et al. 2015b).
The present work is a continuation of our previous research on alternative natural compounds of chemical insecticides. Thus, the objective of the current study was to assess the bioinsecticidal effect of the crude ethanolic extract from the aerial part (AP) and the subterranean part (SP) of the algerian plant *Thapsia garganica* L. on the fifth instar larvae of the migratory locust *Locusta migratoria*. Also, this work, aims to search and identifiate the secondary compounds of this Apiaceae.

Material and methods

Plant material

The perennial Apiaceae, *T. garganica* was harvested on January 2013 in the region of Ain Derias, in the Wilaya of M'Sila-Algeria. This plant has been authenticated by Professor Keddad, phytopathologist at the High National School of Agronomy (ENSA), El-Harrach-Algiers.The harvest was made during the winter outside the flowering period. The sampling concerned the aerial (stems and leaves) and the subterranean (roots) of the plant. The plant, freshly harvested, was washed and dried in the dark at room temperature for about 4 weeks After drying, the spraying of the AP and SP in fine powder was made separately using "Moulinex" electric grinder "Moulinex". The obtained powders were stored in sealed glass dishes.

Insect rearing

Mass rearing of *L. migratoria cinerascens* was carried out in the laboratory according to the method of Pener et al. (1989), using adults collected in the field in the Adrar region, Algeria. Larvae were held in 45 X 50 X 50 cm cages at 30-32 °C, 50-70% RH, and under a 12 h:12 h, L:D photoperiod. Locusts were fed an *Avena sterilis* based diet, complemented with wheat germ.

Preparation of crude ethanolic extract, phytochemical screening and GC–MS analysis

The crude ethanolic extract of the aerials and the subterraneanparts of *T. garganica*was prepared by macerating the powder for 3 days in ethanol, followed by filtration and evaporation at 40°C. The dried extract was kept at 4 °C until further use. The ethanolic extract was tested for plant secondary metabolites, alkaloids, phenolic compounds, flavonoids, saponins, tannins, iridois and coumarins. Phytochemical screening of the extract was carried out according to the standard method of Dohou et al. (2003). Visible color change or precipitate formation was taken into consideration for presence (+) or absence (-) of particular active constituents.
The crude alkaloids extract of *H. tuberculatum* was analyzed for its composition by GC-MS. The GC-MS analysis was carried out using on a Agilent Technologies 7890A gas chromatograph instrument connected with the Agilent 5957C operating in the EI mode at 70 eV, using a DB-5 capillary column (30m×0.25mm, 0.25 µm film thicknesses). The temperature program was 40◦ (1 min) 280 °C at a rate of 5 °C/min. Injector and transfer line temperatures were 280 °C. Helium was used as carrier gas, flow rate of 1mL/min, split ratio, 1:100; injection volume 1µL. The identification of individual constituents was based on the

comparison of their retention indices (retention time's relative) in relation to those to those of authentic samples and matching spectral peaks available with Wiley, NIST and NBS mass spectral libraries.

Insecticidal bioassays against fifth instars larvae

Bioassays for insecticidal activity, for the two extracts (AP and SP), against the fifth instars larvae of *L. migratoria* were carried out using four concentrations for AP extract :
300, 700, 1500 and 3000 μg/larvae. Five concentrations were tested for SP extract : 100, 300, 700, 1500 and 3000 μg/larvae. Appropriate amounts of each of the test compounds were dissolved in ethanol. For treatment, newly emerged larvae fifth instars (0–12 h post emergence) were treated by forced feeding of an insecticide solution (50 μL/larvae) using a micropipette, without anesthesia. Controls were given absolute ethanol only. Thirteen larvae were used for each concentrationand three replicates were done for treated and control larvae for the two tested extract. Percentage mortalities were determined for each treatment. The LD_{50}, the concentration that produces 50% mortality, was determined by Log-probit analysis.

Statistical analysis

Results are expressed as means ± standard deviation (SD). To identify significant effects of the treatments on the variables measured, data were submitted to a monofactorial ANOVA using XLSTAT 7.5.2. Means were compared using Tukey's HSD test (P< 0.05).

Results and discussion

Preliminary phytochemical screening

The results of the preliminary phytochemical composition of the different parts of *T. garganica*by chemical sceening are shown in table I. It's noticed that both extracts (AP and SP) of *T. garganica* contain flavonoids, tannins, saponins as well as alkaloids. These compounds may play a role in insecticidal activity. The preliminary study shows that the plant does not contain antocyans and leucoantocyans. The two extracts are thus poor in comarins and iridoids.

The tannins are present with a high intensity in both parts of the plant. Their presence is confirmed by a positive reaction with the ferric chloride solution giving a greenish blue color for the aerial part and black blue for the subterranean part, so it is gallic tannin. Phytochemical tests have shown, also, the presence of glucosides in this plant.

Table 1. Qualitative phytochemical screening of the crude ethanolic extract of the aerial and subterranean parts of *T. garganica*.

	Alkaloids	Anthocyans	Coumarins	Tannins	Saponins	Irridoids	Flavonoids	Glucosides
A P	+	-	-	+++	+	-	++	+++
S P	++	-	-	+++	+	+	+	++

GC–MS analysis

The GC-MS analysis spectra of the identified compoundsof the two extracts are represented by the below figures and tables.

The CG-MS gave an idea about the composition of the crude extracts of this plant. Eight compounds were identified for the crude extract of AP (Fig. 1 and Table II) and five compounds (Fig. 2 and table III) for the crude extract of SP. The major constituents for these extracts are: phytole, hexadecanoic acid, octadecanoic acid, hexadecanoic acid, erucylamide and 13-docosenoic acid amide erucamide. In addition to these compounds, other cyclic form constituents (at 4, 5 or 6 carbons) linked to sugars are identified (as : L- arabitol, pentakis (trimethylsilyl, Arabinofuranose, 1,2, 3, 5- tetrakis-O- (trimethylsilyl). They are certainly glycosylated flavonoids which are poorly identified by the database of this GC-MS.

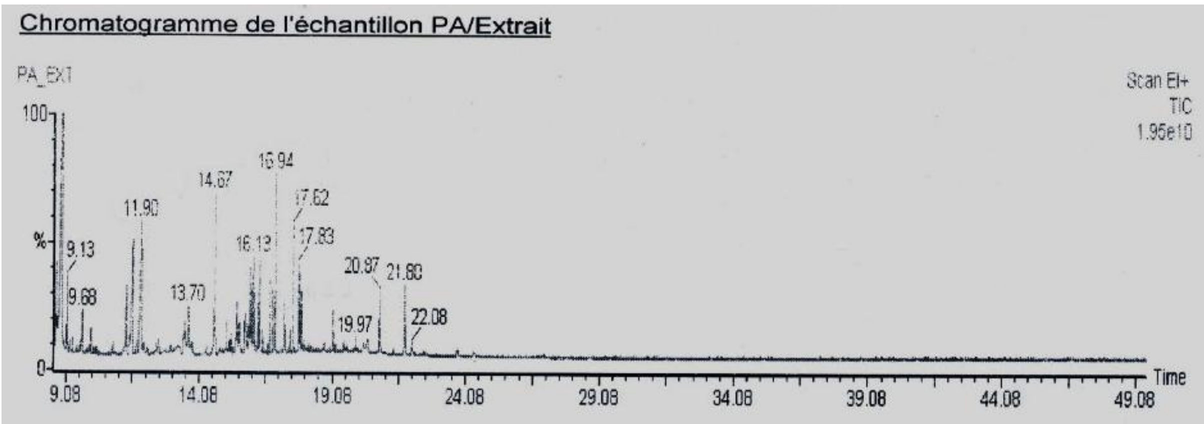

Figure 1: GC-MS chromatogram of the crude extract of aerial partof *T. garganica*

Table 2: Identified compounds by GC-MS for aerial part extract of *T. garganica*

Retention time (mn)	Name of identified compound	Crude chemical formula
8.86	N, O-BIS-(trimethylsilyl) isoleucine	$C_{12}H_{29}O_2NSi_2$

20,45	Erucylamid, 13- docosenoic acid amide - erucamide	$C_{22}H_{43}ON$

Insecticidal activities

From the obtained results (figures 3 and 4), it appears that both parts of the test plant showed larvicidal activity against the five instar larvae of *L. migratoria*. This activity increases with concentration and exposure period. The insecticidal effect of SP was more potent than that of PA.

The results indicate that the cumulative rates mortality on the all treated larvae with extracts from both of the two parts of the plant are significantly higher than those of controls. Regarding the high dose of 3000 µg/larvae (Figs 3 and 4), the 100% of larvae mortality was obtained 4 hours after treatment for SP extract and after 24 hours for PA extract. For the dose of 300 µg/larvae, cumulative mortality rates exceeding 50%, and 70%, respectively for AP and SP, 72 hours after treatment were obtained.

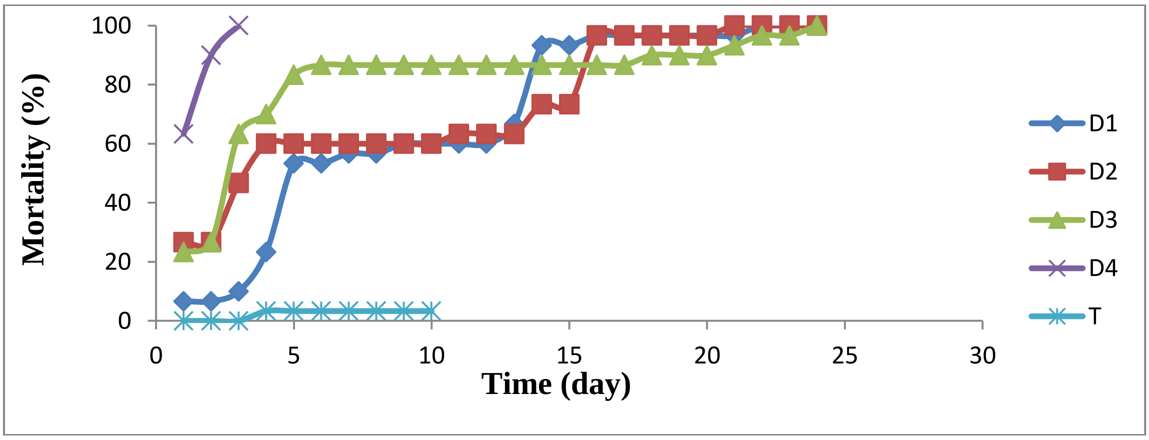

Figure 3: Mean mortality kinetics of *L. migratoria* five instars larvae treated and control with the crude extracts of the aerial part (AP) of *T. garganica*. N=10/replicate

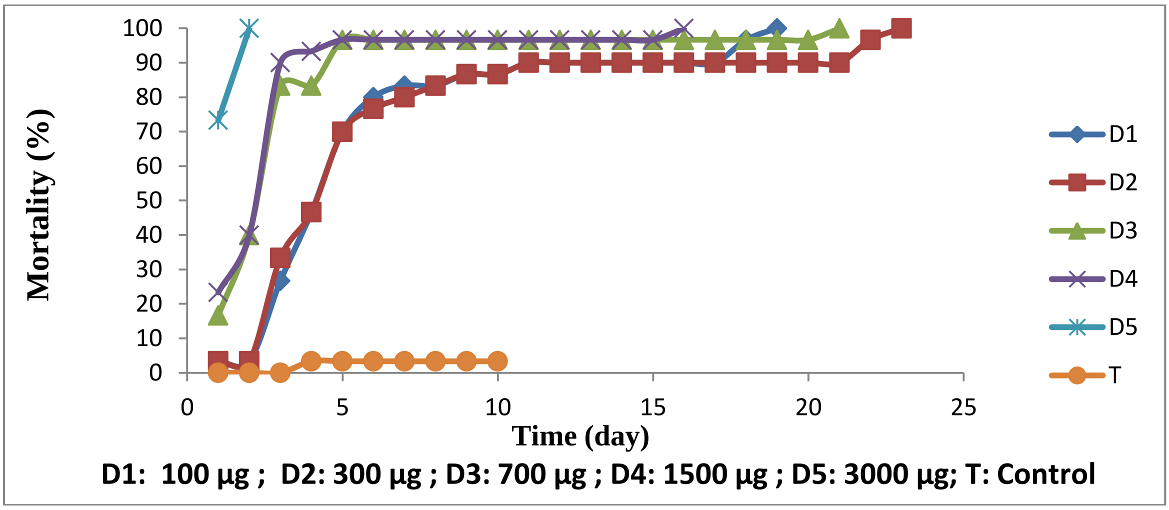

Figure 3: Mean mortality kinetics of *L. migratoria* five instars larvae treated and control with the crude extracts of the subterranean part (SP) of *T. garganica*. N=10/replicate.

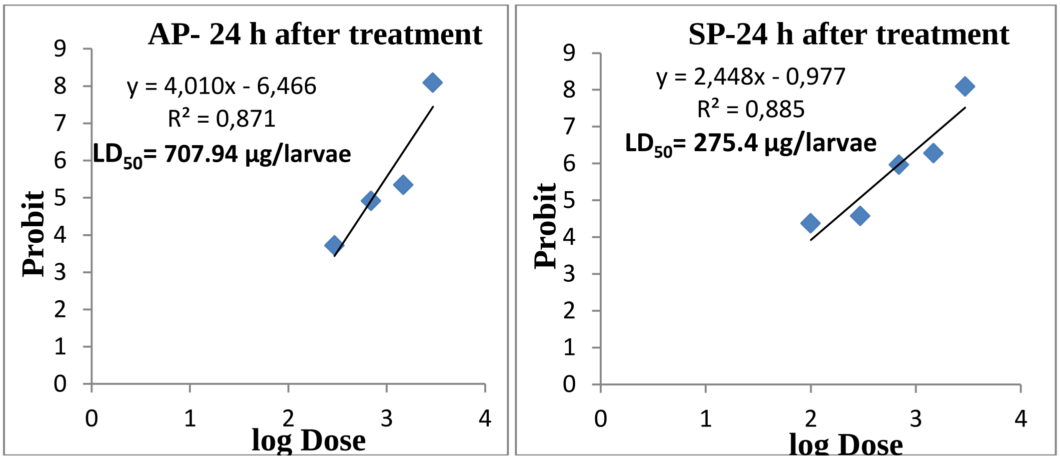

Figure 4. Effect of the crude ethanolic extract of AP and SP of *T. garganica* on the five instars larvae of *L. migratoria* 24 h after treatment, (Mean ± SD). N = 10 insects/replicate.

The LD_{50} calculated 24 h after treatment of the L5 larvae were 708 and 275 µg/larvae respectively for the AP and SP crude ethnolic extract of *T. garganica*(Fig. 4). Therefore, the extract of SP is more toxic than AP.

Effect on behavior

Behavioral observations were carried out from the first hours following treatments until moulting or death of treated larvae.After treatment, the treated larvae with crude extracts of *T.garganica* showed animmediate behavior effect, which resulted in disturbances and incordination of the movements. This state lasts 15 to 30 minutes, followed either by the death of the larvae (high doses) or by athe resumption of activity (low doses). In surviving larvae, a delay in growth and molting was observed. Moreover, these larvae have difficulties to moult and they remain encapsulated in their old exuvia for the two extract (Fig 5 A and B). Others have abnormalities in molting deformations of wings, and legs (Fig 5 C and D).

(A) (B) (C) (D)
Figure 5. Effects of crude extracts of *T. garganica* on growth and molting of the five instar larvae of *L. migratoria*

Plants represent a rich source of bioactive molecules or secondary metabolites that can affect growth, development, behavior, and act as antifeedants, toxins or growth regulators. These natural molecules can replace conventional insecticides and appear to be able to solve the environmental problems caused by synthetic pesticides (Campagne et al., 1992 in Kim et al., 2005). Phytochemical study of the crude ethanolic extract of AP and SP indicate that *T. garganica*contain flavonoids, tannins, saponins as well as alkaloids. Our results are in agreement with fhose obtained by Bouimeja et al., (2018) who report that quantitative colorimetric analysis showed an important amount of polyphenols, flavonoids and condensed tannins. For our plant, major constituents identified by GC-MS, for these extracts are: phytole, hexadecanoic acid, octadecanoic acid, hexadecanoic acid, erucylamide and 13-docosenoic acid amide erucamide. Christensen *et al.*, 1984 and Smitt and Christensen, 1991 report thatthe main constituents in the roots as well as in the ripe fruits are thapsigargin I and thapsigargicin II, whereas nortrilobolid III, thapsivillosin J IV and thapsivillosin I V were found as minor constituents. The crude ethanolic extract of *T. garganica* administered by forced ingestion to the last instar larvae of *L. migratoria* at different doses showed a good insecticidal action of the two tested extracts.Effect of SP extract was more powerful than that of AP extract. Indeed, for SP extract, all the doses showed high % mortality on the first days after.The total death (100 %) of larvae was obtained 2 day after treatment. For the AP extract, the effect of the D5 (3000 µg/larvae)was also potent, the total death of larvae was noticed third day after treatment. Botanical insecticidesare expected to be possible alternatives to the traditional chemicalinsecticides. The neem products were recommended by several researches asalternatives to the currently used harmful pesticides for the control of desert locust (Krall and Wilps, 1994). In their study, Mansour et al.,(2015) indicate that the essential oils extracted from ten different plants belonging to five families tested against the 3rd nymphal instars of the desert locust, S*chistocerca gregaria* (Forskål) (Orthoptera: Acrididae) by topical application, the *Allium cepa*oil proved to be the most toxic followed by the *Petroselinum sativum*. In another study Mansour and Abd El Hamid (2015), Cumin *(Cuminum cyminum)* oil was the highest toxicto the nymphs, while Parsley *(Petroselinum sativum)* was the lowest. They also noticed that Sweet Basil oil decreasedseverly consumption index, efficiency of conversion of digested and ingested food. The rapid effect aof plan extract or phytochemicals against some pests isindicative of a neurotoxic mode of action and there is evidence forinterference with the neuromodulator octopamine or GABA-gatedchloride channels (Priestly et al., 2003; Enan, 2005; Rattan, 2010).
Crude ethanolic extract of SP and AP of *T. garganica* showed, also,molting and growth disturbances at low doses. As our results, Kabir et al., (2013) report that, crude ethanolic seed extractof *Seseli diffusum*, at lower concentration of 100 ppmand 200 ppm, induced a high level of morphological deformities in 4th instar larvae and pupae. These disturbances may be related to a possible interference with hormones governing moulting.

Conclusions

Phytochemical ssreening of the algerian plant T. gatganica revealed the presence of flavonoids, tannins, saponins and glucosides in both parts of the plant as well as the presence of traces of alkaloids. The GC / MS analysis of the of the two parts of our plant allowed to identify eight compounds for the crude extract of the AP and five compounds for the SP extract. The major constituents for the crude extracts are: phytole, hexadecanoic acid, octadecanoic acid, hexadecanoic acid, erucylamide, 13-docosenic acid amide erucamide. Insecticidal activity of the two crude extracts of *T. garganica*se are shown to be active against larvae of the 5^{th} instar of *L. migratoria*. The maximum efficacy (100% of mortality) was observed for the higher dose (3000 µg/larvae) after 24 hours for the AP extract and after 4 hours for the PS extract.These encouraging results suggest the possibility of use of the extracts of this plant in integrated locust control programs. However, further studies on characterization of bioactive compounds, mode of action, formulations, field trials and impact on non-target fauna are recommended.

AMARANTH GRAIN AS ENRICHING INGREDIENT FOR BAKERY TECHNOLOGY

Anastasiia STAKHURLOVA*, Natalia DERKANOSOVA, Irina PONOMARYOVA

Voronezh State Agrarian University named after Emperor Peter the Great, Russia
*Corresponding author: Stahurlova.n@mail.ru

Abstract

Specialized and functional food technology development is able to smooth out a problem of essential elements deficit in populations diets. Bakery products is traditional for Russia – majority of people consume it every day, so its suitable product for enriching. For mass products enrichment it's often to use non-traditional, but perspective raw materials, which an amaranth is. Amaranth is rich with protein, minerals, vitamins, dietary fiber, squalene and other nutrients. At the same time, amaranth varieties are significantly differentiated in composition and properties. The purpose of the first stage of the study was comparing the composition of amaranth as a factor determining the indicators of the purpose of its processed products. 8 grades of amaranth grain were analyzed. According to the results of research, it is recommended to use Universal variety amaranth grain as enriching raw ingredients of multifunctional action. However, the adjustment of the food products composition, including bakery products through the introduction of enriching ingredients often leads to a change in traditional consumer properties of products - the shape, condition of porosity, color, taste and other organoleptic indicators. In this connection, as the second stage of research using flour from extruded amaranth was determining of some indicators - autolytic activity and acidity of dough. Results of study showed indicators increasing with makeweight of amaranth flour. 30% of additive non-traditional flour provides abnormal value of dough acidity, therefore that amount is critical.

Keywords: *amaranth, extrudate, enrichment, acidity, autolytic activity.*

Introduction

Currently, the problem of rational nutrition is one of the main factors determining the state of human health, its performance, and resistance to various adverse environmental factors. A decrease of the consumption of essential elements causes an increase in the number of diseases among the population. Therefore, the problem of maintaining public health is closely related to the production of biologically complete and safe food products. Lately, the production and use of functional foods has become widespread, in particular, the enrichment of mass consumption foods with scarce nutrients (fiber, vitamins, protein, etc.) ((Ryabova, 2015)).

Bakery products undoubtedly belong to the traditional and mass - for example, previously, it was established (Derkanosova, 2015) that 65% of Voronezh residents consume bread products daily. Therefore, the adjustment of the recipes of bakery products may affect the nutritional status of the population.

The enrichment of bakery products is often carried out at the expense of rare, but promising in their properties plant sources. One of these plants is amaranth - an annual herbaceous plant of the amaranth family, with small flowers collected in lush panicle inflorescences. Due to the high content of essential amino acids, vitamin E, mono- and polyunsaturated fatty acids, the use of amaranth in food helps stimulate the immune system, detoxifies the body, and has an antimicrobial, anticarcinogenic and fungicidal effect (Saratovskiy, 2014; Tovar-Pérez, 2018; Coelho, 2018).

Amaranth is widely used in gluten-free diets due to the lack of gluten proteins in its composition. So, I.M. Zharkova and L.A. Miroshnichenko proposes the variable use of amaranth flour - in technologies of "gluten-free" bread, muffins, waffles, etc. (Zharkova, 2012; Zharkova, 2014). At the same time, its use is also effective as an ingredient for traditional baking - it is possible to enrich the product due to the high content of valuable substances in amaranth and preserve the organoleptic qualities familiar to the consumer. A number of researchers (Roslyakov, 2016) developed a technology for obtaining a new variety of bakery products - a loaf "Zebra" type with the addition of amaranth flour, with which the finished products acquire dietary properties. Amaranth attracts additional attention due to the possibility of complex use - for example, it is known to develop a method for producing food colors from the leaf mass of Valentine grade in two colors - green and cherry (Gins, 2015).
However, nutrition problems and dissatisfaction with the range of enriched foods leaves the development of technologies for enriching bakery products with amaranth relevant. Using non-traditional raw material in regular technology requires preliminary check of some characteristics. The aim of our work is identification the most optimal amaranth variety for the use in flour technology and determination the effect of its application on the flour mixtures acidity and autolytic activity.

Material and methods

Over 60 species of amaranth of fodder, food, medicinal and decorative purposes are cultivated in different countries (Saratovskiy, 2014), and, accordingly, the composition of amaranth grain differs significantly depending on the grade. Therefore, preliminarily it was analyzed 8 grades of amaranth of the Voronezh selection and selection of the FSBSI "Federal scientific center of vegetable growing": Voronezh-36, Voronezh, Emperator, Rubin, Universal, Gigant, Dobrynya and Valentina. Amaranth was grown in a collection nursery of Voronezh State Agrarian University. By geographic location, the nursery is located in the forest-steppe zone of the Central Chernozem Region. The soil of the experimental plot is leached medium loamy chernozem. The availability of its mobile forms of nitrogen, phosphorus and potassium is medium and high. Humus content is equal to 4.5%, pH is fluctuated from 5.4 to 5.8. The total rainfall for a period with a temperature above +10 ° C is 250-260 mm. The total amount of active temperatures is 2581° C. Sowing was carried out in the second half of May 2018.
The amaranth grain composition was determined by standardized methods at the accredited research center of the All-Russian Scientific Research Veterinary Institute for Pathology of Pharmacology and Therapy: mass fraction of moisture - according to GOST 13586.5-2015, protein - according to GOST 10886-91, fat - according to GOST 29033-91 , fiber - according to GOST 31675-2012, total sugar - according to GOST 15113.6-77, ash - according to GOST 27494-2016, phosphorus content - according to GOST 26657-97, calcium - according to GOST 26570-95, copper, zinc - according to GOST 30692-2000, iron, manganese - according to GOST 32343-2013.
Amaranth grain was extruded. The extrudate was obtained from whole semi-defatted grains of Amaranth variety Universal on a laboratory universal small-sized extruder (EUM-1). The extrusion temperature was 110-120 ° C. Then the extrudate was ground to granulometry 125 μm and less.
For dough analysis 12 mixtures of wheat flour (of highest and first grade) and amaranth flour were prepared. The method for determining the autolytic activity is standardized by GOST 27495-87 "Flour. Method for determining autolytic activity", for acidity - by GOST 27493-87 "Flour and bran. Method for determining acidity by a talker".

Results and Discussion

Comparative grain characteristics of the studied amaranth grades are given in tables 1 and 2:

Table 1. Composition of amaranth grain

Amaranth grade	Fraction content, %					
	moisture	protein	fat	cellulose	common sugar	ash
Voronezh-36	10.14	15.78	6.46	6.9	2.46	2.98
Voronezh	10.53	16.21	6.38	5.7	2.36	3.41
Imperator	10.19	19.57	11.71	7.5	2.36	3.99
Rubin	11.42	20.66	9.79	7.1	2.65	4.75
Universal	9.46	26.47	13.81	8.9	4.10	8.08
Gigant	10.14	19.29	10.29	7.1	2.94	3.03
Dobrynya	10.91	16.79	7.24	16.3	2.36	4.33
Valentina	11.60	16.10	6.94	19.4	2.55	6.04

Table 2. Composition of the mineral substances of amaranth grain

Amaranth grade	Content					
	phosphorus, %	calcium, %	copper, mg /kg	iron, mg /kg	zinc, mg /kg	manganese, mg /kg
Voronezh-36	0.46	0.17	8.62	108.4	32.54	51.89
Voronezh	0.54	0.24	7.23	76.5	35.80	55.14
Imperator	0.45	0.25	7.20	81.8	30.99	50.78
Rubin	0.55	0.17	6.06	73.4	30.82	50.62
Universal	0.63	0.36	12.98	90.0	30.89	44.88
Gigant	0.54	0.20	14.86	76.9	32.66	28.97
Dobrynya	0.50	0.36	8.11	72.4	28.19	46.72
Valentina	0.46	0.48	5.36	75.9	31.33	82.40

Based on the totality of indicators for further research, amaranth Universal was selected - a variety characterized by high productivity, valuable composition and predominant light grain color (Figure 1).

Figure 1 – Amaranth Universal grade

Due to small size of the grain and the presence of a dense hemicellulosic membrane on its surface, it needs an additional processing. As such process extrusion was selected. The big advantage of extrusion as a technological method is an increase in the degree of assimilation of the product. As a result of hydrothermomechanical processing, gelatinization of starch occurs, it is more easily hydrolyzed by enzymes and is better absorbed by the organism. Protein substances contained in raw materials, under the influence of hydrothermal treatment, are first denatured, and then plasticization occurs due to mechanical action. As a result, they

are better attacked by proteolytic enzymes, which increases the rate of digestion of protein substances by the human body (Ostrikov, 2007). Additionally, a decrease in the severity and softening of the aroma of extruded amaranth was noted in comparison with whole-ground grain.Autolytic activity characterizes the activity of flour α-amylase in the accumulation of water-soluble substances in a water-suspended suspension when it is heated in a boiling water bath and is used to determine the activity of α-amylase in flour. Then more active α-amylase of flour, then more water-soluble substances accumulate in it.
The results are shown in figures 2 and 3.

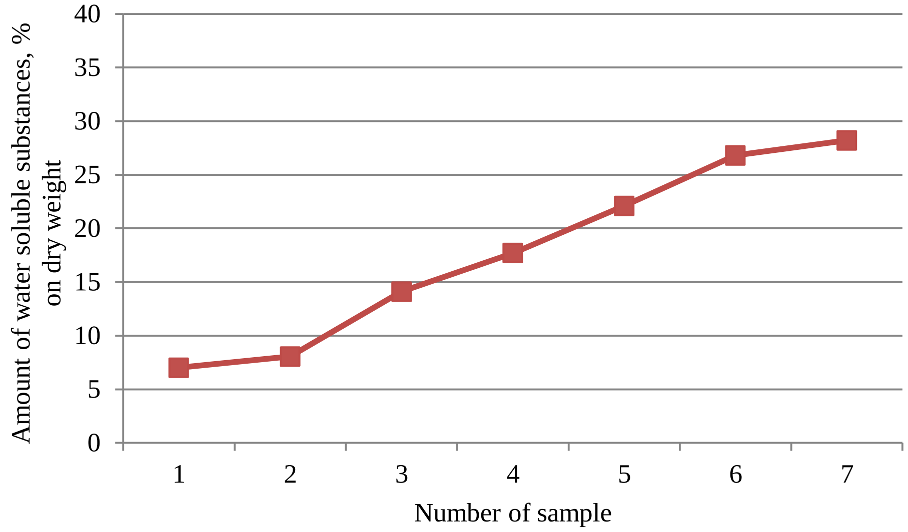

Figure 2 - Autolytic activity change depending on the dosage of extruded amaranth flour mixed with wheat flour of highest grade: no. 1 - without adding amaranth flour, no. 2 - with addition of 5% amaranth flour, no.3 – 10%, no.4 – 15%, no.5 – 20%, no.6 – 25%, no.7 – 30%

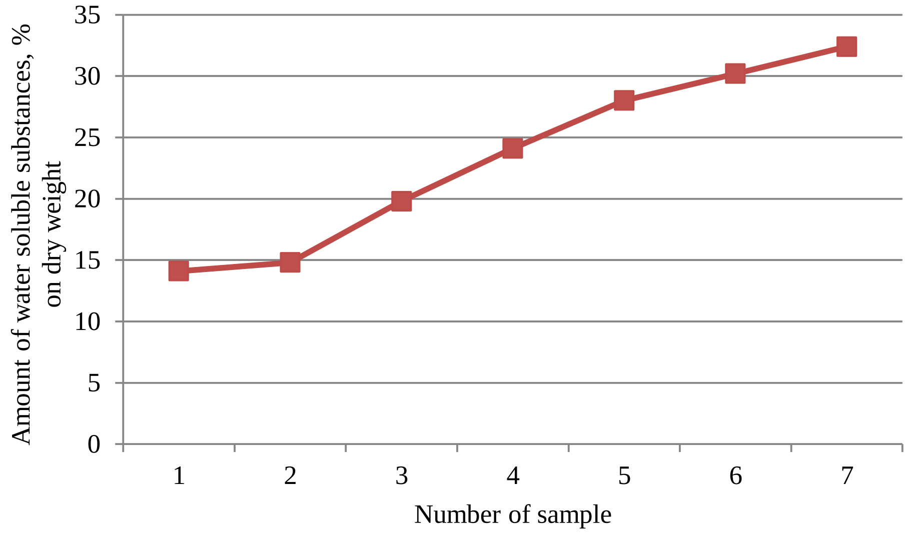

Figure 3 - Autolytic activity change depending on the dosage of extruded amaranth flour mixed with wheat flour of first grade: no. 1 - without adding amaranth flour, no. 2 - with addition of 5% amaranth flour, no.3 – 10%, no.4 – 15%, no.5 – 20%, no.6 – 25%, no.7 – 30%

Studies have shown a higher content of water-soluble substances in mixtures of flour of the first grade compared with wheat flour of the highest grade. An increase in the autolytic activity of flour was noted with an increase in the dosage of amaranth flour in it. However, it is rather difficult to draw an unambiguous conclusion about the increased activity of amylolytic enzymes of flour in the presence of amaranth extrudate. It is likely that the increase in water-soluble substances in model mixtures is associated with their presence in the extrudate. It is known that the extrusion process is accompanied by a partial destruction of biopolymers of grain raw materials with the accumulation of water-soluble substances. The acidity of flour has a serious effect on the quality of bread. The level of acidity of flour depends on its variety and the duration of storage - then lower the grade and then longer the storage period, then higher the acidity. The use of flour with high acidity leads to an increase in the acidity of dough and bread. The increased acidity of the flour leads to a higher initial acidity of the dough and faster accumulation of acids during fermentation. Bread from flour with high acidity is more acidic, with less developed porosity and a lower specific volume. The crumb at the bottom of the product may be compacted. The appearance of the crust worsens: the crust becomes bumpy, the color of the crust is brown. In the baking industry it is recommended to use highest grade of wheat flour with an acidity of 2.5-3.0 degrees; 1 grade - 3.0-3.5 degrees; 2 grades - 4.0-4.5 degrees.
The obtained values are presented in figures 5 and 6.

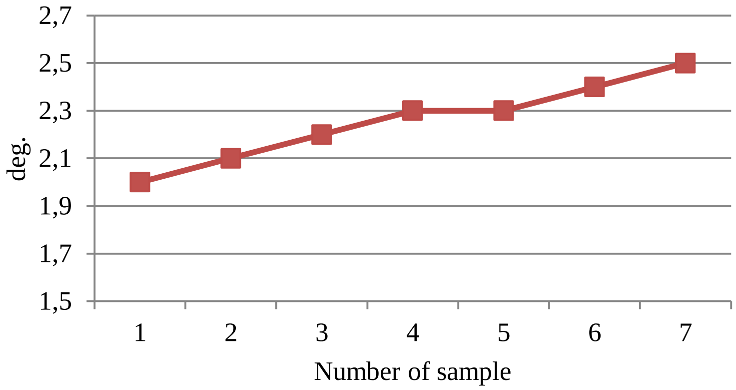

Figure 5 – Acidity change depending on the dosage of extruded amaranth flour mixed with wheat flour of highest grade: no. 1 - without adding amaranth flour, no. 2 - with addition of 5% amaranth flour, no. 3 - 10%, no. 4 - 15%, no. 5 - 20%, no. 6 - 25%, no. 7 - 30%

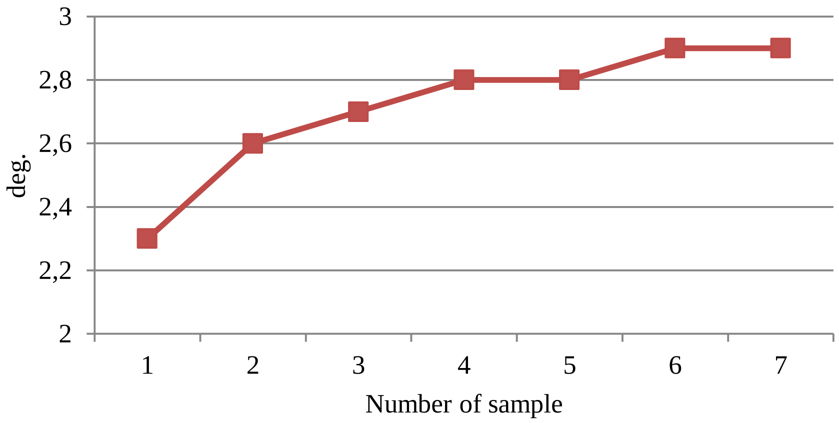

Figure 6 - Autolytic activity change depending on the dosage of extruded amaranth flour mixed with wheat flour of the first grade: no. 1 - without adding amaranth flour, no. 2 - with addition of 5% amaranth flour, no. 3 - 10%, no. 4 - 15%, no. 5 - 20%, no. 6 - 25%, no. 7 - 30%

An increase in acidity was noted with an increase in the dosage of amaranth flour in the mixture in both cases. At the same time, the acidity of flour mixtures with wheat flour of the first grade was naturally above than the highest.

Conclusion

In general, the studies conducted allowed us to draw the following conclusions:

- the addition of extruded amaranth flour of the Universal grade to the composition of bakery mixes affects the baking properties of flour ingredients - the amount of water-soluble substances and acidity increase;
- extruded amaranth flour has an identical effect on the baking properties of flour mixtures based on flour of the first and highest grade;
- increasing the dosage of extruded flour over 30% is impractical due to the achievement of critical values in acid mixtures for acidity and the content of water-soluble substances that affect the quality of bakery products.

Abstract

The exact quantification and concentration of vitamin C in fodder is of critical importance for the normal health of dairy cows that are susceptible to oxidative stress, just like humans. Studies have been carried out on vitamin C (ascorbic acid) of feed (alfalfa hay, concentrates for milk cows and wheat straw) from three farms in different regions used for feeding dairy cows and their milk. Based on the performed tests of the chemical composition of the feed, it was concluded that the total feed used was characterized by the best composition. The concentration of vitamin C was examined in extracts of feed and raw milk. Vitamin C was examined through colorimetric method, using a calibration curve of 2,4-dinitrophenylhydrazine and a spectrophotometer (Pharo 300-Merck spectroquant). The highest concentration of vitamin C was found in alfalfa hay, farm B (40.2 μg/ml), while in the raw milk it was mostly present in milk from farm A (2.8 μg/ml). From the above, it can be concluded that regardless of which farms the tested samples of feed and their milk are, higher values for the concentration of vitamin C are obtained in the samples of extracts of alfalfa hay. If we compare the vitamin C concentration in feed and milk, it is concluded that the raw milk values are much lower than the feed and even much lower than the pasteurized milk taken for standard (2.3 μg/ml).

Key words: *feed, alfalfa hay, concentrate, milk cows, vitamin C.*

Introduction

The need of animals for energy, proteins, minerals and vitamins is basically satisfied through basic foods (hay and straw), and feeding stuffs regularly used for eating cows represent a complement to the basic meal with easily digestible and usable nutrients (Andonov *et al.*, 2014). Classification of food was made very long ago (Popov, 1949). According to Morrison (1955), there are: fodder crops for pasture, for green foods, for grain, hay, silage, etc. Another division is made by Pribičević (1976), which divides food into eight groups, including the group of "green food" (free grasses, meadow plants and silage of their green plants), as and a group of "combined foods from the industry" (Egumenovski *et al*., 1998).

Lucerne (alfalfa) as a forage crop is characterized by a high content of raw proteins (18-22%) and raw fibers (25-35%). In addition to raw proteins, raw fiber, minerals and vitamins, alfalfa contain a large quantity of spoons that are not desirable for daily intake of animal nutrition (Animal Nutrition Group 2012, FAO 2000-2010). Lucerne (alfalfa hay) is a crop with high content of vitamins, and pro-vitamin A-carotene is particularly important (1 kg of green alfalfa has 30-1000 mg of carotene). Alfalfa contains high vitamins: B1, B2, C, E, K, H, and PP,investigated from Collins *et al*., (2014) and also on WebMD, LL (2017) found in their study that the chemical composition of different straw types is different.

Concentrates for dairy cows are mainly a source of lightly digested energy and proteins, but usually contain a large amount of minerals and other important nutrients, vitamins that cannot be met through rough beehives - fodder (Ishler *et al*., 2006, 2018). The milk mixtures for milk cows according to the chemical composition contain: water, raw proteins, various types of

carbohydrates, crude fiber, fats, minerals and vitamins (Ivanovski *et al*., 2011). The term vitamin has been introduced by Kazimir Funk (Egumenovski *et al*., 2011).
The vitamins in the diet is very important because the animal organism needs them to perform normal processes all the way.It is found in all green plants and fresh fruits. In fodder, it is found in fresh green food and silage. Vitamin C in the hay and grains, feeds it in small quantities because it during the drying and during the storage of livestock is lost. The physiological function of vitamin C is great because it participates in the synthesis and creation of many hormones, strengthens the immune system of animals, participates in oxidation-reduction processes of the cell, is needed for the metabolism of amino acids and carbohydrates, and for the excretion of toxic substances from the body (Korr, 2017). Importance of vitamin C is particularly important when the animal is in stress. The intake of vitamin C with food can be through feeding stuffs in which it has a vitamin supplement, which meets the daily needs of dairy cows and other categories and types of animals. The needs of vitamin C are quite high and therefore daily needs in all types and categories of animals are expressed in mg / kg of feed. Thus, according to studies carried out at Cornell University (2018) in the paper "Composition of milk," raw cow milk contains: water 87.3% (85.5 - 88.7%); fat 3.9% (2.4-5.5%); proteins 3.25% (2.3-4.4%); casein 2.6% (1.7-3.5%); serum proteins, small proteins and carbohydrates 4.6% (3.8 - 5.3%); organic acids 0,18% (0,13 - 0,22%), such as citric, lactic, formic, acetic, oxalic acid, minerals, enzymes. It also contains vitamins: A, C, D, thiamine, riboflavin; minerals: 0.65% (0.53-0.80%); cations, K, Ca, Mg, K, anions: chlorides, phosphates, citrates, carbonates; enzymes: peroxidase, catalase, phosphatase, lipase; gas: CO_2, N_2, O_2.
Studies of raw milk with thermal treatment have shown that quality is lost. Higher thermal treatment with ultraviolet temperature (UHT), or pasteurization for extended application in combination with increased storage time of these products, caused by some water-soluble vitamins, leads to a reduction in vitamins and minerals. Thiamine is reduced from 0.45 to 0.42 mg/l, vitamin B12 is reduced from 3.0 to 2.7 μg/l, and vitamin C is reduced from 2.0 to 1.8 mg/l (Crlsen *et al*., 2010). According to studies conducted byTomovska, Menkovska, Ahmad (2018), for the content of vitamin C in milk, it was found that its content is the highest in vitaminized milk where it is deliberately added and the highest number of 1.20 mg/dl. From that study concluded even chocolate milk has a significant amount of vitamin C, up to 0.22 mg/dl, most likely derived from cocoa, which is used as a basic supplement for the production of chocolate milk. In skimmed milk, the smallest content of vitamin C is maximal to 0.25 mg/dl, and a minimum of 0.1 mg/d. Full fat milk has a vitamin C content up to 0.35 mg/dL, which is greater than that in chocolate milk, and this is probably due to the higher amount of vitamin C in whole milk. The low content of vitamin C in skim milk is most likely due to decreased processes, which together with ointment, probably also removes the greater amount of this vitamin, which is closely related to vitamin E, which, in turn, is most concentrated in the membranes of fat drops. The content of antioxidants in milk from vitamin C, that are important contributors or neutralizing agents to free radicals is quite low (Clausen et al., 2009). In this context, it is quite important to mention that the possibility of antioxidant activity of proteins and peptides in food is also investigated (EFSA, 2006).

Material and Methods

1. Extraction of feed

For the extraction, feeding stuffs are used, two types of compound mixtures (concentrates) produced by firm "Agroinvest" (2017), feed mixture for dairy cows with the least crude protein (KMK) - 18% and two types of plant materials: alfalfa hay and wheat grains. Dried feeds are firstly sucked with a homogenized in order to obtain a uniform particle size. The solvency ratio was constant as applied (Kothari *et al*., 2014) for all methods. 1 g powdered feed powder was dissolved in a 50 ml solvent, which could be alcohol, ether, ethyl acetate, and the like. For this type of analysis, absolute methanol (Merck KGaA, Frankfurt, Germany) and 50% ethanol (Alkaloid, Skopje) was used. The extraction is made using a mixture of solvents (methanol and ethanol) in a ratio of 1:1 and using the Soxhlet apparatus after 3 hours for each test (in the case of nine samples), maintaining the constant total volume from the extract of 100 ml.

2. Extraction of milk

Samples of cow's raw milk, which cows feeding on the tested feed from three farms (randomly) from three different places on the territory of The North Republic of Macedonia: Kumanovo, Tetovo and Gostivar are extracted with 6% trichloroacetic acid (CCl_3COOH 99%, Sigma Aldrich company).

• Preparation of the filtrate (whey fraction)

In a 50 ml vial, 15 ml of 6% trichloroacetic acid (TCA) is added, add 5 ml of milk and stir with a stalk rod until a fine suspension, leave at room temperature for 5 minutes. The supernatant is then separated by centrifugation at 7550 rpm^{-1} (RCF = 5410g) in the Hettich Universal 320R centrifuge (Andreas Hettich GmbH - Germany) within 10 minutes. The obtained supernatant is filtered through a filter paper Whatman No. 1.

In this study, a colorimetric method with 2,4-dinitrophenylhydrazine, which is widely used to determine the level of ascorbic acid in biological fluids, has been adapted to estimate the total content of vitamin C in the extracts of feed and milk. The procedure depends on the principle of the oxidation of L-ascorbic acid in dehydroascorbic acid and 2,3-diketo-L-gulonic acid, followed by reaction with 2,4-dinitrophenylhydrazine. After treatment with sulfuric acid, a colored product is formed, which is absorbed at 520 nm. Using the standard of ascorbic acid at different concentrations, according to Lambert Beer's law, a 20 mg/dl concentration range was used, which resulted in the following equation of the linear calibration curve: $y = 0.0344x + 0.0519$, $R^2 = 0.9709$. The most critical and decisive step in the precision reading procedure is the preparation of a final and the clear extract of feed and milk. The analysis of the content of vitamin C in selected feeds and milk is made using a spectrophotometric method.

3. The standard curve of ascorbic acid (Burgos et al., 2014).

- Preparation of the basic solution of ascorbic acid (1000 μg/ml). To this end, 100 mg of ascorbic acid are measured in a glass and dissolved in a 50 ml extraction solution (methanol). Transfer the solution into a volumetric flask protected from light and make up to 100 ml with a solution for extraction (methanol). Standard solutions of ascorbic acid (5, 10, 20, 30, 40 and 50 μg/ml) are prepared by taking 0.25, 0.5, 1.0, 1.5, 2.0 and 2.5 aliquots ml of the basic solution of ascorbic acid and make up to 50 ml with the extraction solution. Mix 1 ml extraction solution with 9 ml of dissolved 2,4 dinitrophenylhydrazine, (2,4-dinitrophenylhydrazine, DNP, Sigma Aldrich) and read the absorbent (reagent + sample) for 1 minute at 520 nm. The final value of absorption is used to make the standard curve: the actual absorbance (A) versus concentration (μg/ml).

4. Procedure for the determination of vitamin C

With minor alterations to the conditions and reagents applied the method from Al-Ani *et al*. (2007). For one sample, 1 ml of three samples of the clear supernatant, 1 ml of water as a blank and 1 ml of standard solutions in test tubes is pipettes per ml. In the same test tubes, add 1 ml of 6% trichloroacetic acid (TCA) and 0.4 ml of 2,4-dinitrophenylhydrazine (DNP). The tubes are sealed and incubated in a water bath at 37 ° C for 3 hours. Then, the tubes are cooled in a cold bath for 10 minutes. Add 2 ml of cold sulphuric acid (12 mmol) to the cooled solutions, close the tubes and mix to the vortex. The temperature of the mixture should not exceed the ambient temperature due to reading the spectrophotometer. The spectrometer (Spectroquant Pharo 300 - Merck) at 520 nm was zeroed and the absorbance of the standard solutions for compiling the calibration curve was first read, and then the absorbance of the samples were read and applied to the calibration curve from which the concentration values were read.

Results and Discussion

Results from examination of vitamin C (ascorbic acid) in samples of feed taken from 3 farms A, B, C: Concentrate 1 and 2 used on the farm B in Tetovo farm; Concentrate 3 and 4 used in farm A - Kumanovo; Concentrate 5 used on the farm C - Gostivar; Alfalfa hay 6 used in the farm A - Kumanovo; Wheat straw 7 used in the same farm A - Kumanovo; Alfalfa hay 8 used in the B - Tetovo farm; Alfalfa hay 9 used in the farm C – Gostivar were subordinated. Also cow's milk samples from three farms and one commercial milk from sale are examined in the following order: Crude cow milk 1 from Farm A, Kumanovo, Crude cow milk 2 from the farm C, Gostivar, Crude cow 3 from the B farm, Tetovo, Cow's milk 4 pasteurized with 3.2% fat (from sales to a carton). The values for the standard ascorbic acid curve was in the measurement range (0.00 to 40.00 μg/ml).
Measured values for the absorption of samples of feed (concentrates and alfalfa) are shown in Table 1. Absorbance values are transferred to the standard ascorbic acid curve and read analogously to their concentration curves. Figure 1 shows the concentration of vitamin C in the feed samples from 3 farms.

Table 1. Statistical Calculation Absorbance and Concentration of vitamin C in feed

N^{o} measurement	Samples of feed Absorbance /A (λ = 520nm)								
	1	2	3	4	5	6	7	8	9
1	0.623	0.789	0.394	0.960	0.640	1.019	0.698	1.187	0.942
2	0.625	0.780	0.393	0.953	0.636	1.02	0.695	1.184	0.947
3	0.624	0.777	0.394	0.954	0.635	1.018	0.696	1.182	0.943
n = 3

(c) (μg/ml)	16.0	23.0	5.2	32.5	16.8	32.5	20.8	40.2	30.5

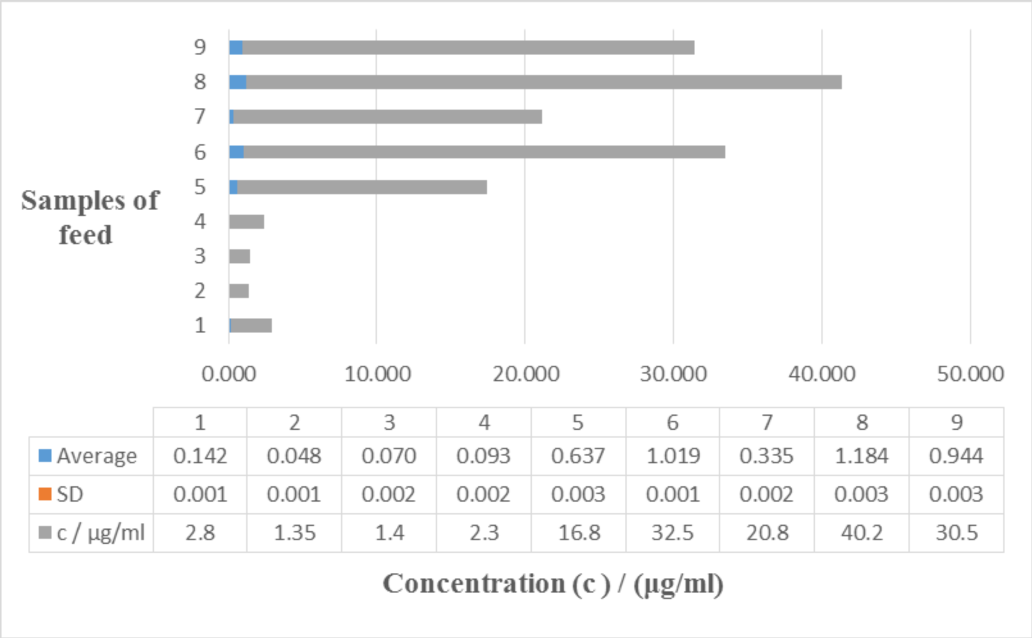

Figure 1. Vitamin C concentration in feed samples (concentrates and alfalfa)

Measured values for absorbance, A of the milk samples are shown in Table 2. Absorbance values are transferred to the standard ascorbic acid curve and read analogously to their concentration curves. Figure 2 shows the concentration of vitamin C in milk samples from the three farms.

Table 2. Statistical Absorbance and Concentration Calculation of vitamin C in milk

N^{o} of measurement	Samples of milk Absorbance /A (λ = 520nm)			
	1	2	3	4
1	0.143	0.049	0.072	0.091
2	0.142	0.047	0.068	0.095
3	0.142	0.047	0.069	0.093
n = 3				
$\bar{x}$ =	0.142	0.048	0.070	0.093
s =	0.001	0.001	0.002	0.002
RSD	0.0040	0.0242	0.0298	0.0215
(c)/ (µg/ml)	2.8	1.35	1.4	2.3

The sampled number of the sample absorbing apparatus (absorbance A) is applied to the calibration curve and reads the concentration values (c) measured in (µg/ml).

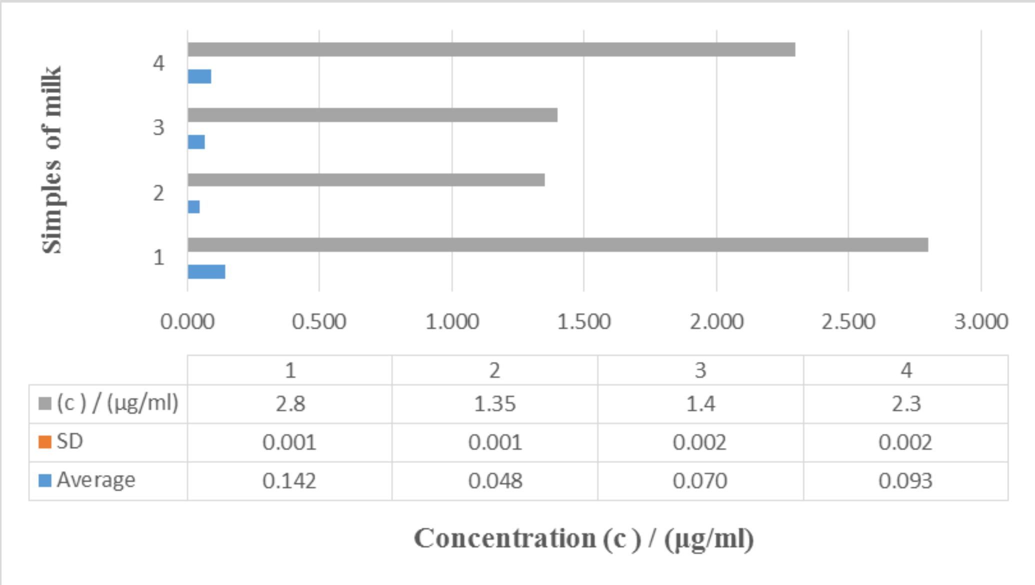

Figure 2. Vitamin C concentration in milk from the three farms

Vitamin C (ascorbic acid), as a strong antioxidant, is most present in feeding stuffs with a concentration of 40.0 µg/ml, in the alfalfa acne from Tetovo. Samples with the same concentrations of 32.5 µg/ml of vitamin C are concentrate 2 and alfalfa from Farm A from Kumanovo. A sample of 30.5 µg/ml is an alfalfa sage from the farm C of Gostivar, which shows that a similar concentration of vitamin C has all the samples of alfalfa, which means that alfalfa is abundant with vitamin C. The presence of vitamin C in milk is shown in Figure 27, which shows that the milk from Farm A from Kumanovo has the highest value of 2.8 µg/ ml, and in pasteurized milk with 3.2% fat has a value of 2.3 µg/ml. The need for vitamin C has been very studied in humans, and there is very little in the domestic animals. Vitamin C can also be added as an additive in feed (Milosavljevic, Pauca, 1978). The presence of vitamin C in milk is low, and this is also shown by this research. This has also been confirmed recently by the investigations of Tomovska *et al*. (2018), for the presence of vitamin C in vitaminized milk species, chocolate milk species and in milk with different concentrations of milk fat.

Conclusions

From the analysis of vitamin C in feed, concentrates and milk, it concludes:
1. The results of the studies of vitamin C in feeds - concentrates and alfalfa hay from the three farms (in the measured range from 0.00 to 40. 00 µg/ml), the highest value is found in the sample of alfalfa hay from farm B of 40.3 µg/ml, and the lowest value on the concentrates (KMK) 1 sample of farm A of 5.2 µg/ml.
2. With respect to the concentration of vitamin C in raw milk, the highest value indicates milk from farm A of 2.8 µg/ml and the lowest value of milk from farm B with a value of 1.4 µg/ml.
The main conclusion is that vitamin C is present in a large amount of alfalfa hay feed, while the amount of vitamin C in the raw milk is low, regardless of the type and diet of the cattle.

Abstract

Cereals are one of the most important crops grown for food, fodder and technical purposes. Reliable yields and grain quality is one of the most important tasks of agriculture. The purpose of this work is to present results on the biological effectiveness and safety of the use of insecticides for protection against a complex of piercing-sucking pests. Field experiment was conducted for two years, according to. Frequency of assessment was carried out the day before spraying and on the 3rd, 7th and 14th days after spraying. The biological effectiveness of the insecticides was determined by Henderson-Tilton formula. The dynamics of the decomposition of residual amounts of thiamethoxam and alpha-cypermethrin in 2016 and 2017 were conducted. Analysed plant material was sampled on the day of spraying and at 8, 15, 23, and 30 days after.

The analysis of residual quantities of thiamethoxam was performed under laboratory conditions using high performance liquid chromatography, residual quantities of alpha-cypermethrin are analyzed by gas chromatography.

The test pesticide showed high biological efficiency. Based on the results of the analyzes, it was established that the level of thiamethoxam and alpha-cypermethrin content in the crop did not exceed the maximum allowable levels.

Key words: *Cereals, Insecticide, Russian Federation, Neonicotinoids, Pyrethroids, Piercing-sucking pests.*

Introduction

The aim of developing and improving the field crop protection system is to obtain high-quality yields. Representatives of the complex of piercing-sucking pests (aphids, thrips, leafhoppers) have a negative impact on the quantitative and qualitative characteristics of the crop. In addition, they are transmitters' of vector born-diseases of plants (Orlov, 2006).

Expanding the arsenal of registered plant protection products allows the producer of agricultural products to compile an optimal protection scheme that will be effective against pests, and will allow obtaining products safe for the consumer.

Neonicotinoids are a perspective group of insecticides that significantly expand the possibilities of creating integrated schemes for the protection of cereals. Compared to other chemical classes of insecticide compounds, neonicotinoids have fundamentally different mechanism of action on the organism arthropods inhibiting nicotine acetylcholine receptors. Pyrethroids similarly interact with the nervous system of insects by acting on calcium metabolism in synapses on the sodium-potassium channels, disrupting the function of the nervous system. This leads to a significant excessive release of acetylcholine during the passage of a nerve impulse (Ibragimhalilova, 2008). Poisoning manifests itself in the defeat of the motor centers, in a strong excitement.

The use of mixed preparations based on neonicotinoids and pyrethroids on crops provides resistance to most pest species.

The aim of the study was to determine the effective and environmentally safe consumption rates of the test mixture, to prove that the pesticide allows effectively pest population control in the field, and also does not have a negative impact on the safety of consumed products.

Materials and Methods

The field part of the experiment to assess the biological efficiency of the insecticide was carried out in the Russian Federation, in the city of Moscow, in the zone of podzolic and sod-podzolic soils. The humus content in the soil is 1.6-1.8%, pH = 5.9. The trail was conducted on the experimental station field, in the Russian State Agrarian University named after K.A. Timiryazev (RSAU-MTAA) in 2016 and 2017. The experiment was set up on four replicates of 4 model plots measuring 50 m^2 in each of the variants (Guidelines for insecticide testing, 2009). The variety of winter wheat is Galina.

The test preparation contained 150 g L^{-1} thiamethoxam and 150 g L^{-1} alpha-cypermethrin in the form of a suspension concentrate. Two rates of consumption of 0.1 and 0.15 L ha^{-1} were studied.

The insecticide based on 106 g L^{-1} of lambda-cyhalothrin and 141 g L^{-1} of thiamethoxam in the form of a suspension concentrate was used as a reference preparation at a rate of 0.2 L ha^{-1}. The spraying were carried out on 17 June 2016 and 30 June 2017.

Frequency of assessment was carried out the day before spraying and on the 3rd, 7th and 14th days after treatment. The biological effectiveness of the pesticide was determined by reducing the number of pests with the correction for control and calculated according to the Henderson-Tilton formula (Guidelines for insecticide testing, 2009).

Plant material was sampled on the day of spraying and at 8, 15, 23, and 30 days after for analyses of dynamics of decomposition of residual amounts of thiamethoxam and alpha-cypermethrin in 2016 and 2017.

Analysis of residual amounts of thiamethoxam was carried out on an Agilent 1260 Infinity liquid chromatography with a diode array detector (Sychev, 2013), and the determination of the residual amounts of alpha-cypermethrin was carried out using an Agilent 6890 N gas chromatograph with an electron capture detector (Tsarev, 2000).

The lower limits of quantitative detection of thiamethoxam and alpha-cypermethrin were established at the level of 0.025 and 0.01 mg kg^{-1}, respectively. The lower limits of the detection of pesticides in agricultural products are established on the basis of the actual maximum permissible levels (MRLs) for the pesticides under study. In Russia, the following hygienic standards for thiamethoxam MDI in products (mg kg^{-1}) in grain cereals for thiamethoxam and alpha-cypermethrin in cereal grains were established at 0.05 and 2.0 mg kg^{-1}, respectively (HS 1.2.3539 -18, 10/05/2018).

Results and Discussion

In 2016 in the complex of piercing-sucking pests dominated aphids (*Rhopalosiphum padi*), from other pests during the counts were observed thrips (*Thysanoptera* sp.) and cicadas (*Cicadellidae* sp.) - in single amounts and only in the control variant.

The spraying of plants was carried out when pests invade 6 to 10% of plants, with an average of 5.8 to 10.2 aphids per one ear. On day 3 after spraying, the effectiveness of the test pesticide at 0.1 L ha^{-1} is 80%; 0,15 L ha^{-1} - 87%, and the standard - 82%. On the 7th day after spraying, the effect of the test pesticide was reduced at 0.1 L ha^{-1} - 72%; 0,15 L ha^{-1} - 81%, and the standard - 70%. On the 14th day after spraying, further decrease in the effect of the test pesticide was noted when the aphid population was restored - 0.1 L ha^{-1} - 69.5%; 0.15 L ha^{-1} - 78%, and the standard - 70%, with the number of pests in the control variant of 7.5 specimens/ear.

In 2017, against the background of incessant precipitation, the appearance of a complex of

piercing-sucking pests on winter wheat was noted from the first decade of May (aphids) to the beginning of June (thrips and leafhoppers). The number of aphids at the time of the treatment was small and varied from 2 to 4 specimens / ear. The number of thrips did not exceed the threshold values, the individuals of leafhoppers were noted singly on the control plots. The date of application of the pesticide was associated with the appearance of colonies of aphids.
After the application of the test preparation, the biological efficacy in fighting the aphids was not inferior to the standard and amounted to 0.1 L ha^{-1} at the rate of application: 91% for the 3 rd day; 7th day - 62%; Day 14 decreased to 39%; at a rate of 0.15 L ha^{-1} was: 3 days - 100%; 7 days - 80%; Day 14 decreased slightly to 53%. The reference preparation provided biological efficacy: for 3 days - 100%; 7 days more than the experimental variant-85%; 14 days below the experimental variant - 50%.
Based on the results of the analysis of the dynamics of degradation, it was established that in the variant of the experiment in 2016 the residual amounts of thiamethoxam (Guidelines 4.1.1142-02) in samples of green mass of winter wheat on the day of treatment amounted to 0.0946 mg kg^{-1}, and in 2017 - 0.09122 mg kg^{-1}. 8 days after spraying, the content of residual amounts of thiamethoxam in the green mass of winter wheat was reduced and was found in an amount of 0.0513 mg kg^{-1}, and in the experiment of 2017, it was detected below the limit of quantification of the control method used. After 15, 23 and 30 days after spraying, thiamethoxam residues in samples of green mass, grain and straw of winter wheat were not detected within the sensitivity of the monitoring method used in both years.

Table 1. The residual quantities of thiamethoxam in 2016-2017

Year of research	Product type	Date of treatment by pesticides	Date of selection samples	Result, mg kg^{-1}

The content of residual amounts of alpha-cypermethrin (Guidelines 4.1.2087-06, No. 4344, 1987) in 2016 in samples of green mass of winter wheat on the day of treatment was 0.8668 mg/kg, and in 2017 0.9458 mg kg^{-1} . In 2016, in samples taken 8 days after spraying, the content of the residues of alpha-cypermethrin decreased to 0.6239 mg kg^{-1}, and after 15, 23 and 30 days after spraying, the residual content of alpha-cypermethrin was not detected. In

2017, 8 and 15 days after spraying, the content of alpha-cypermethrin residues decreased to 0.7986 mg kg^{-1} and 0.6672 mg kg^{-1}, respectively. 23 days after spraying, the content of alpha-cypermethrin residues in the green mass of winter wheat was found to be 0.5523 mg kg^{-1} . 30 days after spraying, the residual content of alpha-cypermethrin in grain and winter wheat straw was not detected within the limits of the quantitative determination of the control method used.

Table 2. The residual quantities of alpha-cypermethrin in 2016-2017

Conclusions

The biological efficacy of the pesticide, containing 150 g L^{-1} f thiamethoxam and 150 g L^{-1} of alpha-cypermethrin, against aphids at a rate of 0.1 L ha^{-1} was 62-91% a week after spraying, and decreased to 40-70% in two weeks. At a rate of 0.15 L ha^{-1}, the effectiveness of the pesticide in the week after spraying varied between 80-100%, after two weeks, 53-78%. The effectiveness of the reference pesticide was at the level of the maximum application rate of an experienced pesticide. Obtained results indicate that this insecticides could be highly effective against other species of the complex of piercing-sucking pests on cereals. In the course of two-year field and laboratory experiments it was found that the active substances of the investigated pesticide-thiamethoxam and alpha-cypermethrin are devastate in successively selected samples of winter wheat for 30 days. At the time of harvesting, the residual amounts of thiamethoxam and alpha-cypermethrin in grain and straw of winter wheat were not detected either in 2016 or in 2017.

Abstract

Myrtle (*Myrtus communis* L.) is an evergreen shrub (Myrtaceae) with a natural habitat in the Mediterranean region. In the Nikitsky Botanical Gardens (the Southern Coast of the Crimea) this culture is studied as a decorative, medicinal and essential oil plant. Myrtle leaves are medicinal raw materials. In the subtropical climate of the Mediterranean type the content of essential oil in myrtle leaves obtained by Clevenger's method (time extraction -1.5 hours) (method of Pharmacopoeia XIII) is 0.82-0.88% on a completely dry mass. Analysis of the component composition of the essential oil, investigated by GC on chromatograph firm Chromatek Crystal 5000 showed that this oil belongs to the 1.8-cineol chemotype: the relative content of 1.8-cineol is 22.05%. Myrtenyl acetate (10.17%), linalyl acetate (5.72%), D-limonene (7.34%), methylevgenol (1.14%) were also identified in the oil. Quantitative analysis of phenolic compounds carried out using HELC method on the chromatograph of Agilent Technologies (model 1100) found that the mass fraction of phenol phenolcarbonic acids (gallic and ellagic) is 3.3%, flavonoids (catechine and its derivatives, quercetine and glycosides of myricetine) - 87.3%. D-catechine, myricetine-3-O-rhamnoside and myricetine-3-O-galactoside are dominate among flavonoids. The mass fraction in the extract of D-catechine is 30.2%; myricetin-3-O-rhamnoside - 26.2%; myricetin-3-O-galactoside - 16.1% The studies have shown that under the conditions of the Southern Coast of the Crimea common myrtle accumulates a significant amount of biologically active compounds, including essential oil of 1.8-cineol chemotype, flavonoids and phenolcarbonic acids, which allows us to talk about the prospects of using this culture as a source of valuable medicinal raw materials.

Keywords: *Myrtus communis* L., *medicinal raw materials, essential oil, 1.8-cineol, flavonoids*

Introduction

Myrtle (*Myrtus communis* L.) is an evergreen shrub (Myrtaceae) with a natural habitat in the Mediterranean region. In the Nikitsky Botanical Gardens (Southern Coast of the Crimea) this culture is studied as a decorative, medicinal and essential oil plant. It is used as a medicinal and food preservative. In Italy, the fruits and leaves are currently used for the production of two well-known liqueurs Mito Rosso and Mirto Bianko. Water-ethanol extracts of myrtle have anti-inflammatory, antidiabetic, anti-mutagenic and anti-atherogenic, anti-ulcerative, insecticidal properties and have proapoptotic effect in cancer cells (Amira et al., 2012; Ogur, 2014; Izgi et al., 2015).

Myrtle leaves contain the essential oil, which contains 1.8-cineol, α-pinene, limonene, linalol, myrtenyl acetate (Mimica-Dukic et al., 2010; Логвиненко, 2017; Bakova et al., 2018). The qualitative composition of the essential oil from different organs of the plant is identical, the differences are observed only in the quantitative ratio of the components (Wannes et al., 2010).

Myrtle essential oil has an inhibitory effect against pathogenic fungi *Rhizoctonia solani* Kuhn. (Curini et al., 2003), *Fusarium subglutinans, F. vertricilioides, F. oxysporum, F. tricinctum, F. sporotrichioides, F. equiseti, F. incarnatum, F. proliferatum* and *Macrophomina phaseolina* (Starovic et al., 2016), against strains of *Escherichia coli*, *Klebsiella pneumoniae, Bacillus subtilis*, *Bacillus licheniformis*, *Candida albicans* (Mosul, Lobe, Slobojan, 2011), against gram-positive bacteria, in particular *Staphylococus aureus* (Cherrat et al. 2013) and can be used as fungicidal agents at Rhizoctonia plant disease. The antifungal and antimicrobial activity of myrtle essential oil has been shown to be significantly higher than that of mint and sage oil (Starovic et al., 2016).

As biologically active components exhibiting a wide range of pharmacological and therapeutic effects, such as antiviral, antibacterial, antifungal effects, the following components of essential oils were identified: 1.8-cineol, α-pinene, myrtenyl acetate, limonene, linalool (Alipour, Dashti, Hosseinzadeh, 2014; Mosul, Dolya, Slobozhan, 2011; Cherrat et al., 2013). The insecticidal and repellent activity of myrtle essential oil is explained by the presence of linalool and α-pinene (Cheraghi et al., 2016)

Antimicrobial, antifungal, antioxidant and insecticidal activity of extracts and essential oil of common myrtle show its prospects of use in pharmaceutical, food and agricultural practice.

The aim of our research was to study the content of biologically active substances (essential oil and phenolic compounds) in the leaves of myrtle in the conditions of introduction in the Nikitsky Botanical Gardens.

Materials and Methods

The Nikitsky Botanical Gardens (NBG) is located on the Southern Coast of the Crimea (SCC) in the zone of dry subtropical climate of Mediterranean type (Plugatar, Korsakova, Ilnitsky, 2015).

Myrtle leaves were collected in the fruiting phase in the 3rd decade of October. The quantitative content of essential oil in fresh and dry myrtle leaves was determined by the Clevenger's method in accordance with the general pharmacopoeia article. 1.5.3.0010.15. of National Pharmacopeia, XIII edition (Pharmacopoeia, 2015). The component composition of the essential oil was determined by gas-liquid chromatography (Tkachev, 2008; Dmitriev et al., 2016) on a chromatograph Crystal 5000.2 with mass spectrometric detector (Chromatek, Russia). Capillary column CR – 5ms, length 30 m, inner diameter 0.25 mm. Phase – 5% phenyl 95% dimethylpolysiloxane, 0.25 microns. The analysis time was 50.25 min. Carrier gas – helium, flow rate 1 ml/min. The temperature of the ion source 200 operating system. The transition line temperature is 250°C. The division of the flow 200. Electronic ionization of 70 eV. The scanning range is 20-450. Duration of scan is 0.2. Identification of the components was carried out on the basis of comparison of the obtained mass spectra with the data of the NIST14 MS Search library. Determination of the ratio of essential oil components was carried out by the method of internal normalization of peaks.

For the study of phenolic compounds, dry leaves were ground to the size of particles passing through a sieve with a hole diameter of 1 mm. The crushed raw material of 1.0 g was boiled in 30 cm^3 of 90% ethyl alcohol containing 0.5% concentrated sulfuric acid in a boiling water bath with a reflux refrigerator for 30 minutes in Soxhlet extractor. The supernatant was poured into a volumetric flask with a capacity of 100 cm^3 and the extraction was repeated again. The combined mixture was cooled, filtered and adjusted to 100 cm^3 by 90% ethanol (Pharmacopoeia, 2015). The total content of phenolic compounds was determined spectrophotometrically by Folin-Ciocalteau technique (Methods ..., 2002).

The study of the phenolic complex was carried out on the chromatograph of Agilent Technologies company (model 1100), equipped with a flowing vacuum degasser G1379A, a 4-channel low-pressure gradient pump G13111A, an automatic injector G1313A, a thermostat of columns G13116A, a diode-matrix detector G1316A. A chromatographic column measuring 2.1 × 150 mm filled with octadecylsilyl sorbent, grain size 3.5 μm, "ZORBAX-SB C-18" was used for the analysis. Identification of phenolic compounds was carried out according to the retention times of standards and spectral characteristics.

Results and discussion

Under the conditions of the SSC common myrtle develops as a perennial evergreen shrub, withstands short-term frosts to 11-12C, and it freezes at a lower temperature. In the seasonal cycle of development of the world there are two periods of growth: spring-summer and summer-autumn. Spring-summer growth of shoots begins in the second half of April – early May, the second one - in August – early September and ends in October. Flowering was observed in July, starting with the third year of life. Flowers of medium size, sepals are short, triangular-ovoid. Petals are white, obovate. At the beginning of August it begins the fruit formation. The period of formation of the fruit under the conditions of the SCC is stretched and is 100-110 days and only by the beginning of October their maturation begins. Fruit is berry, round or ovate-elliptic and has the size of a pea (Logvinenko, 2017).

Myrtle's leaves are medicinal raw materials. The leaves are opposite, leathery, lanceolate, pointed with a length of 30 mm and a width of 5 mm. The yield of raw materials from the plant of three years old is 0.5 kg. Myrtle oil is a transparent, slightly yellowish liquid with a refreshing floral-balsamic odor. The content of essential oil in the leaves obtained by hydrodistillation according to Ginsberg is 0.35% of the wet mass (0.87% of the air-dry mass), in the fruits – 0.007%, in the shoots – trace amounts (Logvinenko, 2017; Bakova et al., 2018).

The period of processing of fresh myrtle leaves for essential oil is limited due to significant fluctuations in air temperature during myrtle fruiting period - the end of October - the second, third decade of November due to a decrease in air temperature, processing of fresh raw materials can last from 3 to 5 days.

One of the criteria for the quality of medicinal raw materials, according to the requirements of National Pharmacopeia, is the content of essential oil obtained by Clevenger's method. The use of this method makes it possible to obtain 35% more essential oil - 0.76-0.82% (from the air-dry mass) compared to Ginsberg's method used (Bakova et al., 2018).

In total, the oil obtained from fresh and dry raw materials is dominated by terpenoids, their content is 86.0-72.6% of the total content of components, and the share of terpene compounds accounts for 4.6-21.6%, the amount of non-terpene compounds is 4.8%. A comparative assessment of the component composition of essential oil from raw and dry raw materials obtained by Clevenger's method showed that the main component of essential oil from raw materials is myrtenyl acetate - its mass fraction was 60%, and in the essential oil from dry raw materials 1.8-cineol (22,0%), linalool (16,6%), α-pinene (13,7%) dominate (table. 1).

The analysis of the literature data on the variability of the component composition of the essential oil showed that it significantly depends on the ecological and geographical place of growth.

∗ Raw fresh materials, ∗∗ Dry materials

The main dominant components of essential oil from myrtle dry raw materials when grown in the NBG can be attributed to 1.8-cineol-linalool chemotype; when grown in Serbia – linalool-1.8-cineol; in Tunisia, Italy, Iran and France – pinene-1.8-cineol (table. 1). As you can see, myrtle essential oil is characterized by high variability depending on the zone of growth.

The quality of medicinal raw materials also depends on the content of secondary metabolites, namely phenolic compounds. 3704.09 mg/dm^3 of phenolic compounds were specified in water-ethanol extraction from myrtle leaves. Phenolic substances are represented by phenol carboxylic acids (gallic and ellagic) and flavonoids (catechin and its derivatives, quercetin and glycosides of myricetin. The concentration of phenol carboxylic acids in aqueous-ethanol extraction was 190.0 mg/100 g, and flavonoids – 3142.9 mg/100 g. The main components of the extract are: (+) D-catechin, myricetin-3-O-rhamnoside and myricetin-3-O-galactoside. It is known that the derivatives of catechin, myricetin-3-O-rhamnoside and myricetin-3-O-galactoside are very strong antioxidants and in their activity they exceed vitamins C and E (Hayder, Bouhlel, Skandrani, 2008; Tsao, 2010), so it causes a high antioxidant activity of myrtle extracts.

Table 2. Phenolic compounds in water-ethanol extract from myrtle leaves

Component	Holding time, min.	Content in water-ethanol extraction, mg/dm^3
Gallic acid	4.48	117,43

Quercetine	23.21	2,03
Sum of polyphenols by HELC	-	3704,09

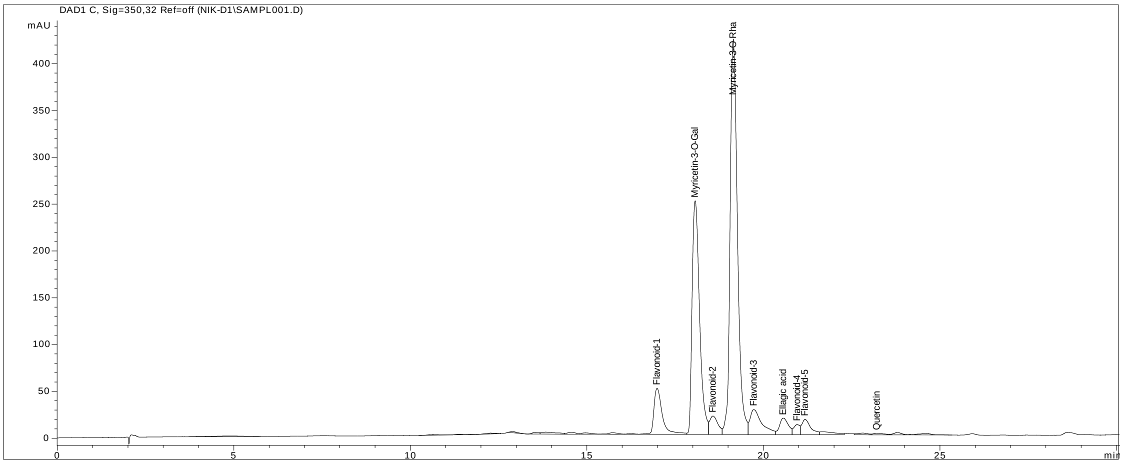

Figure 1. Chromatogram of phenolic compounds of water-ethanol extraction from myrtle dry leaves

Conclusion

The conducted studies have shown that under conditions of the Southern Coast of the Crimea in myrtle dry raw material contains a significant number of biologically active compounds: 0.82% essential oil in absolutely dry mass of 1.8-cineole-linalool chemotypes and 3704.09 mg/dm^3 of phenolic compounds, mostly flavonoids, derivatives of catechin and myricetin. The data obtained allow us to discuss about the prospects of using this culture as a source of valuable medicinal raw materials with antibacterial and antioxidant properties.

Abstract

In terms of importance and occurrence frequency, the most important pathogen of lettuce is fungus causing downy mildew. Considering short vegetation of lettuce and its fresh use in diet, chemical protection must be conducted with caution. Lately, fungicides from the group of carboxamide (boscalid) and strobilurin fungicide pyraclostrobin are used for protection against this pathogen. In this study, the analytical method for the simultaneous determination of boscalid and pyraclostrobin residues in lettuce was developed and validated. The method is based on QuEChERS extraction, followed by HPLC/DAD analysis. The best separation was achieved using Zorbax Eclipse XDB-C18 column, while elution was conducted by acetonitrile and water (75/25) at a flow rate of 0.55 ml/min. The detection wavelength was 210 nm. The retention times for boscalid and pyraclostrobin were 1.492 and 2.211 min, respectively. The accuracy of the QuEChERS method was expressed as recovery at the levels 0.1, 1.0 and 2.5 mg/kg. The recovery values varied at 80–106%. In addition, the RSD obtained was 1.87–13.54%. Precision was evaluated trough repeatability of the peak areas and were 1.59% and 0.31%, while LOQ values were 0.1 mg/kg and 0.05 mg/kg, for boscalid and pyraclostrobin, respectively. The linearity of the detector responses of these compounds within the concentration range 0.1-10 μg/ml, were higher than 0.9995. The results are completely in accordance with SANTE guidelines. The obtained method was applied for the analysis of boscalid and pyraclostrobin residues in lettuce samples, collected on the market in Novi Sad. Obtained results showed that the contents of the analyzed fungicides were below MRLs.

Keywords: *Boscalid, Pyraclostrobin, Lettuce, Residues.*

Introduction

Lettuce (*Lactuca sativa*) is among the most important leafy vegetable. It contains a range of beneficial secondary plant metabolites, including phenolics, ascorbate, α-tocopherol, and lignans. Lettuce production involves intensive agricultural management throughout the year, with short cycles of 30–60 days (Opatovsky et al., 2019). It is commonly cultivated in a greenhouse, under controlled conditions. However, the humidity and temperature, prevailing in these conditions, encourage the development of harmful pests. In terms of importance and occurrence frequency in our agro-ecological conditions, the most important pathogen of lettuce is fungus causing downy mildew. For controlling this pathogen, boscalid and pyraclostrobin based pesticides are used.

In the Republic of Serbia, for the control of downy mildew (*Bremia lactucae*) in lettuce, formulated product based on boscalid and pyraclostrobin are registered. Boscalid, 2-chloro-N-(4′-chlorobiphenyl-2-yl) nicotinamide, a fungicide that contains a carboxamide structure as the functional group (Figure 1). Mode of action is based on inhibition of succinate ubiquinone reductase in the fungal mitochondrial electron transport chain (Hirakawa et al., 2015). Pyraclostrobin is a fungicide belonging to strobilurin family that inhibits mitochondrial respiration by binding at the Quinone Outside site of cytochrome B (Figure 1).

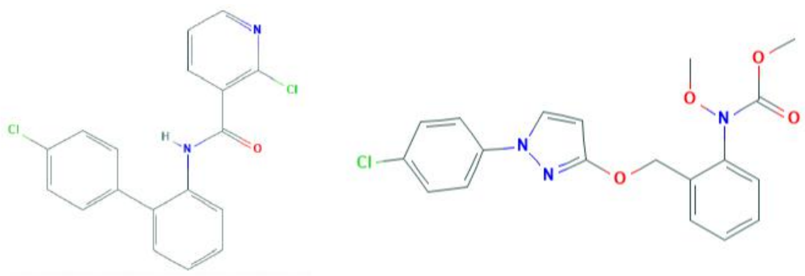

Figure 1. Boscalid and pyraclostrobin

In addition to controlling pests, these substances are often harmful to nontarget organisms. Consumers can be affected by the presence of pesticide residues in agricultural produces, especially when they are consumed fresh. The toxic nature of these compounds makes the monitoring of pesticide residues obligatory in food products in order to assess human exposure to pesticides through foods. Leafy vegetables have been given a lot of attention in monitoring programs since most of them are highly consumed and expected to contain higher pesticide residue levels than other food groups of plant origin (Esturk et al., 2014; Thabet et al., 2016).

Since lettuce is used in fresh, it is important to control the presence of pesticide residues, including boscalid and pyraclostrobin fungicides. Maximum residue levels of fungicides boscalid and praclostrobin in lettuce in the European Union and in the Republic of Serbia are 50 mg/kg and 2 mg/kg, respectively.

This study was conducted in order to obtain enough reliable and sensitive method that could be used for the analysis of boscalid and pyraclostrobin residues in lettuce samples.

Material and methods

Experiments were conducted in the Laboratory for biological research and pesticides, at the Department for Environment and Plant protection, of the Faculty of Agriculture, University of Novi sad, Serbia.

Extraction of boscalid and pyraclostrobin of the lettuce was carried out using QuEChERS methods (Figure 2). Briefly, 10g of the untreated sample was weighed and transferred to a 50 ml polypropylene cuvette. The extraction process was then carried out using acetonitrile; the cuvette was vigorously shaken for 1 minute, then a buffer mixture of salts (4 g $MgSO_4$, 1 g NaCl, 1 g trisodium citrate dihydrate, 0.5 g disodium hydrogen citrate sesquihydrate) was added, shaken vigorously for 1 minute and centrifuged for 5 minutes at 3000 rpm.

In the clean-up process, a 6 ml aliquot was transferred into a cuvette with 150 mg PSA and 900 mg $MgSO_4$ and carbon shaken vigorously for 1 minute and centrifuged for 5 minutes at 3000 rpm. The purified extract was evaporated to dryness, dissolved in 1 ml of acetonitrile, filtered through a 0.45 μm membrane filter, transferred to a vial and analyzed by HPLC-DAD.

Figure 2. Extraction and clean-up procedure

Simultaneous determination of boscalid and pyraclostrobin was performed using high-performance liquid chromatograph Agilent Technologies 1100 Serie (HPLC-DAD) with Zorbax Eclips column (50 × 4.6 mm, 1.8 µm). As a mobile phase acidified water pH 2.8 with H_3PO_4 and acetonitrile (ACN/pH 2.8 H3PO4, 25:75 v/v) was used; flow rate 0.55 ml/min; injected volume 20 µl; detection wavelength of 210 nm, 230 nm and 254 nm.

Results and discussion

The method for the simultaneous determination of boscalid and pyraclostrobin in lettuce is based on the reverse-phase high-performance liquid chromatography. Figure 3 show the chromatogram of a mixture of boscalid and pyraclostrobin standards in acetonitrile, obtained under the previously mentioned conditions. The satisfactory separation was obtained at all applied wavelength, however, the best response of pyraclostrobin was at 210 nm, and for further analysis this wavelength was used (Figure 4).

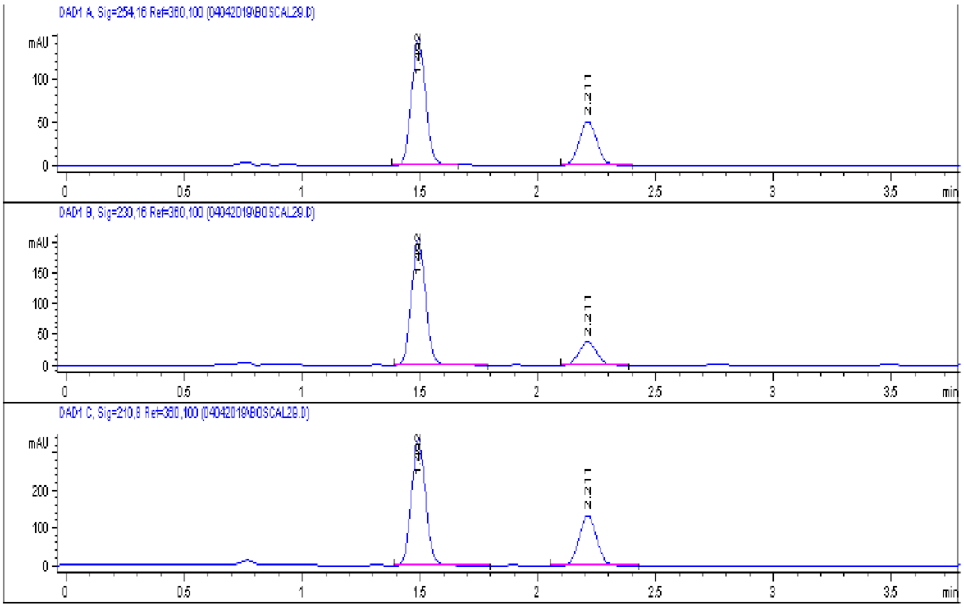

Figure 3. Chromatogram of the mixture of boscalid and pyraclostrobin analytical standards in acetonitrile at 210 nm, 230 nm and 254 nm

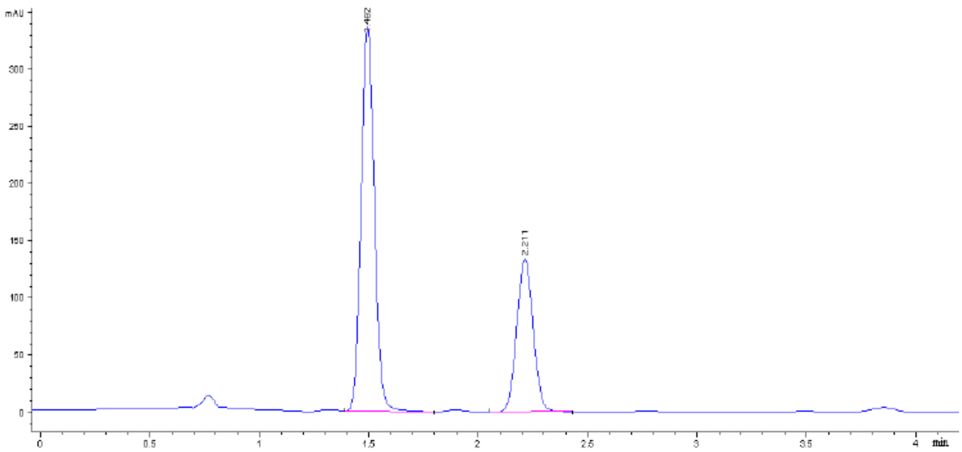

Figure 4. Chromatogram of the mixture of boscalid and pyraclostrobin analytical standards in acetonitrile at 210 nm

In addition to the retention time, for the confirmation of the presence of a compound, overlapped the spectra of the analytical standard in acetonitrile with the spectra of the peak at the same retention time in the test sample, was used (Figure 5).

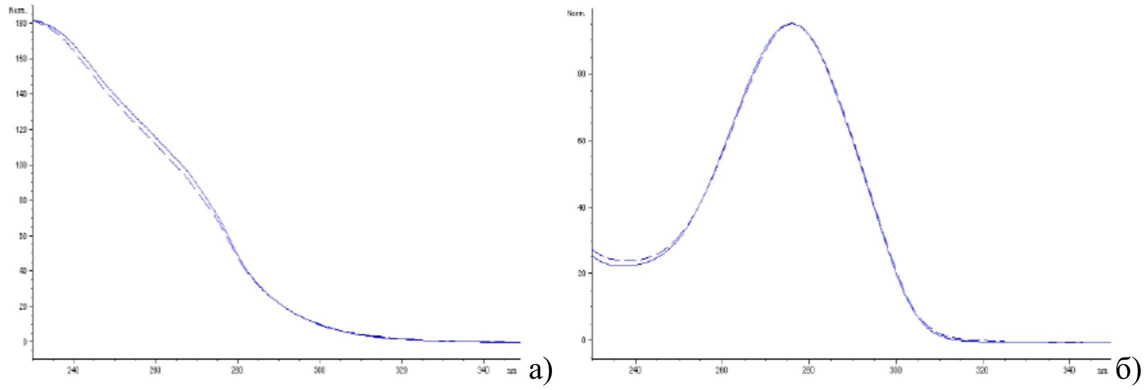

Figure 5. Overlapped spectra of boscalid a) and pyraclostrobin b) in analytical standard and in lettuce matrix

Validation of the method was evaluated through the linearity, reproducibility, recovery and limit od quantification (LOQ). A calibration curve of boscalid and pyraclostrobin exhibited good linearity ranging from 0.1-0.10 μg/ml with the correlation coefficient (r^2) of 0.999 and 0.997, respectively. According to the analysis of standard solutions, 0.1 mg/kg and 0.05 mg/kg were determined as the LOQ, which was satisfactory for the residual analysis of boscalid and pyraclostrobin, respectively. These values are below maximum residue level (MRL) of 50 mg/kg for boscalid and 2 mg/kg for pyraclostrobin in lettuce. For obtaining the recovery rate, the control samples were spiked with a mixture of boscalid and pyraclostrobin standard solution at two three concentrations and analyzed according to described method. Average recovery rates from 80-105% and 81-106% (RSD=1.87–13.54%) for boscalid and pyraclostrobin in lettuce, respectively.

In addition, the effect of lettuce matrix on the determination of boscalid and pyraclostrobin was analyzed. The obtained results indicate the influence of lettuce matrix on the reduction of boscalid and pyraclostrobin signals by only 1.3% and 2%, respectively, and a calibration curve of analytical standards dissolved in acetonitrile is used to determine the content of these fungicides in real lettuce samples. Repeatability was determined by injecting 20 μl of the standard solution of boscalid and pyraclostrobin prepared in the lettuce matrix at a concentration of 1.0 μg/ml six times. A relative standard deviation value (RSD%) of 1.59% and 0.31% indicates that a high reproducibility of the determination of boscalid and pyraclostrobin by the method used has been obtained, since RSD≤20% are acceptable according to SANTE/11813/2017.

The validated method was applied for the analysis of boscalid and pyraclostrobin residues in lettuce samples. Samples were collected at markets in Novi Sad, Serbia. In total, 60% of lettuce samples were with positive findings. Obtained results showed that the contents of the analyzed fungicides were below MRLs.

Conclusions

In this study method for the simultaneous determination of boscalid and pyraclostrobin fungicide residues in lettuce was developed and validated. All parameters are completely in accordance with SANTE/11813/2017 criteria. The reliable and sensitive method is based on the QuEChERS extraction technique, followed with HPLC-DAD. The described method was applied for the control of the presence of boscalid and pyraclostrobin resides in lettuce for the markets in Novi Sad. Obtained results showed that the contents of the analyzed fungicides were below MRLs, thus agricultural producers apply fungicides in accordance with good agricultural production.

Abstract

Expected climate changes, especially elevated CO_2 content can significantly disrupt the host-pathogen-herbivore relationship. Previous studies analyzed the influence of increased CO_2 content in relations between herbivores and their host plants, according to scenarios, which predict concentrations between 550 and 750 ppm in the future. This paper presents the results of influence of biotic stress, caused by inoculation with a root pathogen (*Phytophthora plurivora* T. Jung & T. I. Burgess) or gypsy moth (*Lymantria dispar* L.) herbivory, on the properties of Turkey oak (*Quercus cerris* L.) seedlings in elevated CO_2 conditions in extreme scenario, which predicts concentration of up to 1000 ppm in the future. For testing the influence of infection with *P. plurivora*, and feeding of gypsy moth larvae on the seedlings, analysis of covariance (ANCOVA) with plant status (exposure to infestation, feeding on the leaves or no biotic treatment) and environmental conditions (ambient or elevated CO_2 level) as independent variable and leaf mass, shoot mass and plant height as dependent variables, were used. Plants height before treatment was used as covariate. Fisher's least significant difference test was used to examine the differences in mean values of individual treatments. Biotic treatments (infestation and feeding on the leaves) significantly influenced the shoot mass and height of the seedlings, while the CO_2 concentration significantly influenced all the three observed plant properties. Interaction between biotic and environmental conditions showed no statistically significant influence on any of the analyzed properties. Plants height before treatment, used as a covariant in the analysis of variance, significantly influenced all of the analyzed properties.

Keywords: *gypsy moth, Phytophthora spp., Quercus cerris, elevated* CO_2

Introduction

Natural and artificial regeneration of oak stands is threatened by numerous biotic and abiotic factors. Success of this process depends on the characteristics of the species on one side, and from environmental conditions on the other. The most vulnerable are the seedlings during their first few years after afforestation or natural regeneration, when their survival depends on the capability of the species to survive the attack of different organisms (Price, 1991; Chaar *et al*., 1997). Most often, the influence of individual harmful factor like pathogens or harmful insects is studied (Milenković, 2015; Dobrosavljević *et al*., 2018), However, the detailed analysis of interactions of abiotic and biotic factors, when one can reduce the harmful influence of the other, or increase it in the case of synergistic activity, is needed for deeper understanding the decline of particular plant species, e.g. oaks (Thomas *et al*., 2002). Performance of the plants, in addition to pathogens and herbivores, significantly depends on the environmental conditions whose influence can be achieved directly or indirectly (Aldea *et al*., 2006). Environmental conditions influence the plants indirectly, by enhancing or diminishing the effect of the pathogens and herbivores. Expected climate changes, particularly

extreme occurrences like drought or extreme amount of precipitation, can enhance or diminish the effect of harmful organisms. Also, elevated content of CO_2 can significantly influence the relations between the host and the pathogen, as well as between the food plants and herbivorous organisms (Aldea *et al*., 2006).
Results of the research on the influence of biotic stress caused by infestation with a root pathogen (*Phytophthora plurivora* Jung and Burgess) and feeding of the gypsy moth larvae (*Lymantria dispar* L.), on the properties of the Turkey oak seedlings in the conditions of elevated and ambient CO_2 concentrations is presented in this paper.

Material and Methods

Plant material: One-year old Turkey oak (*Quercus cerris* L.) seedlings, grown from acorns that were collected on multiple locations in the vicinity of Belgrade, were used for the experiment.
The seedlings were grown on peat and perlite substrate (70:30 ratio), in PVC bags of 750 cm^3.
Inoculum: 500 cm^3 of fine vermiculite and 40 cm^3 of millet were measured in one liter Erlenmeyer flasks. Then, 350 ml of liquid V8 substrate was added to the mixture. The V8 substrate was prepared with 200 ml/l of V8 juice (Biotta, Swiss), 3 g/l of CaCO3 and 800 ml/l of distilled water (Jung *et al*. 1996). After mixing, the mixture was sterilized in an autoclave for 20 minutes at 120°C. Pure culture of *P. plurivora* was taken from the University of Belgrade-Faculty of Forestry collection, maintained by Milenković I., and developed for 3-5 days on V8-agar media (200 ml/l of V8 juice (Biotta, Swiss), 20 g/l of agar (Torlak, Serbia), 3 g/l of CaCO3 and 800 ml/l of distilled water). After inoculation, the Erlenmeyer flasks were closed with a sterile plug made out of wadding and aluminum foil. Incubation was at room temperature in the dark for 4-6 weeks. Before the inoculation itself, the inoculum was washed in sterile distilled water, so that the potential bacterial contaminants and sugar from the substrate that could be a carrier of bacterial colonies could be removed.
Inoculation: The inoculation was conducted by adding of around 40 cm^3 of inoculum to the plants rhizosphere. After inoculation, the plants were immediately flooded for 72 hours.
Insect material: Gypsy moth egg masses were collected in an oak forest in the vicinity of Bor. They were kept in a freezer at a temperature of 4 °C until the spring 2018. Before the beginning of the experiment they were put at a temperature of 25 °C in order to induce hatching. After hatching, the larvae were fed with artificial food in petri dishes (120 x 15 mm) at a temperature of 23º C, Rh 75% and light regime 15:9 (day: night) until molting to the fourth larval stage.
Experiment design: After germination of the acorns in the laboratory, from January, the seedlings were kept in controlled conditions at a temperature of 20 +/-1 °C. At the beginning of March half of the total number of plants were exposed to the elevated CO_2 concentration, while the rest of the plants were grown in the conditions of ambient CO_2 concentration. At the beginning of April, a part of the plants was subjected to the inoculation with *P. plurivora*, and then to the feeding of the gypsy moth larvae. Thus, 6 experimental groups were formed as such: CA (no biotic treatment, ambient CO_2), CE (no biotic treatment, elevated CO_2), PA (inoculated with *P. plurivora*, ambient CO_2), PE (inoculated with *P. plurivora*, elevated CO_2), LA (feeding of *Lymantria dispar*, ambient CO_2) and LE (feeding of *Lymantria dispar*, elevated CO_2). The influence of biological stress in the conditions of ambient and elevated CO2 levels on Turkey oak seedlings was estimated by comparing the leaf mass, shoot mass and plants height.
Statistical analysis: For testing the influence of inoculation with *P. plurivora*, and feeding of the gypsy moth larvae on the Turkey oak seedlings, analysis of covariance (ANCOVA) with plant status (exposure to larval feeding on the leaves, inoculation or no biological treatment) and environmental conditions (ambient or elevated CO_2 level) as independent variable and

leaf mass, shoot mass and plants height at the end of the experiment as dependent variables, were used. Plants height before treatment was used as covariate. Fisher's least significant difference test was used to examine the differences in mean values of individual treatments.

Results and discussion

Results of the research on the influence of inoculation with *P. plurivora*, feeding of the gypsy moth larvae as well as elevated CO_2 concentrations on the performance of Turkey oak seedlings are presented in Table 1 and Graph 1. The results of the covariance analysis (ANCOVA) shoved statistically significant influence of the biotic treatment (inoculation and feeding on the leaves) on the shoot mass and height of the Turkey oak plants, while the CO_2 concentration had a significant influence on all of the 3 monitored properties of the plants. Interaction between biotic and environmental conditions showed no statistically significant influence on any of the analyzed properties. However, plants height before the beginning of the experiment, used as a covariant in the analysis of variance, significantly influenced all of the analyzed properties (Table 1).

Plants from the LA group had the lowest average leaf mass, while the plants from the LE group had the greatest average leaf mass (Graph 3a). Statistically significant difference existed between the leaf mass in these two groups, while the other groups except the PA group showed no statistically significant differences (Table 1, Graph 3a). No statistically significant differences in the shoot mass existed between the plants which grew in the conditions of elevated CO_2 concentration, regardless of the biotic treatment, as well as between these three groups and groups of plants of the PA group (Table 1, Graph 3b). However, between this group of seedlings, and the other two which grew in the conditions of ambient CO_2 concentration, statistically significant differences in the average shoot mass existed (Table 1, Graph 3b). The shoot mass was about 50% lower in the CA and the LA group. The same pattern was recorded with the height of the plants, although the differences between the PA group and the other two groups that were grown in the same conditions was about 30% lower (Table 1, Graph 3c)

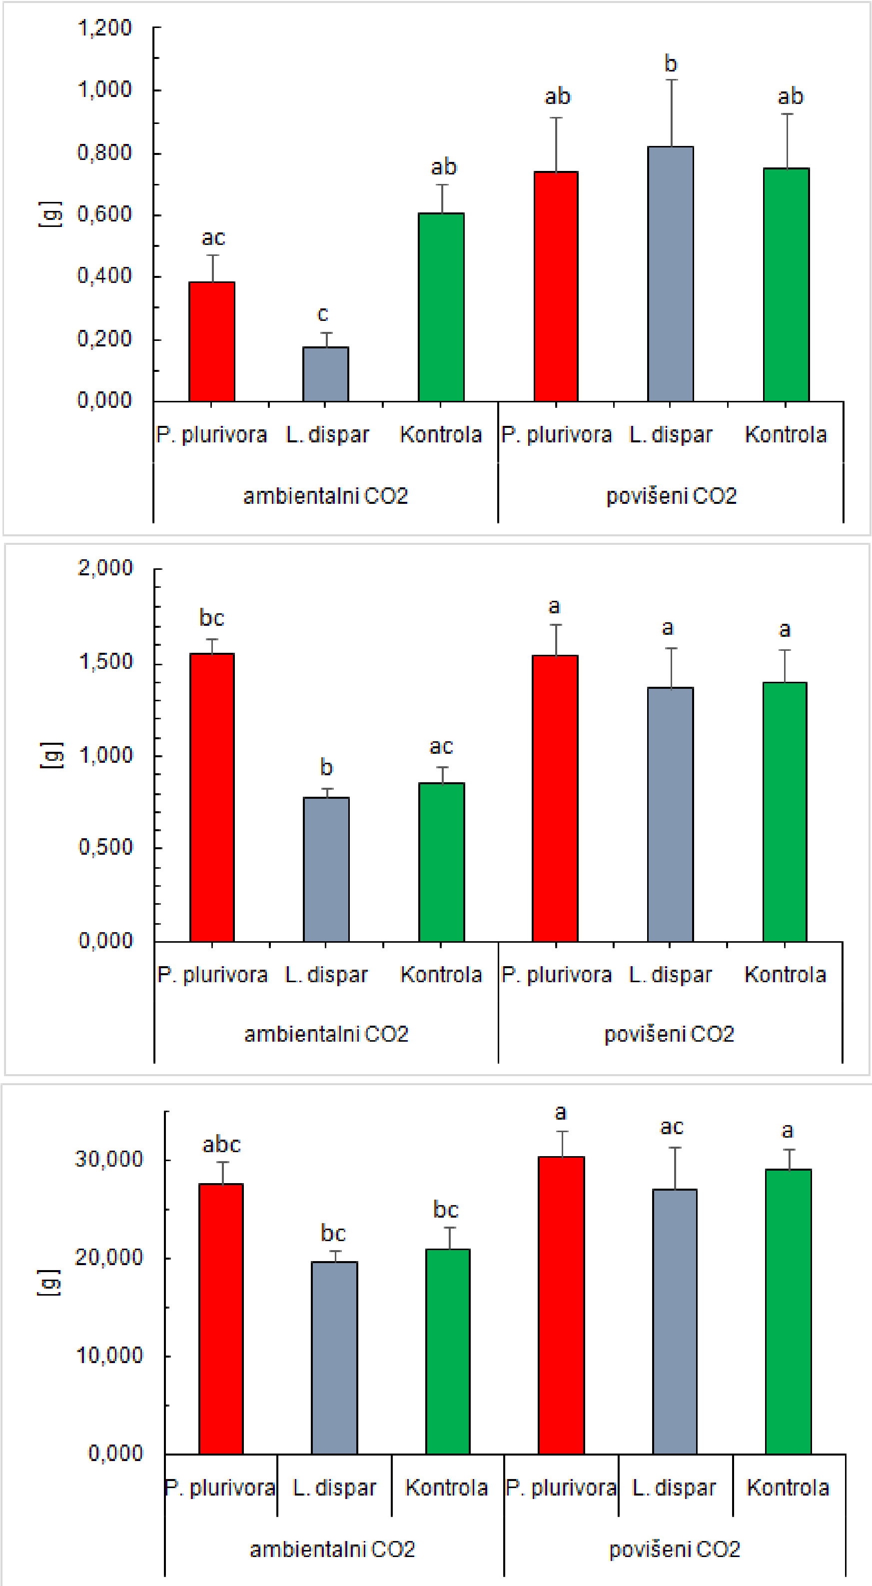

Graph 3. Influence of elevated CO_2 content on (a) leaf mass, (b) shoot mass and (c) plants height

Turkey oak, as well as other oak species are threatened by many pathogens such as fungi-like organisms from the *Phytophtora* genus (Jung *et al*., 1996, 2000; Balci and Halmschlager, 2003 a, b; Balci *et al.*, 2007). Among them significant damage is caused by the species *P. plurivora*, previously known worldwide as *P. citricola* (Balci and Halmschlager, 2003 a, b;

Jung and Burgess, 2009). In the same time, Turkey oak is the most favorable host plant for the development of the gypsy moth larvae (Milanović, 2014). This harmful pest causes the most significant damage in its forests (Mihajlović, 2015). On the other side, we are witnesses to the changes that are happening under the influence of elevated CO_2 concentration, that can also influence the insects. A large number of scientists researched the influence of CO_2 on the feeding and development of insects on different tree species (Traw *et al.*, 1996; Henn and Schopf, 2001; Hättenschwiler and Schafellner, 2004; Wang *et al.*, 2009).
As Turkey oak seedlings are concerned, an interesting fact is that the greatest leaf mass was recorded on the plants which were exposed to the conditions of elevated CO_2 concentration. It was 30% higher compared to the leaf mass of the plants that grew in the ambient CO_2 conditions. Broadmeadow and Jackson (2000) determined that the sessile oak (*Quercus petraea* (Mattuschka) Liebl) leaf mass was 39% greater if the plant were exposed to the elevated CO_2 concentrations. The plants height and shoot mass were also higher if the plants were exposed to the elevated CO2 concentration. The research of Norby *et al*. (1986) shows an increase in growth of white oak (*Quercus alba* L.) seedlings by 85% if the plants are grown in conditions of increased concentration of CO_2 (690 ppm).
According to Jankowiak *et al*. (2014) *P. plurivora* is a common species that occurs in oak forests, and next to *P. quercina* Jung (Jung *et al*., 1996, 1999), *P. cinnamomi* Rands (Jung et al., 2018) it is considered as one of the most aggressive pathogens threatening the oak trees.

Conclusion

The results obtained in this paper show that the inoculation of the root with a pathogen can have a stimulative effect on plants height and shoot mass. As the root of the plant was attacked, the resources were allocated to the unaffected parts of the plants, which eventually led to the increase in growth of the above ground parts.

Abstract

The study was conducted to investigate the macro and micro elements of several herbs and condiments. Mineral contents of samples were measured by Inductively Coupled Plasma Atomic Emission Spectrometry (ICP-AES). The macro elements of herbs and condiments were Ca (234-40059 mg/kg), Mg (649-7312 mg/kg), K (5788-37781 mg/kg), P (526-8412 mg/kg), and S (741-8117 mg/kg). The highest Ca, P and S contents were found in urtica, black cumin and ginger, respectively. Basil had the maximum Mg (7312 mg/kg) and K (37781 mg/kg) contents. The lowest Ca (234 mg/kg) and K (5788 mg/kg) amounts were determined in sesame, while the cinnamon, turmeric and sumac have the minimum Mg, P and S contents, respectively. The micro elements of samples were B (6.4-51.1 mg/kg), Cr (0.10-2.62 mg/kg), Cu (5.9-22.8 mg/kg), Fe (36-781 mg/kg), Mn (3.6-624.3 mg/kg), Ni (0.12-5.80 mg/kg) and Zn (5.0-62.1 mg/kg). The highest and lowest Fe contents were found in balm (781 mg/kg) and rose (36 mg/kg) samples, respectively. While Zn contents of samples change between 5.0 (rose) and 62.1 mg/kg (black cumin), Cu contents ranged from 5.9 (turmeric) to 22.8 mg/kg (basil). The Mn content of clove (624.3 mg/kg) was higher than other condiments. Additionally, rosemary and thyme contained higher B content, with the ranges of 48.1 mg/kg and 48.0 mg/kg, respectively. The study revealed that investigated edible condiments are good source of P, K, Ca, Mg and Fe. The urtica, senna and basil condiments are thought to be beneficial for bones and teeth due to their high Ca content. However, the clove, rosemary and thyme contain a high amount of Mn and B elements, so over-consumption of these herbs can create toxic effects.

Key words: *condiments, herbs, mineral, heavy metal, ICP-AES*

Introduction

Herbs and spices, grown wildly in various regions of the world, have been used for several purposes since ancient times. Several uses of these plants are known for culinary purposes (Baytop, 1984; Koedam, 1986). Spices refer to all of the edible parts of a plant used for flavoring or coloring foods, including fruit, seed, root, bark or vegetable substance (Bouba et al. 2012; Susheela, 2000). Some are often used as preservative against the harmful bacteria or prevented their growth (Bitting and Sherman, 1998). Actually the specific uses of spices tend to vary considerably among cultures and countries: medicine, religious rituals, cosmetics, perfumery and foods. As food, they have been shown to play an important role in health partially as sources of nutrients (Brakat et al., 2003; Takruri and Dameh, 1998; Bouba et al., 2012). Plants constitute an important source of active natural products, which differ widely in terms of structure and biological properties. They have played a remarkable role in the traditional medicine of various countries. In recent years, the prevention of cancer and cardiovascular diseases has been associated with the ingestion of spices, fresh fruits, vegetables, or teas rich in natural antioxidants (Virgili et al., 2001). In terms of structure, biological properties and role in the traditional medicine, plants are an important source of active natural products (Virgili et al., 2001). Spices stimulate the appetite and increase the flow of gastric juice. They also play a role in many of the industries, and are used in perfumery, soaps, incense, as dyes in histology and in various acts (Onyesom and Okoh, 2006).

Macro and micro elements have significant effect on bio-chemical processes in the human body (Arceusz et al., 2010). The proper intake of elements such as sodium, potassium, magnesium, calcium, manganese, copper, zinc and iodine reduces the risk of especially cardiovascular diseases in humans. In addition, the main minerals function as structural components of tissues and show great importance in cellular and basal metabolism and water and acid-base balance (Imelouane et al., 2011). Some micro elements exhibite a significant role as catalysts or parts of prosthetic groups for enzymes, and therefore, element deficiency causes various health problems (Ebrahim et al., 2012). However, excessive consumption of mineral-rich plants causes to various health problems (Jabeen et al., 2010). Herbal plants and spices include not only essential but also toxic elements in different concentrations (Soylak et al., 2012). Accordingly, determination of mineral content of herbal plants and spices have importance and it is necessary to investigate the mineral contents of these plants for quality controls. The objective of present study was to determine the mineral and heavy metal contents of several herb and condiments used for several purposes in Turkey.

Material and Methods

Materials

Spice samples were purchased from local market in Turkey (Konya). Samples were dried at 70 ^{o}C in oven, and than the dried materials were then ground in a mortar and the ground material sieved in 10 mesh diemater, and sealed in bottles for storage until analysis. The common, scientific and family names of the spices are given in Table 1.

Determination of mineral contents

Methods

Provided condiment samples were dried at 70 ºC in a drying cabinet with air-circulation until they reached constant weight. Later, about 0.5 g dried and ground samples were digested by using 5ml of 65% HNO_3 and 2 ml of 35% H_2O_2 in a closed microwave system (Cem-MARS Xpress). The volumes of the digested samples were completed to 20 ml with ultra-deionized water, and mineral contents were determined by Inductively Coupled Plasma Atomic Emission Spectrometry (ICP AES) (Varian-Vista, Australia). Measurements of mineral concentrations were checked using the certified values of related minerals in the reference samples received from the National Institute of Standards and Technology (NIST; Gaithersburg, MD, USA) (Skujins, 1998).

Working conditions of ICP-AES:

Instrument	:ICP-AES (Varian-Vista)
RF Power	: 0.7-1.5 kw (1.2-1.3 kw for Axial)
Plasma gas flow rate (Ar)	: 10.5-15 L/min. (radial) 15 " (Axial)
Auxilary gas flow rate (Ar)	:1.5 "
Viewing height	: 5-12 mm
Copy and reading time	:1-5 s (max.60 s)
Copy time	: 3 s (max. 100 s)

Statistical analyses

Results of the research were analysed for statistical significance by analysis of variance (Püskülcü and İkiz, 1989).

Table 1. Plants used in this study

General Name	Botanical name	Family	Used parts
Sage	*Salvia officinalis* L.	Labiatae	Leave+Flower
Ginger	*Zingiber officinale*	Zingiberacae	Root
Rose	*Rosa canina* L.	Rosaceae	seed
Clove	*Syzygium aromaticum*	Myrtaceae	Flower bud
Turmeric	*Curcuma longa*	Zingiberaceae	Root
Marshmallow	*Althaea officinalis*	Malvaceae	Leaves + Flower
Fennel (sweet)	*Foeniculum vulgare* subsp. *dulce*	Umbelliferae	Fruit
Thyme	*Thymbra spicata* L.	Labiatae	Leave+Flower
Tilia	*Tilia* sp. L.)	Tiliaceae	Leaves + Flower
Black cumin	*Nigella sativa* L.	Ranunculaceae	seed
Paprica	*Capsicum annuum* L.	Solanaceae	Fruit
Mint	*Mentha piperita* L.	Labiatae	Leave
Cumin	*Cuminum cyminum* L.	Umbelliferae	Fruit
Pepper (black)	*Piper nigrum* L.	Piperaceae	Fruit
Rosemary	*Rosmarinus officinalis* L.	Labiatae	Leave+Flower
Sumac	*Rhus coriaria* L.	Anacardiaceae	Pericarp
Cinnamon	*Cinnamon zeylanicum*	Lauraceae	Bark
Sesame	*Sesamum indicum* L.	Pedaliaceae	seed
Basil	*Ocimum basilicum* L.	Labiatae	Leave+Flower
Coriander	Coriandum sativum	Umbelliferae	Fruit
Muğla Sage	Salvia fruticosa	Labiatae	Leave +Flower
Scotch thistle	*Onopordum acanthium* L.)	Compositae	seed
Olive	*Olea europaea* L.	Oleaceae	Leave
Urtica	*Urtica dioica* L.	Urticaceae	Leave
Senna	*Cassia spp.*	Fabaceae	Leave
Anise	*Pimpinella anisium* L.	Umbelliferae	Fruit
Parsley	*Petroselinum crispum* L.	Umbelliferae	Leave
Fenugreek	*Trigonella foenumgraecum* L.	Fabaceae	seed
Balm	*Melissa officinalis* L.	Labiatae	Leave
Fennel (bitter)	*Foeniculum vulgare* subsp. *piperitum*	Labiatae	Fruit

Results and Discussion

The macro element compositions of several condiments and spices are given in Table 2. Mineral contents changed in regard to condiment types. According to results, Ca, Mg, K, P and S contents were very high in all the condiments. Cr, Cu, Mn and Ni contents of condiments were found low an important level (Table 3) ($p<0.05$). The level of potassium of all samples in this study was found to be higher than other elements. K contents of samples ranged from 7567 mg/kg (Cinnamon) to 37781 mg/kg (Basil). Also, Ca contents were found between 549 mg/kg (turmeric) and 40059 mg/kg (urtica). While Mg contents of condiments change between 649 mg/kg (cinnamon) and 7312 mg/kg (basil), P contents ranged from 526 mg/kg (turmeric) to 8412 mg/kg (black cumin). In addition, S contents of condiments changed between 741 mg/kg (sumac) and 8117 mg/kg (ginger). Micro element and heavy metal contents of condiments are shown in Table 3. While the highest Fe content is found in balm (781 mg/kg), the lowest Fe was determined in rose (36 mg/kg). Zn contents of all condiments were found between 5.0 mg/kg (rose) and 62.1 mg/kg (black cumin). Cu contents of samples ranged from 5.9 mg/kg (turmeric) to 22.8 mg/kg (basil).

Özcan (2004) reported that sahlep (*Orchis* spp.) and dill (*Anethum graveolens* L.) contained 2384 ppm and 35723 ppm potassium, respectively. According to the same researcher, while iron content change between 46.7 ppm caraway (*Carum carvi* L.) and 1229 ppm (*Lavandula officinalis* L.), selenium content varied from 0.15 ppm in savory (*Satureja hortensis* L.) to 5.03 ppm in mustard (*Sinapis alba* L.). Besides, zinc contents of spices were found between 5.54 ppm sumac (*Rhus coriaria* L.) and 49.7 ppm in black cumin (*Nigella sativa* L.) (Özcan, 2004). The result shows that the aniseed contained phosphorous (2027.10 mg/kg), iron (5.40 mg/kg), magnesium (270.10 mg/kg), calcium (602.8 mg/kg), sodium (365.10 mg/kg) and potassium (887.80 mg/kg). The poppy seeds had phosphorous (3980.0 mg/kg), iron (5.475 mg/kg), magnesium (287.20 mg/kg), calcium (690.50 mg/kg), sodium (81.16 mg/ kg) and potassium (746.70 mg/kg) contents. The Fenugreek seeds contained phosphorous (2950.0 mg/kg) and potassium (124.82 mg/kg) (Kumaravel and Alagusundaram, 2014). In other study, K content was found very low in *T. spicata* (1200.99 ppm), *R. canina* (5316.84 ppm) and *C. angustifolia* (6728.64 ppm), but was very high in *M. chamomilla* (27497.81 ppm), *C. casia* (29167.53 ppm) and green tea (28890.93 ppm). In addition, *C. casia* (11733.96 ppm), *F. vulgare* (10145.48 ppm) and green tea (12698.05 ppm) were rich in P (Özcan et al., 2008). Our results shown partly differences with literature values conducted on different spice and herbs. These differences might be due to growth conditions, geographical variations and analytical procedures.

The most of elements which may contribute to biological processes, but which have not been established as essential, are garium, copper, crom and nickel (Macrae et al., 1993). Decreasing of these toxic element contents is an advantage. This study supports to contribute to knowledge of the nutritional properties of these plants. In addition, knowledge of the mineral contents, as condiments is of great interest.

Conclusion

These spices have the potential of contributing tothe nutritional and health needs of their consumers. The results show that spice powder is a good source of calcium, sodium, potassium, magnesium, selenium and phosphorous and spice was a very important human nutrient since their consumption has increased in recent years (Kumaravel and Alagusundaram, 2014). As a result, minerals are important in the diet because they serve as cofactors for many physiologic and metabolic functions. K, P and Mg were detected at significant levels in condiment and herbs. A significant levels of Ca, Fe, Mn and Zn were also present in the condiments. The study revealed that investigated edible condiments are good source of P, K, Ca, Mg and Fe. Heavy metals in spice are a problem for human consumption and hence a detailed study of minerals in spices is needed.

EFFECT OF SALICYLIC ACID APPLICATION ON PHENYLALANINE AMMONIA-LYASE ACTIVITY AND TOTAL PHENOLIC CONTENT IN WHEAT (*Triticum aestivum* L.) AND BUCKWHEAT (*Fagopyrum esculentum* MOENCH) PLANTS UNDER CADMIUM STRESS

Yana KAVULYCH*, Myroslava KOBYLETSKA, Olga TEREK

Abstract

Salicylic acid (SA) is considered as one of the most important signaling molecule involved in both abiotic and biotic stress tolerance. Application of optimal concentrations (0,05 mM) of SA enhances plants tolerance to cadmium stress by modulating levels of several metabolites including components of antioxidative defense, osmolytes, secondary metabolites, and metal-chelating compounds. When SA and cadmium (Cd) were applied simultaneously, the damage was less pronounced than without SA. Salicylic acid treatment itself also caused the oxidative stress, but decreased the phenylalanine ammonia-lyase activity, regulating phenolic synthesis. Thys, when the SA treatment was used prior the Cd stress, it prevented the damaging heavy metal effect.

Keyworlds: *Phenylalanine ammonia-lyase (PAL), phenolic compounds, salicylic acid, cadmium chloride.*

Introduction

Wheat is a major staple agricultural crop in Ukraine and other countries. Buckwheat (*Fagopyrum esculentum* Moench) belongs to crops of secondary importance in many countries. The main producers of buckwheat are China, Ukraine, Kazakhstan and Russian Federation, but generally it is consumed or traded locally. A heavy metal contamination issues have been of increasing in Ukraine and worldwide, with many documented cases of metal toxicity in a mining industries areas, foundries, smelters, coal-burning power plants and agriculture. The heavy metals accumulation in soils is of concern in agricultural production due to the adverse effects on food safety and marketability, crop yields and environmental health of soil organisms. Cadmium toxicity has a high impact on plants and consequently it affects an ecosystem, where plants form an integral component (Pinto *et al*., 2004; Bessonova *et al*., 2005; Topchiy, 2010; Versieren *et al*, 2017). On the other hand salicylic acid (SA) plays a key role in a plant disease resistance and responses to abiotic stressors. There are report that Cd exposure increased the free SA contents and increased total phenolic content in wheat and buckwheat plants.

Current research data support the possible mediatory role of the salicylic acid (SA) in protecting physiological and biochemical processes under the cadmium toxicity. Seed pretreatment with SA alleviated the negative effect of Cd on plant growth parameters. The same tendency was observed for the chlorophyll level. The positive effect of SA on salt-resistance for different plant species reported Who?. SA belongs to the class of phenolic compounds (Kohli, 2017). SA pretreatment of 0,05 mM also decreased the extent of negative Cd effect on wheat plants, as revealed by the decline in the level of phenolic content (Kolupaev, 2010; Szalai, 2013).

It was shown that SA activated and regulated phenylalanine ammonia-lyase (PAL), the key enzyme of phenolic compounds biosynthesis, in roots of wheat and buckwheat plants. This assumption is supported by the data on significant decline in Cd accumulation in SA-pretreated plants, especially in the shoots. We have studied the influence of the SA pretreatment of wheat and buckwheat seedlings on plant resistance to subsequent treatment with cadmium chloride. The aim of this work was to investigate the influence of exogenously applied SA on the content of phenolic compounds and PAL activity under the cadmium stress.

Materials and Methods

Wheat plants (*Triticum aestivum* L.) Podolianka variety and buckwheat (*Fagopyrum esculentum* Moench.) Rubra variety were used in the laboratory experiments. SA was applied for the seeds pretreatment. Previously sterilized how? seeds were soaked for 5 h in the SA (0,05mM) solution or distilled water (control). Then the seeds were germinated on a filter paper in Petri dishes at 23 °C, for three days. After that uniform seedlings were transfferred to the pots with a sterile sand and grown under the controlled conditions (16-h photoperiod). Cadmium chloride was applied in the dose 25 mg/kg to the which one ? part of plants. For our research we used plants grown without Cd and SA treatments – control, plants grown from seeds, treated with SA+Cd in substrate, and plants seeds treated only with SA, without $CdCl_2$. The content of phenolic compounds and phenylalanine ammonia-lyase activity were determined on the 7, 14 and 21 days of plant growth.

Phenylalanine ammonia-lyase activity assay. The PAL activity was determined spectrophotometrically by modified Zucker method (Zucker, 1965). For enzyme analysis 0,5 g of plant tissue were homogenized manually in 2 ml 25 mM borate buffer (pH 8,8) containing 23 μL mercaptoethanol. The homogenates were centrifuged for 20 min at 8000 g. The supernatant was used for enzymatic assay. The PAL assay system contained of 1 ml of the supernatant, 1 ml of buffer, 1 ml of 12 mM L-phenylalanine. The resulting mixture was incubated at 37 °C for 1 hour, the reaction was stopped by 15% trichloroacetic acid. Absorbance of the mixture was measured using spectrophotometer (ULAB 101). PAL activity was expressed in mM of cinnamic acid per gram of protein. Protein was determined by of Bradford method (Bradford, 1976).

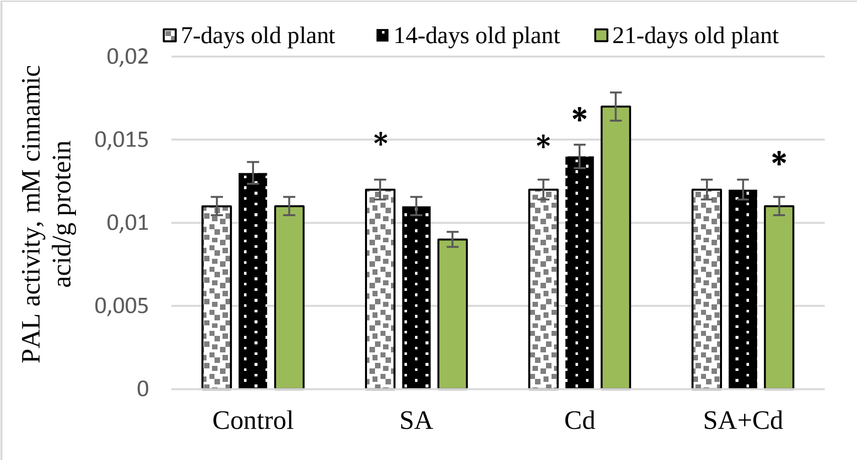
The content of phenolic compounds in the leaf and root extracts were determined by the Folin-Denise method. Absorbance readings were performed at 725-730 nm with ULAB 101 Spectrophotometer (Zaprometov, 1971).

Statistical analysis. Each experiment was performed in five replications. The means and standart deviations were calculated by the JMP Pro and Microsoft Office Excel. Statistical significance of difference was evaluated with Student's t-test ($P<0.05$).

Results and Discussion

PAL a key enzyme in the phenylpropanoid pathway, it is involved in the defense responses of plant cells (Apel, 2004). Synthesis of phenolic compounds and their accumulation under the stress conditions may be associated with an increased activity of PAL (MacDonald, 2007). Therefore, PAL has been generally recognized as a marker of environmental stress in different plant species (Korobkova, 2009). The PAL activity show significant changes for a short period of time in plant tissues (Smirnov, 2012). There are data whose? that PAL salt stress increased dynamic changes of the PAL activity in the 7-, 14-, and 21-days plants.

In our experiments under the SA (0,05 mM) treatment we observed significant 5 fold increasment of PAL activity in both wheat and buckwheat plants on the 7-day of experiment (Figure 1). But it decreased in 14- and 21-days old plants. Moreover, wheat plants had significantly higher PAL activity in roots tissue, than in shoots tissue. The obtained results indicate that roots are the main place of synthesis and localization of the phenolics. $CdCl_2$ increased the PAL activity by 3 times in the 7-days old plants. But, on the next time points $CdCl_2$ decreased enzymatic activity. PAL activity was lower under cadmium stress with SA (Figure1).



* P<0.05

Figure 1. Effect of $CdCl_2$ and SA on phenylalanine ammonia-lyase activity in wheat roots,

.

In shoots we observed linear change of enzyme activity, with a slight increase under cadmium stress. Salicylic acid has positive effect on the PAL activity in the wheat (Fig.2). The obtained data confirm data about early changes in PAL activity under the stress condition.

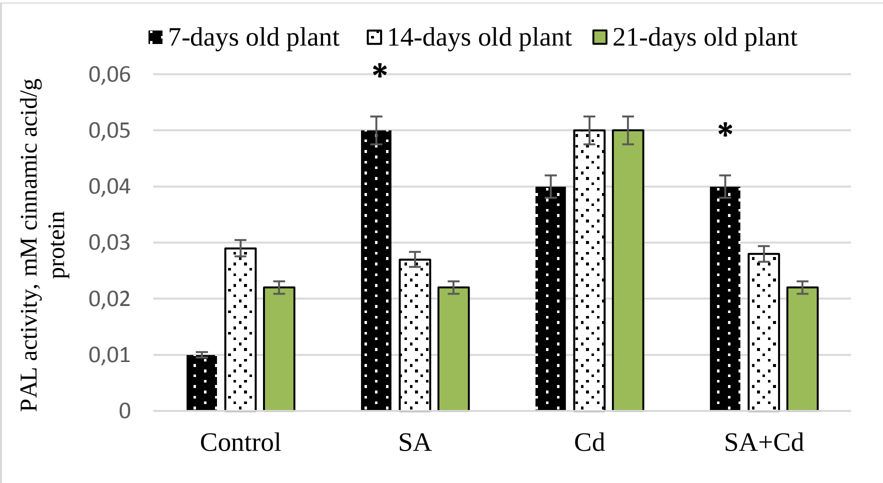


Fig.2 Effect of $CdCl_2$ and SA on phenylalanine ammonia-lyase activity in wheat shoots,
* – P< 0,05

Buckwheat plants in control have been characterized by a comparatively high level of the PAL activity in the roots. Under the $CdCl_2$ impact the enzyme activity increased 2-fold. Prolonged influence of cadmium caused a higher enzyme activity (Fig.3).

An increase of the enzyme activity have been shown in the shoots of the 7-days old plants under the cadmium stress, and decrease of this activity by 3 times in the 21 days-old plants. SA led to increase of the PAL activity, suppose, salicylic acid is phenolic compound and has a common way of synthesis with phenols (Fig.3, 4).

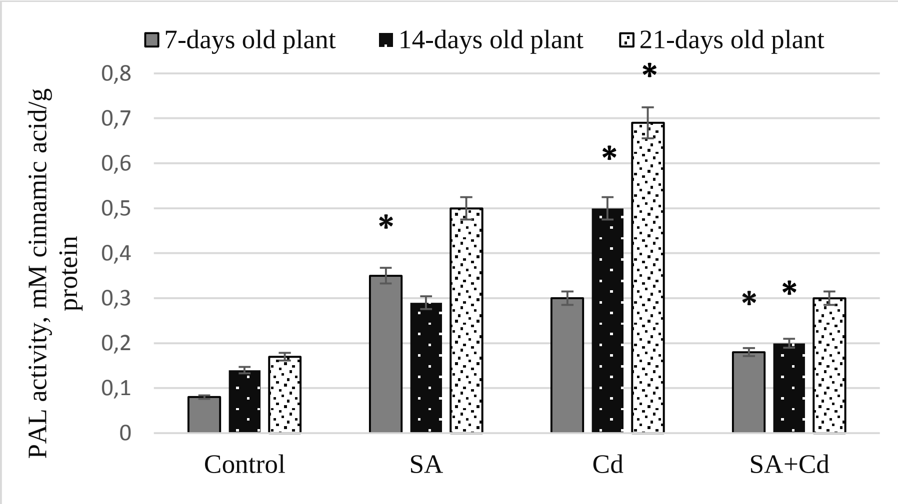

Fig.3 Effect of $CdCl_2$ and SA on phenylalanine ammonia-lyase activity in buckwheat roots, * – P<0,05

Comparing results with literature data, plants tissue usually have early PAL activity. The short-term increase in the activity of PAL and peroxidase enzymes, which activate the protective mechanisms of plants, was shown by (Evtushenko, 2008). Also changes in PAL activity caused by the action of biogenic factors - chitosan and salicylic acid (Szalai, 2013). Our results showed changes in the enzymes activity, without time or age dependence. Whereas, it was revealed that the enzyme activity depends on the cadmium chloride and SA. The higher PAL activity in buckwheat plants was detected (Fig. 3,4).

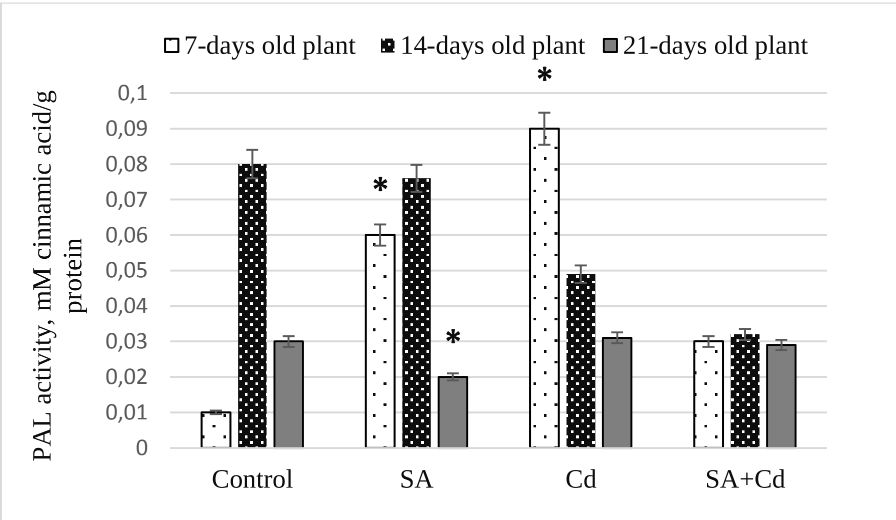

Fig.4 Effect of $CdCl_2$ and SA on phenylalanine ammonia-lyase activity in buckwheat shoots, * – P<0,05

The changes of PAL activity led to an increase or decrease in the content of total phenolic compounds, that are involved in a major processes, such as: cell wall formation, photosynthesis, respiration, plant-plant allelopathic interactions, protection plants against pathogens and herbivores. They are produced by plants in response to biotic or abiotic stresses (Pinto, 2004).

Determination of the total phenolic compounds in the wheat showed a differential accumulation predominantly in the roots tissues, and its decrease in the shoots of 14 and 21-days old plants (fig.5 A,B).

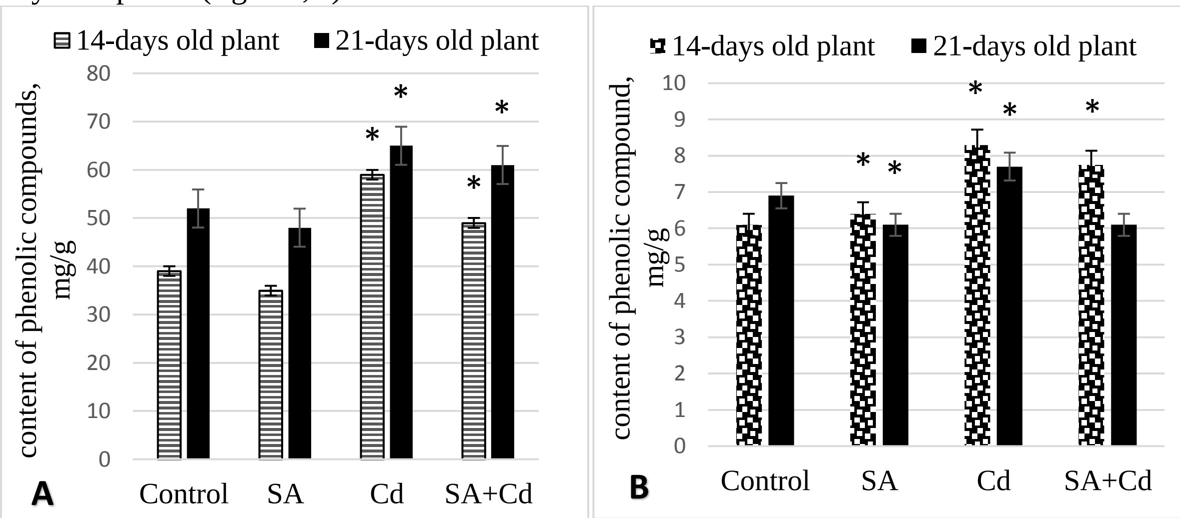

Fig.5 Effect of $CdCl_2$ and SA on phenolic contents in wheat A-roots, B-shoots, * – P< 0,05

The obtained results are consistent with the literature data, where in most cases the root tissue is the place of synthesis and localization of phenolic compounds. Significant accumulation of phenolic compounds is determined under the heavy metal stress. Cd induced an increase in the phenolics in the wheat roots and shoots. Under the prolonged action of cadmium chloride we noted the increase of the phenolic compounds in the roots, which is consistent with their protective functions and the ability to form chelate complexes with heavy metals (Clemens, 2006). Roots are first exposed and are the main source of a heavy metals in the plant organism. The high content of the phenolic compounds in roots and its relatively low content in shoots serve as a protective mechanism and a logical redistribution of phenolic compounds under the action of the stressor. The SA induced decrease in the content of phenolic compounds in both the roots and shoots of wheat plants.

In the buckwheat plants - the content of total phenolic compounds was high. Cadmium led to the increase of phenolic compounds by 1,5 time at the both time point – 14-, and 21 days-old plants (Fig.7).

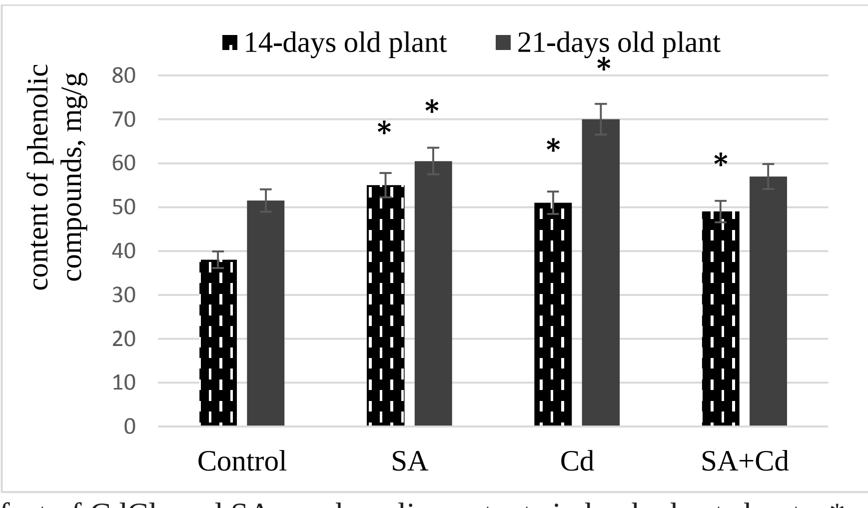

Fig.7 Effect of $CdCl_2$ and SA on phenolic contents in buckwheat shoots, * – P< 0,05

SA alone also increase their accumulation, but in the presence of cadmium chloride the concentration of phenolics was lower than in variants with Cd or SA. These results confirm the involment of SA in the stress responces under the cadmium impact.

Conclusions

In this research the effects of cadmium stress and salicylic acid on wheat and buckwheat plants in laboratory experiments were studied. SA can be recommended for the pretreatment of wheat and buckwheat seeds to alleviate cadmium toxicity. The protective role of salicylic acid in cadmium-stressed plants is unambiguous and can be related to inhibited antioxidant process, enhanced PAL activity or decreasing in content of total phenolic compound in leaves tissues and increasing in roots tissue.

CORNERSTONE OF STRATEGY AIMED AT CREATION OF RESISTANT VARIANTS OF CARROT (DAUCUS CAROTA L.) TO WHITE AND GRAY ROT PATHOGENS AT THE FEDERAL SCIENTIFIC VEGETABLE CENTER (FGBNU FNCO, RUSSIA)

Irina ENGALYCHEVA*, Elena KOZAR, Alexandr USHAKOV

Federal State Budgetary Scientific Institution (FGBNU) "Federal Scientific Vegetable Center" (FNCO), Russia

Abstract

The storage period of carrots (garden carrots) in Russia lasts 210-250 days, and commercial product losses exceed 25-40%. In this period, roots may be damaged by microorganisms representing 75% of all pathogens of this economically valuable crop. Composition and proportion of pathogens are variable and depend on year, carrot variety and place of growing. This impacts objectiveness of assessment of resistance to both individual and multiple pathogens and effectiveness of search for resistance sources for selection for immunity. In Moscow region, the most damage of carrots is caused by storage rot, especially by low temperature sclerotial pathogens *Sclerotinia nivalis* and *S. sclerotiorum* (white rot) and *Botrytis cinerea* (gray rot) and more rarely *Typhula ishikariensis* (Typhula blight). Major challenge of collaborative studies of FNCO phytopathologists, geneticists and crop breeders is search for resistance sources and creation of resistant forms for carrot protection. Samples of different origin are annually put into operation. Wild species of *Daucus L.* are engaged, inter- and intraspecific hybridization, inbreeding are used. The resistance of initial samples and resultant progeny is evaluated both at natural infection background (field, storage facilities) and *in vitro* with artificial inoculation with pure cultures of pathogens. Selection for resistant variants is based on population and individual multistep evaluation during the vegetation period, after placement for storage, before the mother roots planting. This resulted in carrot varieties and hybrids with highly resistant roots (Margosha, Rif F_1, Nadezhda F_1). The Institute is heavily involved in variety-improving selection of the key economic varieties for resistance to the most aggressive races of white and gray rot agents.

Keywords: *Daucus carota* L., varieties, resistance, *Sclerotinia*, *Botrytis.*

Introduction

Carrot is one of the most widespread and essential vegetable crops in Central Russia (Stepanov V., 2018; Zaltsman V.,2018). To resolve the problem of year-round supply of fresh carrot to the population, it is necessary to have cultivars that maintain high commercial quality for the storage period of 220-250 days (Borisov V., 2010; Yanchenko E.,2009). About 75% of the representatives of all pathogenic microorganisms inhabiting roots of this economically important crop were detected within this period. Phytosanitary situation deteriorates due to the fact that, along with increasing aggressiveness of local races of pathogens, introduction of new races with imported commercial produce of foreign cultivars takes place in recent years (Pidoplichko N., 1977).Current assortment comprises carrot cultivars and hybrids of Russian and foreign breeding, but foreign ones are often nonresistant to local races of phytopathogens, what leads to a need for using additional plant protection agents and to a rise in net cost.

Low-temperature-tolerant sclerotial fungi and fungal-like organisms that cause pit-storage rot do the most damage to carrot during storage. Causative agents belong to different taxonomical groups and have a common trait – they are adapted to cool environmental conditions. In relation to temperature, low-temperature-tolerant fungi comprise two types (Morita R., 1976).

They are obligate psychrophiles, with the optimum temperature for development about 0°C, and psychrotrophs having the optimum temperature about 20°C, but being able to maintain growth at a temperature 0°C or less. They include: fungal-like low-temperature-tolerant organisms from the kingdom Chromista, genera *Pythium* and *Phoma* (order Peronosporales); true fungi (*Mycota*, or *Fungi*) - anamorphic hyphomycetes of the genus *Fusarium*, several sac fungi (division Ascomycota) - *Sclerotinia* spp. and *Botrytis cinerea* of the order Helotiales, and a basidiomycete *Typhula* spp. There are psychrotrophic fungi of the agonomycete genus *Rhizoctonia* (Tkachenko O.,2017). At present, selection of resistant carrot cultivars and hybrids remains the most efficient method of storage diseases control. Therefore, one of the fundamental requirements of modern selection for immunity is the search for sources of resistance not only against a single agent, but against a complex of agents.

Researches of the Laboratory of Immunity at FGBNU FNCO have the following priority directions:

- Annual monitoring of storage diseases distribution; isolation, identification, and evaluation of aggressiveness of isolates of economically important carrot pathogens;
- Search for sources of resistance to pit-storage rot agents to obtain source material as a basis of a strategy of protection of carrot against these diseases.

The work is carried out in close collaboration with leading plant breeders of the center, which use obtained material for creation of new cultivars and hybrids of carrot.

Material and Methods

Studies were carried out in 2009-2019. The material for the studies includes carrot samples of different provenance and genetic origin from collection and breeding pool of the Laboratory of Edible Roots Selection and Seed Production and the Laboratory of Genetics and Cytology at Federal State Budgetary Scientific Institution "Federal Scientific Vegetable Center" (FGBNU FNCO). To broaden genetic diversity, our center uses inbreeding, intra- and interspecific hybridization, with involvement of wild species of *Daucus* L. as sources of resistance.

Roots were stored in a vegetable store cellar at a temperature of 1-2^{o}C and 90-92% humidity for six months (from the last ten days of September through the second ten days of April). Examination during storage period, sampling of affected roots in spring for analysis, evaluation of the degree of damage and resistance level of cultivar samples, identification of species composition of pathogens were conducted using appropriate methods and identification keys (Gannibal F., 2011; Gagkaeva T., 2006; Levkina L., 2013; Nelson P., 1983; .Pidoplichko N., 1977; Simmons E., 2002). Resistance of the collection and breeding carrot samples during storage period was evaluated using conventional indices: prevalence (%), affect index (mean score), disease progression degree (%).

Immunological appraisal of carrot sample resistance was done using the method of artificial inoculation of root discs under the conditions of dampening chamber *in vitro* by means of placing of an agar block of corresponding isolate of ten-days-old culture of the agent (Czapek medium) in the center (Fig. 1). The most aggressive isolates of main phytopathogens were used for inoculation. Cuvettes with inoculated discs were placed in the refrigerated heating circulator and incubated in accordance with biological characteristics of a phytopathogen at corresponding temperature (2-4°C, 10-12°C, 18-20°C, 24-26°C). The number of replicates was five. On the 7th and 14th days after inoculation, the diameter and depth of affected zone were measured, macro- and micromorphological characteristics of development of phytopathogens at discs were described (color, mycelium growth intensity, presence of conidial fructification, exudate, etc.).

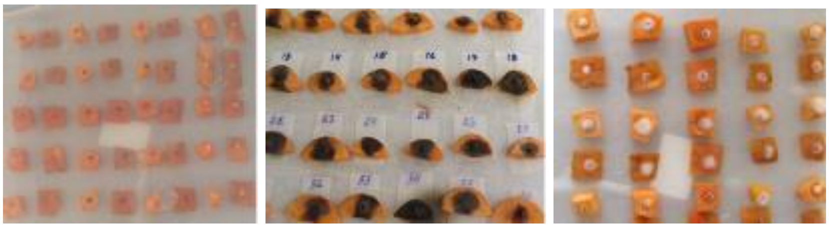

Figure 1. Inoculation of carrot root disks with agar blocks and isolates of different agents.

Samples were classified in respect of resistance against each agent according to the magnitude of total damage volume within an individual variant to five groups: resistant (I), tolerant (II), medium susceptible (III), susceptible (IV), and highly susceptible (V). Evaluation of samples for group resistance against examined groups of pathogens was conducted on the basis of analysis of all data obtained in natural conditions *in vivo* and in laboratory experiments *in vitro*. Promising sources of resistance were distinguished on the basis of the complex of all estimates.

Results and Discussion

Selection of adequate preventive and well-timed protective measures shall be based on understanding of composition of the most deleterious agents in vegetable crops with due account for ecological and geographical peculiarities of agricultural zones. Recently, the following factors further changes of phytosanitary situation: rise of aggressiveness of local pathogen races; introduction of new races with imported seeds; insufficient knowledge about species composition of micromycetes; and increasing of abiotic stress level in agrocoenosis of vegetable crops. All these factors lead to significant alteration of geographical distribution and genetic composition of populations of phytopathogens and influence appraisal of host plant resistance/susceptibility, what is especially important to take into account when searching for sources and donors of resistance in breeding.

Monitoring of carrot cultivation within last 40 years demonstrates structural changes of pathocomplex, replacement of dominant species, increase of virulence and aggressiveness of microbial groups being of little pathogenicity earlier. The causes of these population shifts are related mainly with ecological factors influencing interactions in pathogen-plant system. The most important factor in this system is thermal balance of agro-ecological niche in Moscow region –observations demonstrate sharp rise of mean daily atmospheric temperature in the last decade as compared with 1970-1980s (Fig. 2).

Under the conditions of Moscow region, white rot caused by fungi of the genus *Sclerotinia* inflicted the most damage to carrots within the

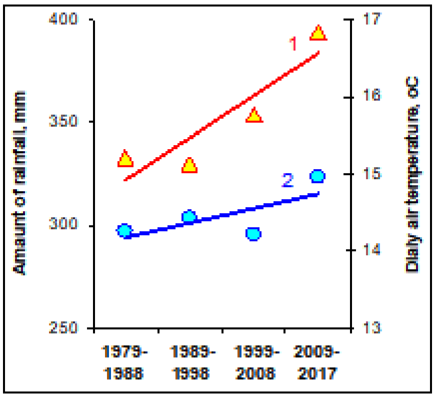

Figure 2. Mean daily atmospheric temperature (1) and total precipitation (2) per vegetation at different times (1979-2017).

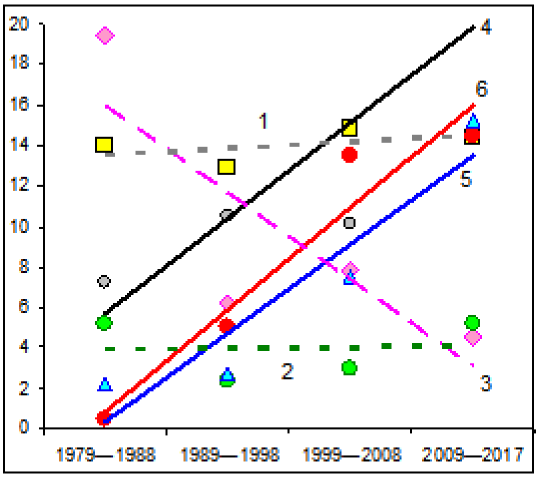

Figure 3. Динамика распространения вредоносных болезней корнеплодов моркови столовой при хранении в разные интервалы времени (1979-2017 годы): 1 - Sclerotinia spp.; 2 - Phoma spp.; 3 - Botrytis spp.; 4 - Alternaria spp.; 5 - Fusarium spp; 6 - Pectobacterium carotovora

whole observation period (Figure 3-1). In the last decade, apart of previously widespread *Sclerotinia sclerotiorum* (Fig.4C), increase of aggressiveness of the fungi *S. nivalis* (Fig. 4B) and less often *Typhula ishikariensis* (typhulosis) is detected.
For the first time, staff of the Laboratory of Immunity at FGBNU FNCO detected *S. nivalis* on carrot roots in storage in 2009, and *T. ishikariensis* – in 2011 (Timina L., 2010). It is difficult enough to obtain a perfect stage of *S. nivales*, hence, to identify this species, polyacrylamide gel electrophoresis of globulins that allows distinguishing *S. nivales* among systematically closely related fungi was used (Tkachenko O., 2017). The local population of this pathogen is heterogeneous and consists of strains with various aggressiveness (Tkachenko O., 2010). Losses in carrots in storage caused by white rot amounted to 10-60% depending on the conditions and cultivars.

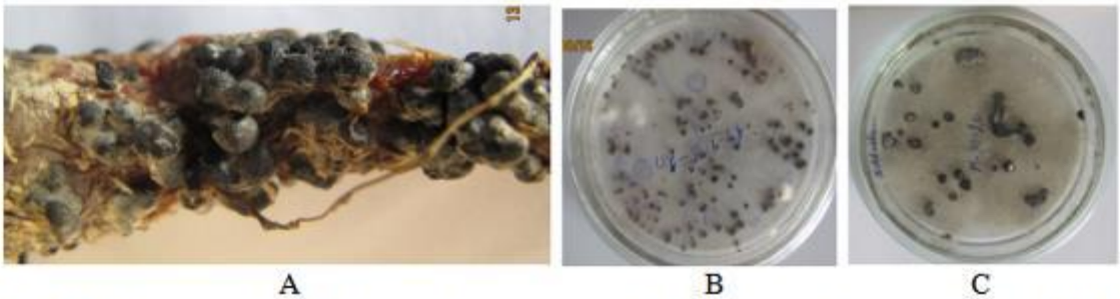

Figure 4. Симптомы поражения корнеплода моркови столовой белой гнилью (A); склероции гриба *S. nivalis* (B); склероции гриба *S. sclerotiorum* (C) на КМА.

Starting from 2000s, along with the rise of mean multi-year temperatures, decrease of harmfulness of grey rot (caused by *Botrytis cinerea*) (Fig. 3-3) and expanding of distribution and increase of aggressiveness of bacteriosis (caused by *Pectobacterium carotovora*), fusariosis and alternariosis occur (Fig. 3-6).
The assemblage of pathogens involved in Alternaria rot or black rot includes alternarioid hyphomycetes of the genera *Alternaria*, *Stemphilium*, *Ulocladium*, *Embilisia*. The fungi of the genus *Alternaria* - *A. radicina* (Fig.5A), *A. cheiranthi* (Fig.5B), *A. corotiincultae* (Fig. 5C), *A. cinerariae* (Fig.5D) are the most harmful; in some years, their expansion reaches 34%.
According to the data of long-term monitoring, species composition of micromycetes of the genus *Fusarium* in the Moscow region has expanded. Among the fungi of this genus being the agents of Fusarium rots, the following species were isolated and identified: *F. oxysporum*, *F. avenacium*, *F. nivale*, *F. chlamidosporum*, *F. solani*, *F. culmorum*, *F. semitectum*. Occurrence of new species is explained by extreme plasticity of majority of them. Having high adaptivity and prompt modifiability, the fungi of the genus *Fusarium* are highly persistent (Seredin T., 2018). In recent years, *F. solani*, *F. semitectum*, and *F. oxysporum*

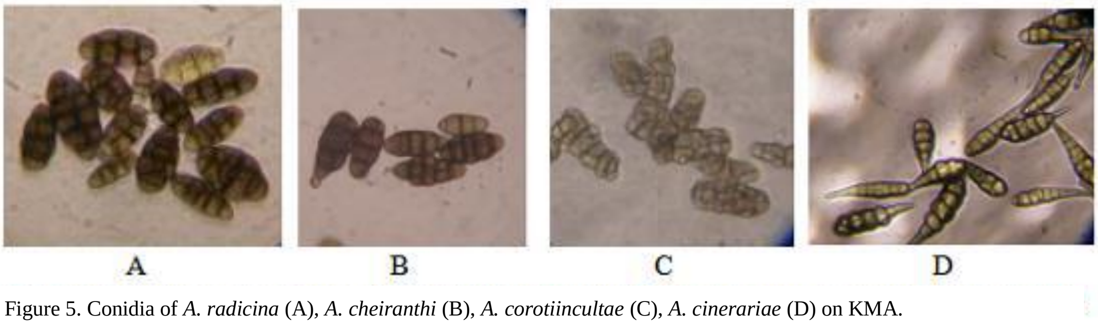

Figure 5. Conidia of *A. radicina* (A), *A. cheiranthi* (B), *A. corotiincultae* (C), *A. cinerariae* (D) on KMA.

dominate (Fig. 6 -A,B).

Recently, we isolated and identified on damaged carrot roots a thermophilous fungus *Trichotecium roseum* causing soft pink rot of roots in storage (Fig.6-C). In 2013 and 2015, roots of susceptible cultivars were damaged by 23 and 55%, respectively (Timina L., 2015). One of the causes of significant post-harvest carrot losses in storage may be Gliocladium rot, caused by a fungus *Gliocladium roseum* (Fig. 6-D). It is poorly known in carrots, but detected previously in the Far East causing wilting in kidney bean, pea, soybean, as well as soft watery rot on tomatoes. In Germany, Gliocladium rot of potatoes was described (Timina L., 2015). According to our data, this agent may occur in carrot roots both in mixed dry rots and separately.

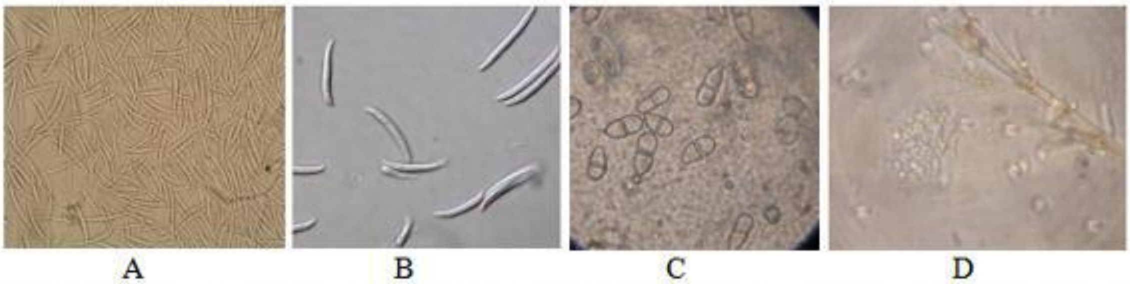

Figure 6. Conidia of *F. oxysporum* (A), *F. solani* (B), *Trichotecium roseum* (C), *Gliocladium roseum* (D) on KMA.

In the pathogenesis of pit-storage rot, assemblages of microorganisms may include the fungi of the genera *Pithium* (Pithium rot), *Cylidrocarpon* (cavity spot), *Verticillium* (verticillosis), *Aspergillus* and *Penicillium* (storage molds) along with aforementioned pathogens.

As noted above, harmfulness of some pathogens is of epiphytotic nature, while others demonstrate focal occasional character as yet. Therefore, the Center conducts proactive breeding continuously, because cultivars resistant against some pathogens are in many cases nonresistant against others. Moreover, the requirements of contemporary breeding for immunity determine the necessity of search for sources of resistance both against single agents and against a complex of pathogens. To make reliable estimate of carrot cultivar types resistance against main agents of storage diseases, the Laboratory of Immunity at FGBNU FNCO conducts laboratory immunological examination by the method of artificial inoculation annually. The most virulent fungal isolates of the genera *Sclerotinia*, *Botrytis*, *Alternaria*, *Stemphilium*, and *Fusarium* from the Laboratory's collection are used for inoculation. In accordance with the results obtained in recent years, cultivar types Margosha, Nadezhda F_1, Rif F_1, Chantenay 2461 have group resistance against fungal storage diseases, therefore, they may be of interest as a valuable source material for carrot breeding for resistance (Fig. 7).

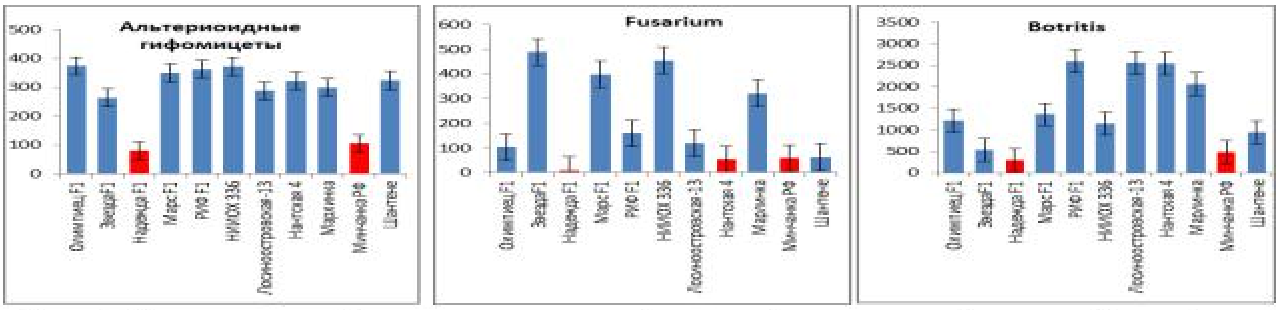

Figure 7. Comparison of carrot cultivar types in respect of resistance against pathogens in conditions of artificial inoculation of root discs. The vertical line sets mean size of damage zone of discs in mm^3.

On frequent occasions, economically valuable cultivar types lose eventually their resistance against storage diseases agents. Damage level varies to a large extent within populations of some cultivars. This gives us an opportunity to conduct intrapopulation selection of the most resistant forms as a part of strain-improving breeding. The Laboratory carries out artificial

inoculation and individual evaluation of resistance of genotypes against the complex of pathogens; groups of roots with different levels of resistance against a complex of pathogens are formed in populations, and they are passed to breeders for obtaining seed progeny in group isolators on isolated plots. The most valuable group is the group comprising genotypes with high resistance against most agents. In the majority of cases, their ratio does not exceed 10% of all analyzed roots. The material obtained as a result of immunological examination is passed to breeders, who include it into breeding process of creation of new cultivars and hybrids of carrot.
The degree of resistance of roots of a particular cultivar/hybrid to storage diseases eventually influences preservation and output of carrot roots following storage, and high crop yield not always ensures low costs of commercial produce at the time of selling (see Table).

Table – Comparative characteristics of Russian and foreign cultivars of carrot on the basis of resistance against storage diseases (2018-2019)

Group	Sample	Crop yield, t/ha	Losses due to storage diseases		Cost of commercial products after storage, rub/kg
			%	t/ha	
I	Marlinka (Russia)	46	11,7	5,4	8,71
	Narman	42	17,2	7,2	9,52
	Spedo	42	22,2	9,3	9,60
	Nantes 2 Tito	42	56,5	23,7	10,71
II	Nadezhda F_1 (Russia)	55	2,6	1,4	7,35
	Chantenay 2461 (Russia)	69	6,1	4,2	6,10
	Baltimore F_1	60	37,5	22,5	7,45
	Kuroda 5 Sun	65	16,7	10,8	6,56
	Nerac F_1	61	18,2	11,1	6,94
	Kuroda Power	70	40,0	28,0	7,69
III	Rif F_1 (Russia)	86	4,9	4,2	5,09
	Margosha (Russia)	99	5,9	5,8	4,56
	Purple Haze F_1	75	7,7	5,8	5,72
	Morelia F_1	73	17,6	12,9	6,99
	Mello Yello F_1	103	7,1	8,2	5,19

According to the results of production testing of Russian (FGBNU FNCO) and foreign cultivars of carrot, four groups according to crop yield was formed: group I - 40-50 t/ha, group II - 50-70 t/ha, group III - >70 t/ha. Within each group, samples were graded according to the level of damage to roots due to pit-storage rot at the end of storage period (April). The overall percent of damaged roots for all analyzed samples was from 3% to 56% and varied considerably within each group. It should be noted that the in-storage losses of commercial roots within each crop-yield-ranked group were lowest in case of Russian cultivars and hybrids (1,4-5,4 t/ha), and though several foreign hybrids were superior in respect of crop yield, profitability of growing Russian cultivars was in general higher or similar in comparison with foreign ones taking into account long-term storage.

Conclusions

Created by joint efforts of breeders, geneticist and phytopathologists, productive Russian cultivars and hybrids of carrot having high resistance against local populations of phytopathogens should be considered not only the basis of the strategy of integral crop protection against diseases, but also supporting the interests of domestic agricultural producers within the framework of national policy of import substitution and ensuring food security of the country. Taking into account increasing variability of the pathocomplex and aggressiveness of pathogens, immunological and molecular investigations aimed at the creation of donors of complex resistance against storage diseases of different ethiology should be now a priority direction in the framework of targeted selection along with continuous phytomonitoring and detection of new economically deleterious carrot diseases.

3. ORGANIC AGRICULTURE

DEPENDENCE OF GRAIN YIELD OF SPELT ON LOCALITIES AND DIFFERENT TYPES OF FERTILIZER

Abstract

Investigations of organic technology for spelt in the different regions were carried out by placing the field experiment using the random block system method, in three repetitions, during 2010/11 and 2011/12 year, at the "Radmilovac" experimental school of the Faculty of Agriculture in Belgrade, in the village Jasenica near the town of Valjevo and on Zlatar, Radijevici village. As a material was used late varieties of spelt (Nirvana).
Commercial organic fertilizer was used in the form of granules under the trade name "Biohumus Royal offert". The second treatment was the use of zeolite and hydrogel soil conditioners, which is also ploughed down in autumn, with the aim of keeping moisture, preventing nutrient losses and, consequently, positively affecting useful microorganisms, as well as stabilizing heavy metals in the soil. The third variant was the combined application of organic fertilizer and soil conditioner. Also, it was used microbiological fertilizers "Uniker" and "Slavol" and their combination with organic fertilizer and soil conditioners.
Statistical analysis of data for grain yield was performed using analysis of variance for one factorial experiment and for individual comparisons; we used the least significant difference (LSD test). The grain yield of spelt cultivated in the organic production system in the different regions of Serbia was statistically varied depending on the fertilizer variant. The average yield of grain of spelt was 4954 in first, 3093 in second and 2241 kg ha^{-1} in third locality. The best result was achieved by combined use of zeolite and biohumus, where the average two-year yield of spelt grain was 3550 kg ha^{-1}. It is interesting to note that yields (4377, 2756 and 2216 kg ha^{-1}) were obtained on the control treatment without the use of fertilizers, is not much lower than the yield in fertilizing variants, because crop rotation effect in first and the soil has not been used for agriculture production for a long time in other localities. This fact is very important because in Serbia there are a lot of those lands, which can be used for organic production, especially low-input crops, such as a spelt.

Key words: *growing technology, organic fertilizer, soil conditioner, yield*

Introduction

Organic agriculture as a comprehensive food production management system is based on ecological practice, a high degree of biodiversity and the conservation of natural resources. Although the organic production area in Serbia records constant growth (Simić, 2017), the lack of organic fertilizer, due to the insufficiently represented organic livestock breeding, calls into question the sustainability of the entire system, especially when it comes to maintaining the natural fertility of the soil. Manufacturers are forced to use commercial certified fertilizers, which significantly increase production and undermine its economic justification. There are many types of cereals, "alternative", which can be successfully grown in different regions of our country. One of them is the Spelt wheat (*Triticum spelta* L.), that belongs to the hexaploid group of cultivated *Triticum wheat* with fragile spikes and hulled kernels (Glamoclija *et al*., 2015). Spelt is an old subspecies of soft wheat whose use is constantly growing in the world because it is considered healthier and more natural compared to modern varieties of common wheat (Schober *et al*., 2006), but it is very poorly represented in production and nutrition in Republic of Serbia. It can be cultivated at altitudes higher than 800-1100 m, but certainly its place can occupy in crop rotations at lower altitudes. Grain yields are lower than for common wheat, but are more stable (Roljević Nikolić *et al*., 2018). In Serbia, spelt is grown on about 300 ha, which represents 6.3 % of organic areas under cereals (4607 ha). Investigations by Kovačević *et al*. (2007) showed that the spelt responds very positively to the application of organic fertilizers. The studies that were concerned with the study of productivity of spelt in different locality of cultivation (Dolijanović *et al*., 2014; Ugrenović *et al*., 2018) showed that there is no single solution for maximizing the genetic potential of the spelt, and the cultural practices must be adapted to the conditions of production in different regions.

Establishment and maintenance of soil fertility in organic farming systems is based on improving the physical, chemical and biological properties of the soil by increasing the content of organic matter and the activity of microorganisms. Optimum amounts of nutrients in organic production are provided by the most commonly applied alternative methods, which include the addition of organic and natural mineral fertilizers, plant residues, use of leguminous plants, green manure, as well as stimulating the activity of useful soil microorganisms using microbiological fertilizers. The application of organic fertilizers influences the correction of the physical and chemical properties of soil rhizosphere (Tobiašová, 2011), as well as the increase in biomass and activity of microorganisms in relation to the application of mineral fertilizers (Chang *et al*., 2007). Also, there are results on the very positive effect of the use of organic and microbiological fertilizers on the yield of crops in organic production (Ebrahimpour *et al*., 2011; Jablonskytė-Raščė *et al*., 2013). Zeolites, as soil conditioners, can alleviate the rinsing of ammonia by taking ions from sources, such as manure and fertilizers, which are then released and made available to plants (Karličić *et al*., 2017). Also, zeolites improve the water-air and physical properties of heavy soils, but also bind to toxic elements (Stojiljković *et al*., 2002), reducing their bioavailability. Ćupina *et al*. (2017) deals with the topics of annual cover crops and nitrogen management, and more research is available with various commercial certified organic fertilizers and soil conditioners (Oljača *et al*., 2012; Dozet *et al*., 2017).

For these reasons, the main goal of this research was to examine the influence of locality (L) and types of fertilizer (Y) on the grain yield of spelt wheat produced in Serbia.

Material and methods

Adaptation of organic technology for spelt in different regions was carried out by setting field trials using the random block system, in three repetitions, during 2010/11 and 2011/12 years. The study in the plain area was carried out at the "Radmilovac" experimental school of the Faculty of Agriculture in Belgrade (44^{o}45'N, 20^{o}35'E), 130 meters above sea level, in a hilly area in the village Jasenica near the town of Valjevo (44° 19'0.6 "N , 19° 57'12.6 "E), 300 meters above sea level, while the investigation in the mountainous region was carried out on Zlatar, on the territory of Nova Varos municipality, Radijevici village (43° 23'52" N, 19° 52'33 " E), 1065 meters above sea level.

At the first locality, the soil is chernozem luvic soil type with the following characteristics: pH (in H_2O) 8.04, total nitrogen content 0.13%, P_2O_5 22.18 mg, K_2O 19.10 mg, humus content in the ploughing layer is 2.45 %. The area under examination was in the organic production system since 1992, in the area of four-crop rotation, which implies the following rotation of crops: maize - winter wheat – spring barley spring barley + red clover - red clover. The surface of the elementary plot was 6 m^2. Sowing was carried out manually, October 21 in first and October 07 in second Year with the amount of seed of 500 seedlings m^{-2}. To maintain and increase the potential fertility of the soil, the following varieties have been applied:

- T_1 - fertilization only with microbiological fertilizer in top-dressing (5 l ha^{-1});
- T_2 - fertilization with biohumus (3000 kg ha^{-1}) and microbiological fertilizer in top-dressing (5 l ha^{-1});
- T_0 - control - no fertilizer application.

Harvest was done on July 5, 2011 and June 30, 2012 years.

In the second locality, the soil is of the type of eutric cambisol, the following characteristics: acidic chemical reactions (pH in KCL = 5.3-5.5), with about 3% humus, high reserve of mineral nitrogen (over 200 kg N ha^{-1} for the whole investigated layer), poorly provided with avialable phosphorus (2.4-2.6 mg per 100 g of soil) and well secured with potassium (34-37 mg per 100 g of soil). The surface of the elementary plot was 12 m^2. Sowing was carried out manually, October, 15 2010 and October 05, 2011 with the amount of seed of 550 seedlings m^{-2}. The experiment included the following variants:

– T1 - organic commercial fertilizer (3000 kg ha^{-1}),
- T2 - zeolite (2670 kg ha^{-1}),
– T3 - combined application of biohumus (3000 kg ha^{-1}) and zeolite (2670 kg ha^{-1})
- T4 - control variant without fertilizer application.

Harvest was done on July 10, 2011 and July 04, 2012 years.

In the third locality, the soil is of the type pseudoqley that exhibits unfavorable chemical and physical properties, as well as the scarce content of nutrients, primarily phosphorus. Phosphorus is considered to be a weakly moving element in the soil, and in pseudogley the additional problem is the chemical mobilization of phosphorus Al, Fe and Mn due to high acidity. The areas under examination were certified for organic production and no agricultural crops were cultivated in the previous seven years. The surface of the elemental plot was 12 m^2. Sowing was done by hand, November 01, 2010 and October 20, 2011 with the amount of seed of 600 seedlings m^{-2}. The following variants have been applied:

– T1 - soil conditioner zeolite (2670 kg ha^{-1})
– T2 - microbiological fertilizer "Uniker" (10 l ha^{-1})
– T3 - microbiological fertilizer "Uniker" + zeolite
– T4 - microbiological fertilizer "Uniker" + hydrogel (20 kg ha^{-1})
– T5 – control

Harvest was done in August 2011 and 2012.

The different number of treatments at the investigation localities is the result of differences in soil use (crop rotation), soil characteristics and meteorological conditions (multi-year average). As a material, late varieties of spelt (Nirvana) were used, selected at the Institute of Field and Vegetable Crops in Novi Sad. The best results are achieved on moderately fertile soil, it is resistant to winter, but it is sensitive to intensive nitrogen fertilization because it has a high stem and can be laid down. The yield potential of spelt is over 4000 kg ha^{-1}. "Biohumus Royal offert" is ploughed down in autumn. Characteristics of fertilizers are as follows: pH 8.63, N 2.2%; P_2O_5 4.8% and K_2O 2.8%. Zeolite (manufacturer "AquaVitadi Natura" doo) was also ploughed down with basic tillage treatment in autumn, and top dressing application with microbiological fertilizer (trade name "Slavol") was performed at the beginning of the tillering phenofase (BBCH 31-33) in the amount of 5 l ha^{-1}.

Statistical analysis of data for grain of yield was performed using analysis of variance for factorial experiments and for individual comparisons, we used the least significant difference (LSD test).

Results and discussion

The grain yield of spelt cultivated in the organic production system in different agricultural regions of Serbia were significantly different (Table 1). Lower yields are specific for marginal, mountainous areas, while higher yields are achieved in better cultivation conditions. The highest average grain yield of 4954 kg ha^{-1} was obtained in the plain area, on the chernozemian soil, with optimal physical and chemical characteristics. Significantly lower grain yields of 3093 kg ha^{-1} was obtained by cultivating the spelt in a hilly area, on eutric cambisol soil, acid reactions and low content of light-chain phosphorus. In the hilly-mountainous region, at an altitude above 1000 meters above sea level, the average grain yield of spelt was 2241 kg ha^{-1}, which is statistically significantly lower than yields in the flatland and hilly agricultural area.
In the first and second locality, all treatments of fertilizer application compared to the control variant showed statistically significant influence on the grain yield of spelt. In the third locality, the lowest grain yields were obtained, both on the control variant and on the fertilizer variants applied. What should be emphasized is the fact that the application of individual fertilizers did not lead to an increase in grain yield compared to the control variant. Only the combined application of the investigated fertilizers led to an increase in the grain yield of spelt (Table 1). This can be explained by the fact that the soil was not used for a long time in agricultural production and that it was of high potential fertility and rich in useful species of microorganisms.

Table 1. Grain yield of spelt in different regions in organic growing system

Locality	Treatment	Grain yield (kg ha^{-1})
Locality 1 (Radmilovac, Belgrade)	T1 - microbiological fertilizer	4883
	T2 - biohumus + microbiological fertilizer	5601
	T3 - Control	4377
	Average	4954
Locality 2 (Jasenica, Valjevo)	T1 – biohumus	3139
	T2 – zeolite	2925
	T3 – biohumus + zeolite	3550
	T4 - Control	2756
	Average	3093
Locality 3 (Radijevići, Nova Varoš)	T1 – zeolit	2193
	T2 - mikrobiološko đubrivo	2190
	T3 - microbiological fertilizer + zeolite	2303
	T4 - microbiological fertilizer + hidrogel	2301
	T5 - Control	2216
	Average	2241

When individual fertilizers were concerned, each area of cultivation or agro-ecological conditions had their own specificities. In the plain and hilly region, good grain yield results were achieved by combined application of organic and microbiological fertilizers/soil conditioners, and in the mountainous region the best combination were soil conditioners and microbiological fertilizers. In experiments with winter rye, hulles oats, buckwheat and spelt, it has also been found that different microbiological fertilizers combined with soil conditioners give maximum results (Oljača *et al.*, 2010). With the independent application of microbiological fertilizer (T1) in the plain region, grain yield of spelt was 4883 kg ha^{-1}, which is significantly higher than the control (T3)-4377 kg ha^{-1}. Spelt recharged with microbial formulation (Slavol) gave higher yields compared to the variant where was used only the basic fertilization (Dolijanović *et al.*, 2013). Kovačević *et al.* (2011) cited that they achieved significantly higher yields of different alternative types of winter wheat (*Triticum spelta*, T. *durum*, T. *aestivum* ssp. *compactum*) in treatments with top dressing of microbiological fertilizers. Having used ecological fertilizer (Ekoplant), spelt grain yield increased by 7%, and having used it in combination with bio-activator (Biokal 01) the yield increase amounted to 8% (Jablonskytė-Raščė *et al*., 2013).

Table 2. Analysis of variance of grain yield of spelt

	df Effect	MS Effect	df Error	MS Error	F	p-level	$LSD_{0.05}$
Locality 1	2	19.00	6	0.67	28.50	0.0009	120.00
Locality 2	3	28.08	8	3.33	8.43	0.0074	100.15
Locality 3	4	42.73	10	3.40	12.57	0.0007	25.03

Conclusion

By applying adequate and balanced fertilizer formulations, the grain yield can be significantly influenced in all three production locality. In the flatland area, the highest grain yield of 5601 kg ha^{-1} was obtained by combined application of organic and microbiological fertilizer (T2). On the hilly region, the best result is achieved by the combined application of zeolite and biohumus, where the average grain yield of spelt was 3550 kg ha^{-1} (T3). In the mountainous region where the soil is pliable and poorer physico-chemical characteristics compared to the flatland and hilly regions, and meteorological conditions are sharper, the best result achieved by ploughing zeolite and microbiological fertilizer, when the spelt had a yield of 2303 kg ha^{-1} (T3).

Abstract

Common vetch (*Vicia sativa* L.) originates from southern Europe and is also widespread in the Mediterranean region of Croatia. Due to the economic and ecological dimensions of growth, it is valuable to ascertain whether the application of seed inoculants or growth bio stimulators can enable ecological management of this crop in mixture with wheat (*Triticum aestivum* L.). Research was conducted through field experiment set up on agricultural area near city of Zadar, Dalmatia, during the vegetative seasons 2016/17 and 2017/18. The effect of different common vetch *cv*. Poppelsdorf sowing rates (40, 60, 80, 100 grains/m²) in mixture with wheat *cv*. Valerius (200 grains/m²), on fodder yield was evaluated through 3 treatments (control without fertilization, seed inoculation with strain *Rhizobium leguminosarum* bc *Viciae* 1001 and Bio-algeen growth bio stimulator application). The highest dry matter yield (DMY) determined on control was achieved in both years with 100 grains/m², 7,98 t ha^{-1} in 2016/17 and 8,82 t ha^{-1} in 2017/18, ($P<0.05$). The highest DMY determined with growth stimulator application was in both years significantly highest ($P<0,05$) with 100 grains/m², 9,24 t ha^{-1} in 2016/17 and 10,29 t ha^{-1} in 2017/18, respectively. The DMY determined with *Rhizobium leguminosarum* bc *Viciae* 1001 seed inoculation treatment in both years was not significantly different between 80 and 100 grains/m², although those 2 higher rates had significantly higher yield ($P<0,05$), compared to 2 lower seeding rates (40 and 60 grains/m²). The highest DMY and the biggest potential for ecological management in both years was shown by applying seed inoculation with *Rhizobium leguminosarum* bc *Viciae* 1001 (11,34 t ha^{-1} in 2016/17 and 10,71 t ha^{-1} in 2017/18).

Keywords: *Vicia sativa* L.**,** *legume cereal mixture***,** *seed inoculation, Mediterranean*

Introduction

Common vetch (*Vicia sativa* L.) originates from southern Europe and is also widespread in the Adriatic part of Croatia and other Mediterranean countries. It provides good quality palatable forage biomass, and it is usually sown mixed with a cereal companion for animal feeding (Lithourgidis *et al*. 2006, Uher *et al* 2019). Oat, barley, wheat and triticale are added to provide a climbing frame for the legumes and to increase the bulk of feed produced (Tuna and Orak, 2007). Due to its high ability to fix nitrogen and to produce quality fodder, it could serve as one of the richest, yet potentially the cheapest protein source for profitable ecological management. The price of common vetch seeds is high, so it is important to optimize the sowing rate. It is documented in previous research that mixture of legumes and small grain cereal has some advantages over pure stands, as crops within the mixtures use the environmental resources efficiently and produce more yield than their pure stands (Atis *et al*., 2012, Roberts *et al*. 1989, Štafa *et al*. 1998, Uher *et al*., 2009). Intercropping of legumes and cereals has produced higher yields than sole cereal crops primarily on soils with no N-fertiliser (Jensen, 1996; Hauggaard-Nielsen *et al*., 2001a, Lauk and Lauk, 2005). The above-ground plant material of common vetch may contain more than 100 kg N ha^{-1} originating from N_2-fixation (Papastylianou 1999, Mueller and Thorup-Kristensen, 2001). Cereal crops use the nitrogen fixed by the legume crops and that fact could influence not only quantity of fodder, but quality. Uher, et al., 2007 reported that the highest forage pea crude protein yield was obtained in mixture with wheat compared to other cereals, and all cereals in mixtures with forage pea significantly better yielded in late boot vegetative stage compared to early head. Protein and carbohydrate rates of feed originated from mixtures are balanced and the feed from mixture has higher feeding value compared to the feed from pure sowings of mixture components (Atis *et al*., 2012, Caballero *et al*., 1995, Lithourgidis *et al*., 2006, Karadag and Buyukburc, 2003, Tuna and Orak, 2007, Mariotti *et al*., 2009, Uher, *et al*., 2007). Feeding vetch in mixtures with small grain cereals is reported to increase milk yields of cows and growth performance of beef cattle (Štafa *et al*., 2001). The choice of a legume species and compatible plant densities are very important for high forage yields and quality in intercrops with cereals (Altinok *et al*., 1997). Furthermore, it is valuable to ascertain whether the application of seed inoculants or growth bio-stimulators can enable ecological management and successful fodder production in the Mediterranean region of Croatia.

Material and Methods

Research was conducted through field experiment set up on agricultural area near city of Zadar, Dalmatia, during the vegetative seasons 2016/17 and 2017/18. The effect of different common vetch *cv*. Poppelsdorf sowing rates (40, 60, 80, 100 grains/m²) in mixture with wheat *cv*. Valerius (200 grains/m²), on fodder yield was evaluated through 3 treatments (control without fertilization, seed inoculation with strain *Rhizobium leguminosarum* bc *Viciae* 1001 and Bio-algeen growth bio stimulator application). Four common vetch seeding rates (40, 60, 80, 100 grains/m²) in mixture with wheat *cv*. Valerius (200 grains/m²), were grown through three treatments (control without fertilization, seed inoculation with strain *Rhizobium leguminosarum* bc *Viciae* 1001 and Bio-algeen growth bio stimulator application), in all possible combinations in a randomized, completed block experimental design with 3 replications. The dates of sowing were on 10th of October 2016 and 12th of October 2017. Common vetch and wheat seeds were mixed prior to sowing and were sown in the same row using a special plot drill. The area of the test plots was 30 square meters. The previous crop was wheat in both years of the study. A 5 m^2 section was harvested for green herbage and samples of 1 kg were dried at 60 °C for 48 h, to determine dry matter yield. The experiment was established on an anthropogenic carbonate, moderately dry soil having a slightly sandy-clayey texture. The soil characteristics were as follows: PH_{KCl} of the ploughed layer was 4.65, organic matter content 2.45 %. An analysis of variance was carried out using SAS 9.3 (SAS Institute Inc. 2011). The statistical significance of the treatments was determined at the $P<0.05$ probability levels using the F-test.

Results and Discussion

The excellent stand establishments in both years were obtained due to suitable soil moisture and temperature conditions for germination and emergence of crops. As expected, increasing the seeding rate resulted in increased plant density. Therefore, the plots sown at high common vetch seeding rates (80 and 100 grains/m²) covered the ground faster in early spring. The green mass yield (GMY) is shown on Table 1.

Table 1. Green mass yield of the mixtures seeding rate as affected by the treatment (t ha^{-1}).

Seeding rate / seed no. /m^2	Treatment/Year					
	Control		Growth bio stimulator		*Rhizobium leguminosarum bv. viciae* 1001	
	2016/17	2017/18	2016/17	2017/18	2016/17	2017/18
40 vetch + 200 wheat	20,0^c	21,0^d	23,0^c	22,0^d	28,0^c	29,0^c
60 vetch + 200 wheat	24,0^b	28,0^c	27,0^{bc}	28,0^c	39,0^b	43,0^b
80 vetch + 200 wheat	35,0^a	34,0^b	33,0^b	32,0^b	54,0^a	51,0^a
100 vetch + 200 wheat	38,0^a	42,0^a	44,0^a	49,0^a	54,0^a	50,0^{ab}

Values with the different small letters in column in a year are significantly different according to the LSD test at P <0.05.

The highest green mass yield (GMY) determined on control was achieved in both years with 100 grains/m², 38,0 t ha^{-1} in 2016/17 and 42,0 t ha^{-1} in 2017/18, (P<0,05), respectively. The highest GMY determined with growth stimulator application was in both years significantly highest (P<0.05) with 100 grains/m², 44,0 t ha^{-1} in 2016/17 and 49,0 t ha^{-1} in 2017/18, respectively. The GMY determined with *Rhizobium leguminosarum* bc *Viciae* 1001 seed inoculation treatment in both years was not significantly different between 80 and 100 grains/m², although those 2 higher rates had significantly higher yield (P<0.05), compared to 2 lower seeding rates (40 and 60 grains/m²). Furthermore, The GMY determined with *Rhizobium leguminosarum* bc *Viciae* 1001 seed inoculation treatment was in both years higher, compared to control and bio stimulator treatments at the same seeding rate (between columns).

The dry matter yield (DMY) is shown on Table 2.

Table 2. Dry matter yield of the mixtures seeding rate as affected by the treatment (t ha^{-1}).

Seeding rate / seed no. /m^2	Treatment/Year					
	Control		Growth bio stimulator		*Rhizobium leguminosarum bv. viciae* 1001	
	2016/17	2017/18	2016/17	2017/18	2016/17	2017/18
40 vetch + 200 wheat	4,20^b	4,41^c	4,83^c	4,62^c	6,44^b	6,74^b
60 vetch + 200 wheat	5,04^b	5,88^{bc}	5,67^{bc}	5,88^{bc}	8,19^b	9,03^{ab}
80 vetch + 200 wheat	7,89^a	6,92^b	6,93^b	6,72^b	11,34^a	10,71^a
100 vetch + 200 wheat	7,98^a	8,82^a	9,24^a	10,29^a	11,34^a	10,50^a

Values with the different small letters in column in a year are significantly different according to the LSD test at P <0.05.

The highest dry matter yield (DMY) determined on control was achieved in both years with 100 grains/m², 7,98 t ha^{-1} in 2016/17 and 8,82 t ha^{-1} in 2017/18, (P<0,05), respectively. The highest DMY determined with growth stimulator application was in both years significantly highest (P<0,05) with 100 grains/m², 9,24 t ha^{-1} in 2016/17 and 10,29 t ha^{-1} in 2017/18, respectively. The DMY determined with *Rhizobium leguminosarum* bc *Viciae* 1001 seed inoculation treatment in both years was not significantly different between 80 and 100 grains/m², although those 2 higher rates had significantly higher yield ($P<0,05$), compared to 2 lower seeding rates (40 and 60 grains/m²). The highest DMY and the biggest potential for ecological management in both years was shown by applying seed inoculation with *Rhizobium leguminosarum* bc *Viciae* 1001 (11,34 t ha^{-1} in 2016/17 and 10,71 t ha^{-1} in 2017/18). Seeding rate treatments showed significant effects on fodder yield as well as higher seeding rates of common vetch in mixture with wheat.

Conclusions

Our study clearly shows that common vetch-wheat fodder crop mixture could be grown under organic management for purpose of animal feeding in the Mediterranean-type climate of Croatia. High seeding rates provided greater dry matter yield. A seeding rate of 80 seeds of common vetch inoculated with *Rhizobium leguminosarum* bc *Viciae* 1001 in mixture with 200 seeds of wheat per 1 m^2 proved to be the optimum, and there is no need to apply higher seeding rates.

Abstract

In Portugal, the expansion of organic agriculture has become crucial within national agriculture context The methodology included interviews with farmers and field visits to confirm the regional database. The first region to be analyzed was Beira Litoral and then, based on the results obtained, surveys were carried in the Lis Valley for a more delimited analysis and with the objective of evaluating the predisposition for agricultural system change. This work revealed elements that have enabled researchers to develop organic agriculture, to overcome the obstacles faced by farmers, to help boosting chain elements' confidence and reducing confusion between different farming practices. In the Lis Valley the improvement of the agricultural system was considered to allow more efficient production, while saving resources; also, the improvement of the agri-environmental system would allow the conversion to organic agriculture. The conversion is not achieved solely by means of a holistic approach, and it is necessary to use both personal communication and social groups in each region to show farmers the importance and the benefits that may result from this change. According to the evidence available, providing farmers with credible information is essential to increase their confidence in organic farming. Trust in organic farming also depends on farmers' confidence. It is necessary to work on creating adequate training for their needs and to provide accurate and real information on the difficulties and benefits of organic agriculture.

Keywords: *Organic farmer, Portuguese Center Region, Lis Valley irrigation district*

Introduction

The organic farming movement in Europe emerged in the early 20th century as a result of a set of ideas, beliefs and philosophies. According to FAO/WHO (1998), organic agriculture is a holistic production management system that promotes and improves the reality of the agroecosystem, including biodiversity, biological cycles and soil biological activity. IFOAM (2019) defines organic farming as a "… production system that promotes the health of soils, ecosystems and people". It is based on ecological processes, biodiversity and adapted cycles. Organic agriculture plays a dual role, satisfying consumers' demand for organic products and, on the other hand, offering public goods. The consumer's understanding of the word "organic" is complex and several studies show that this understanding changes between different countries and cultures. Vega-Zamora et al. (2014) show that "organic" plays an important role as a heuristic attribute that allows the consumer to infer product quality. The concept of quality has two dimensions: an objective dimension linked to the technical product and a subjective dimension, i.e the consumer's perception. Some authors refer two dimensions of quality perception: a horizontal dimension of quality perception (before and after purchase), and a vertical dimension that includes a set of intrinsic or extrinsic characteristics and the way consumers perceive these attributes as desirable and interconnected with the variable of human behaviour; the attribute of promoting health and the environment is perceived by consumers as one of the most important ones (Steenkamp, 1990; Grunert, 2005; Magistris and Gracia, 2008). The consumer of products cannot evaluate their quality at the time of purchase so, they can only evaluate this quality at the light of the idea they have about the product, and by using information and the perception of this information. Considering information, it is undeniable that the label is a fundamental tool for the differentiation of the organic product (Van Loo *et al*., 2011). The objectives of this study are to analyze the structure of agriculture and carry out the socioeconomic characterization of organic agriculture in the Central Region of Portugal and assess the willingness to change to organic farming.

Materials and methods

This study presents two case studies in two subregions of the Center region. In the first case study, interviews were conducted with farmers of organic agriculture in Beira Litoral (BL) and the second case study, carried out the in Lis Valley (LV) interviews were conducted with a stratified sample. In BL 86 interviews were carried out (38% of the organic farmers and 69% of the organic area in BL. In BL, for the socioeconomic organic producer analysis only the replies of the owners of the holding were considered. The interviews took place in 2018. In the LV, interviews were conducted with all farmers and not only with organic farmers; these interviews were supposed to evaluate the predisposition to change to organic agriculture. The study area is managed by the Lis Valley Water User Association (LVWUA), which covers approximately 2000 hectares and has a high heterogeneity in relation to the areas of holdings. Stratification was performed in order to obtain the sample, according to Gauss's Law and resulting in three samples: 20 owners with the largest area (> 8.5 ha), called "Large"; 20 owners with a very small area (area ≤ 25 m2), called "Small" and 21 owners with areas between 0.5 and 2 ha, called "Medium". This stratification was required because small area owners are predominant, but owners of large farms are the ones with the highest sales and those with the greatest participation and influence in the LVWUA decisions. From March to April 2019, 57 inquiries were carried out. The data were analysed using SPSS 25 software. The correlation coefficient of Pearson (r) and Spearman's correlation coefficient (ró) was used to measure the strength of the association between the variables.

Results and discussion

Organic Agriculture in Portugal

Portugal has had several Rural Development Program (RDP) programs to develop organic agriculture, namely the PRODER (Rural Development Program, 2007-2013) through Action 2.2.1 (Modification of agricultural production modes) and the PDR2020 (RDP 2014-2020) through Action 7.1 (Organic farming), that includes two Operation (OP): OP. 7.1.1- Conversion to Organic Agriculture and OP. 7.1.2- Maintenance in Organic Agriculture. These agricultural policy programs allowed the development of Portuguese organic agriculture, as well as the expansion of the organic area, which reaching 7% of the Portuguese Utilized Agricultural Area (UAA) and representing in 2017 about 2% of UAA organic area in European Union (EU). The Portuguese organic area recorded a growth rate between 2012 and 2017, similar to that of the EU-28. From 2012 to 2017, the total area converted to organic agriculture in Portugal increased by 26%, a growth above the EU-28 average of 25%. (Eurostat, 2019). It was found that in 2010 most of the organic area was supported by PRODER (114 thousand hectares). Between 2010 and 2014 there was a progressive reduction of the organic area supported by PRODER, reaching a minimum of approximately 72 thousand hectares in 2014. The adoption of the new Community framework (RDP2020) allowed a significant increase in the area supported by the RDP, in OP. 7.1.1-Conversion to Organic Agriculture, reaching approximately 80 and 50 thousand hectares in 2016 and 2017, respectively. Action 7.1 supported 222 and 225 thousand hectares in 2016 and 2017 respectively. In 2015 and 2016, the area supported for conversion to organic production was systematically lower than the area receiving maintenance support, ie, there was not an increase of new entries in relation to the previous periods, but there was a switch from OP. 7.1.1. to OP. 7.1.2. The behaviour of the Center region is similar to the evolution Portuguese mainland, only differing in OP. 7.1.1 where there is an increase in new areas for conversion in the Center region. The budgeting of Common Agricultural Policy (CAP) is consistent with the areas supported. In 2011, PRODER attributed a maximum value of 15025 thousand € to organic farming in Portuguese mainland, but between 2011 and 2014 there was a progressive reduction of subsidies granted via PRODER. PDR2020 allowed a significant increase in the allocation of organic farming to the conversion of 21,008 thousand € in 2016. It should be noted that PRODER did not separate conversion to organic agriculture from maintenance. PDR2020 shows this separation and, considering the two supports in 2016, the total reached 51,672 thousand €. In 2017 the financing of both operations was reduced to 26102 thousand € in total. In 2015-2017 the Center region received 22% from RDP financial support for conversion aid (OP.7.1.1) and 24% from national support for organic farm maintenance (OP 7.1.2). The highest value for both operations was reached in 2016, with 12191 thousand €. There was both a potential growth and a linear growth of the organic area and of the number of organic producers, respectively (Fig.1). It should be noted that between 1994-1998 (five-year average) in Portuguese mainland, the average area *per* holding (ha/hold) in organic farming was 39 ha/hold, and grows to 72 ha/hold in 2013-2017. This value is much higher than the average value for Portuguese agriculture, which in 2016 was 14.9 ha/ hold (INE, 2017)

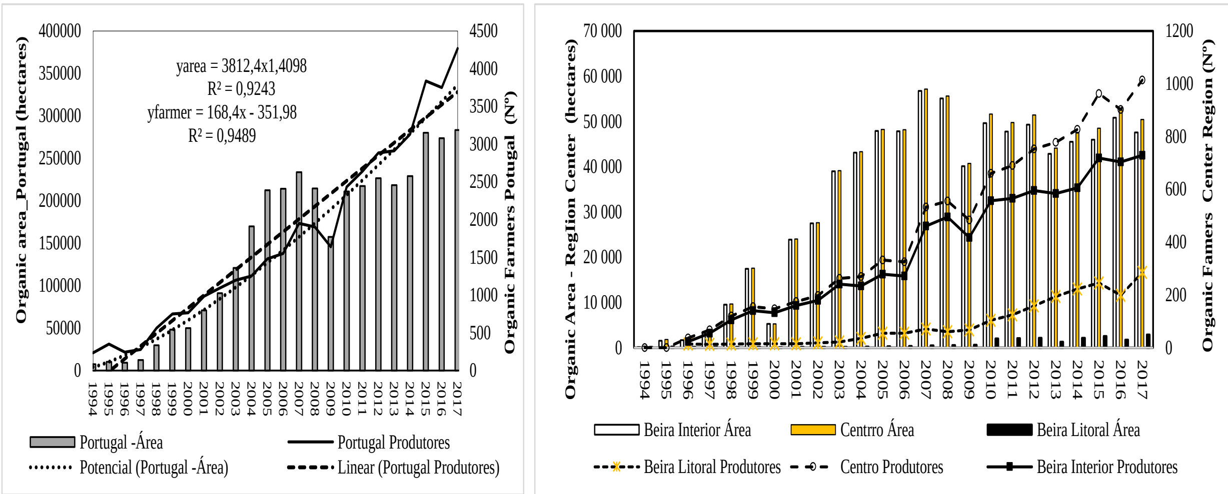

Figure 1, Evolution of the organic area and of the number of producers in Portugal
Source: DGADR (2010), accessed on 21/05/2019

The allocation of the organic area supported by crop type remains similar in both PRODER and PDR2020 programs. Permanent pasture and biodiverse permanent pasture accounted for about 60% of the total area supported by PDR. In 2017, permanent pastures and pastures accounted for 61%, other temporary crops 22%, olive groves and nuts represented about 13% of the area supported by PDR2020 through OP 7.11 and OP. 7.1.2. Between 2008 and 2017, pastures accounted for around 67% of organic crops, followed by forage (9%), with an increase of this crop in relative and absolute terms (growth of 128% between 2011 and 2017), followed by olive grove that represents 9% of organic crops (growth rate of 16% between 2011 and 2017). The most significant growth rate was observed in nuts (451%) and horticulture (253%). Between 2013-2017, the Center Region represented 19% of the organic area and 25% of organic farmers in Portuguese mainland. There was an increase in the number of producers in relation to the national figures and a share reduction of the area by increasing surfaces in other regions. However, it is important to emphasize the importance of the Center region plays a pioneering role in the development of organic agriculture. The differences between the two sub-regions, Beira Litoral (BL) and Beira Interior (BI) between 1994 and 2017 are clear, as regards the areas and the number of producers in the Center region. Between 2013-2017 the BL region contributed with 4% (five-year average) to the organic area in the Center region and represented 25% of organic farmers. Between 2013-2018, BI represented 96% of the organic area and 75% of the organic agriculture of the Center region. Between 2013-2017, in the Center region, the average area was 55 ha *per* holding (BL: 9 ha/hold., BI: 70 ha/hold.) (DGADR, 2019). The allocation of crops in mainland Portugal and the Center region is similar. In the subregions, there is a difference in terms of area and crops. It is relevant to refer that in 2017 about 51% of the aromatic herbs grown in the Center region were found in the BL subregion. However, the weight of these crops is negligible.

Survey Results

The first case study was conducted with organic farmers in BL by means of interviews; 65% of the respondent are land owners and 12% work the land as tenants. The owner is usually male (72%); 62% of them are between 30-49 years old, 36% are between 40-49 years old and 50% of farmers have higher education. Only about 25% of the farmers have training in agriculture, but 55% of them depend on agriculture as their main activity. These figures are higher than the average for Portuguese agriculture, where only 5.8% of farmers have higher education, only 6% of farmers depend exclusively on agricultural income and 12.8% have agriculture as their main income activity. (INE, 2017). The main motivation to take up farming was the profitability of the land (64.5%). Family experience in agriculture and professional discontent were important factors. About 62% of respondents indicated that they adopted organic farming as a philosophy of life which is also economically viable, due to the highest market price in relation to products resulting from other cultivation systems. The versatility of organic farming products to be marketed as produced under another mode of cultivation was reported by 22% of respondents. Most farmers (61.4%) financed their farming activity only with their own resources. Producers stated that technical support comes from internal agricultural expertise or from consultancy and/or commercialization of agricultural products and from peer associations. In what concerns marketing orientation, 52% of the producers sell to wholesalers, 34% sell their production directly to the final consumer and 33% sell to small retailers (short circuit). However, around 33 producers (40%) sell directly for export. The sale price of the production is mostly established by customer (51%). and 53% of the producers do their own marketing. Some farmers wanted to increase farm areas, but it was difficult to find land either to buy or to rent. Owners prefer, regardless of the proposed lease or purchase values, to keep abandoned land. In the interviews, criticism about the lack of mandatory training initiatives, both in terms of dispersion throughout the territory and in terms of frequency of performance and publicity, was revealed. Questions and problems related to the quality of training were mentioned, considering that the contents of the programs are superficial and out of touch with the reality of agriculture. Criticisms have been submitted to certifying bodies and agricultural advisory/consultancy. Regarding consumer perception, it was mentioned that the consumer of organic products values certification, but the general public does not recognize the difference between organic agriculture and integrated production agriculture. Other names such as "natural production" or "traditional production" are also sources of misunderstanding. The different designations generate confusion and make it difficult to distinguish between different agricultural systems. In the second study case, in the Lis Valley, the results of the survey conducted with farmers showed that about 76% of the respondents in the LV belong to the age group > 50 years old, 35% are over 65 years old, and 84% are male. The education level is lower than the one of the previous case study: 54% only attended primary school. This may be related to the fact that in this study all respondents were landowner farmers, according to the stratification, but their production is done under different agricultural systems, whereas in the previous case study only organic farmers were interviewed. At the same time, it is related to the higher age group of respondents. Agricultural activity plays a secondary role as income source for 58% of the respondents. The majority of owners work their own land (78%). The owners who rent land intend to continue to do so, but do not intend to sell the land. The income obtained allows adding extra income to the one they get from their main activity. This confirms the importance of family farming in Portugal and of self-consumption of the agricultural structure (DR, 2018). There was a weak positive correlation which is significant at 5% level of significance (*p-value*= 0.05) between the relevance of the agricultural activity and the size of farms (r = 0.301; ró = 0.328). As the size of farms decreases, farming becomes less important as a main activity and becomes a secondary source of income. The motivation for the practice of agriculture is related to the profitability of the land (43%) and 30% of the farmers are in the business due to the fact they want to keep the family activity. About 44% of the respondents sell all their production and 33% only produce for self-consumption. However, there is a weak positive correlation (*p-value*= 0,05), between these farm sizes and marketing orientation (r = 0.282; ró = 0.314), i.e. small farms tend to produce for self-consumption. There is also a positive correlation (r = 0.433 and ró = 0.432; *p-value*= 0.05) between the farmer age and the destination of the production, which means that farmers within a higher age group tend to produce for self-consumption. Only one farmer practises organic agriculture and the remaining indicated that they apply integrated production. Concerning the predisposition to change, the majority (84%) of the respondents replied that they were not interested in changing their production system to organic agriculture. Out of the 45 responses obtained for the predisposition to change, 32 responses indicated that there is no public support for changing the production system to organic farming. However, the surveyed respondents who were available highlighted two fundamental supports for helping the conversion/change of decision, ensuring both the sales outflow and higher production prices. There is a significant negative correlation at *p-value*= 0.05, between literacy and the predisposition to change (r = -0.37 and ró = -0.34). If we correlate this with age, this correlation is negative, significant at 1% level of significance (r = -0.49; ró = -0.45). The higher the education level is, and the younger the farmer is, the greater the predisposition to change is. Farmers converted to organic farming as well as non-converts have adequate knowledge of the benefits of this production system and acknowledge the need for more sustainable agriculture in order to enhance the economic sustainability of farms. The fact that in the case of BL the respondents were farmers converted to organic farming and that in the Lis Valley interviewed farmers are producing under integrated production system, allowed to conclude that some of the difficulties are common even when different production systems are adopted or when farmers' socio-economic characteristics are different.

Conclusion

The results obtained point several obstacles to the conversion of the productive systems and to the maintenance of those already engaged in this mode of production**.** The two case studies in the Center Region allowed characterizing the organic farmer and assessing the predisposition to change in two geographically nearby areas. The age factor, land ownership and size for the development of organic agriculture should be noted. It is important to emphasize the importance of consumer's recognition of the differentiation of organic farming products through price. The two areas present different forms of commercialization, but the short circuit is an issue to be developed. The responsibility of Public Institutions in the promotion of organic agriculture is evident, through the clarification of the various production systems and also of the way of commercialization; however, the development of organic agriculture should result from consumption by the valorization of the product in terms of price and sales development. The increase of farm plots and the clarification of production costs, mechanization, support to young farmers and generational renewal are important issues and will be factors to be taken into account, when developing policies for this type of agriculture. Great responsiveness to expand knowledge to support decision-making, through dissemination actions or participation in demonstrative actions has also been highlighted.

Abstract

The most important soilborne fungi are mycorrhizal fungi, including Arbuscular mycorrhiza. Their importance is that they create a symbiotic relationship with the roots, therefore helping the plant to absorb nutrients and water. Recently, more research has been done on their use in agriculture, with more promising results. Our experiment took place parallel in Szent István University, experimental fields of conventional and organic farming system, Budapest, Hungary. Control, alfalfa and rye straw mulch treatments were prepared. We investigated the correlation between mulching, mycorrhizal colonization, morphological and inner content parameters of lettuce. In addition, the effect of the two kind of cultivation methods on mycorrhizal colonization was Lettuce is one of the leaf vegetables grown worldwide in the largest area, and the importance of an environmentally conscious lifestyle is becoming more and more important, and as a result the role of organic farming has become more valuable. Alternative methods are applied to the occurring problems (pests, diseases) in organic farming. One of these methods is mulching, which has positive effects, such as: weed control, regulation of soil water balance, fertilizing effect and soil life stimulation. studied. Results showed several correlations between the different parameters. Mulching and farming system affected the quality of lettuce and mycorrhizal colonization of roots. Also, colonization affected the phosphorus uptake of the plants. However, due to the method of conventional cultivation, these differences were less remarkable. Altogether, more environmentally friendly cultivation has a positive effect on the amount of mycorrhizal fungi.

Keywords: *mycorrhiza, lettuce, inner content, organic farming, conventional farming.*

Introduction

Lettuce is one of the most important leaf vegetables. Due to low energy content, easy digestibility and high fiber and mineral content makes it easy to integrate it into modern diets. The spread of salad mixes and eating trends, occured an increasing interest in different salad specialties. As a result of environmentally conscious lifestyle the role of organic farming has become more valuable (Terbe, 2000). Alternative methods are applied to the occurring problems (pests, diseases) in organic farming. One of these methods is mulching, which has positive effects, such as: weed control, regulation of soil water balance, fertilizing effect and soil life stimulation (Grünefeld, 2010). Mycorrhiza fungi is a symbiont fungus which infects the plant roots and obtains photosynthetic products from the plant, in return, contributes to the supply of nourishing water (Brundrett, 1991; Ishii, 2016). In vegetable growing systems the most common mycorrhiza fungi is arbuscular mycorrhiza (AM). It is a type of endomycorhizza which goes into the root cell. The name is derived to a characteristic structure which occur within the cortical cell. It is a tree-like structure which enlarge the nutrient uptake surface (Smith and Read, 2008). Plant inoculation with arbuscular mycorrhiza (AM) can be a sustainable technique for the improvement of yield and plant resistance to biotic and abiotic stresses (Gosling et al., 2006; Guillermo et al., 2009).

The experiment was carried out to investigate the effect of alfalfa and rye straw mulch on the morphological -, inner content parameters and mycorrhizal colonization of lettuce, and to find out if there is any correlation between mycorrhizal colonization and morphological and inner content parameters.

Materials and methods

The experiment was carried out at Soroksár Experimental farm of Szent István University (SZIU) parallel in Conventional and Organic systems in 2018. Soil analysis was made for both systems. Important results of the analysis marked in the Table 1. The places are close to river Danube, and they are categorized by sandy casting that has the physical properties of sandy soil.

Table 1. Most important parameters of soils

	Organic system	**Conventional system**
pH (KCl)	7,45	7,10
NO2+NO3-N (mg/kg)	71,6	33,6
P2O5 (mg/kg)	577	1000
K2O (mg/kg)	166	99

"Voltron" Batavia lettuce from Rijk Zwaan was used. Seeds were sown 11th April in styrofoam trays, the media was Latagro KB2 type peat moss. The transplants were planted in 3 twin-row with 3 repetition with borders after and between treatments on 24th May in both places. The treatments were: *Control*, *Alfalfa mulch* and *Rye straw mulch*. Abbreviations of treatments marked in the Table 2. There were two sampling time: 26th June and 4th July. Morphological (stem and head diameter, weight), inner content parameters (dry matter, nitrogen, phosphorous, potassium), and SPAD were measured, furthermore roots were collected for mycorrhizal colonization measurements. Roots were painted with arbuscular-mycorrhiza painting method based on Phillips and Hayman et al. (1970). According to Giovanetti and Mosse (1980) colonization was measured with gridline intersect method with an Olympus Szx7 stereomicroscope. The partial results were calculated further with MycoCalc software. From these head diameter, nitrogen, potassium, SPAD and root colonization measurements will be presented.

Table 2. Applied abbreviations

Treatments	**Organic system**	**Conventional system**
Control	O-S1	Z-S1
Alfalfa mulch	O-S2	Z-S2
Rye straw mulch	O-S3	Z-S3

Results and discussion

<u>Morphological parameters: Head diameter</u>

At the first sampling time (26.06.2018.), in the Conventional system the head diameters did not show significant differences. On average, the diameters from all the three treatments were around 29 cm. The largest head diameter was measured in case alfalfa mulch (Z-S2) treatment with 37 cm, while the smallest, 23 cm, was measured in the rye straw mulch treatment (Z-S3). There were major differences in the Organic system. Here, the size of the control (O-S1) and

alfalfa mulched (O-S2) areas was similar in size, with an average of 21-22 cm heads, while the average diameter from the rye straw mulched (O-S3) parcels was 15 cm.
At the second sampling time (04.07.2018.) in both systems the controls (S1) were the largest with around 36 cm (the largest measured head was 46 cm) and rye straw mulched treatments (S3) were the smallest with around 32 cm. In the Organic system the lettuce heads taken from the control (O-S1) were ca. 17 cm, the highest measured was 23 cm. The rye straw-treated (O-S3) lettuces were around 14 cm. The ANOVA-probe proved significant difference between the two systems (Figure 1.).

Figure 1. Lettuce heads at 2nd sampling time at Conventional system (photo: author)

<u>Inner content of lettuce:</u>
<u>Nitrogen and SPAD measurement</u>
In the Conventional system all the three treatments showed an almost balanced nitrogen content of about 40 mg/g. In the Organic system, the highest values, average 23mg/g, were measured on alfalfa mulched (O-S2) plants. In rye straw-treated (O-S3) samples, the average was about 19 mg/g, while in control (O-S1) plants it was 17 mg/g.
In the Conventional system the SPAD values correlated with the nitrogen content. In all three treatments values were around 21. There were differences in the Organic system. The lowest chlorophyll content was found on rye straw-treated (O-S3) plants with values around 12. The results of alfalfa-treated (O-S2) and control (O-S1) were similar, with 17-18 SPAD value. Thus, the correlation between nitrogen and chlorophyll content was less visible in this place (Figure 2.).

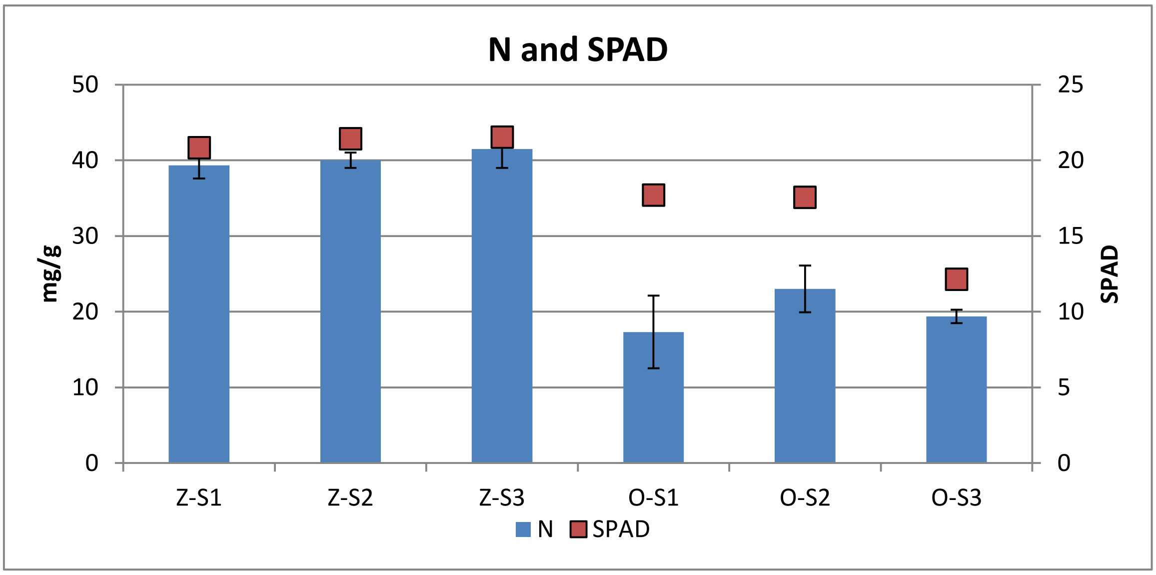

Figure 2. Nitrogen and SPAD values of lettuce samples

<u>Phosphorous content and mycorrhiza colonization</u>

Colonization was higher in the Organic System for both sampling times. After the first sampling, the highest colonization, 68%, was found on the control (O-S1) plants. Plants treated with alfalfa (O-S2) and straw (O-S3) had 52% and 50% colonization. However, the increase in colonization in the two treated areas was observed in the second harvest, but a decrease occured in control plants. Fungus samples on O-S1 plants decreased to 55.5% and increased to 62% and 65% in O-S2 and O-S3 treatments.

Of the samples taken at both times in the Conventional system, the Z-S2 plot showed the highest colonization ratio. First time 28,5% second time 40%. Samples of Z-S3 were first measured at 25% and second at 30%. The amount of mycorrhiza was 22% and 36% on the control plants. Thus, all treatments showed an increase in the degree of colonization. ANOVA-probe showed significant differences in the colonization both times.

We also examined the arbuscules, but the results were not sufficient for definite conclusions. There is a definite relationship between P content and root colonization. In the Organic system, the P content was significantly lower than the Conventional system. For the first sampling time, the highest value of 2,6 mg/g was measured in O-S1 plants, the lowest, 2,15 mg/g on O-S3, and 2,53 mg/g on O-S2. Mycorrhization on these plants followed the same trend. However, there was a change at the time of the second sampling. The average P content decreased to 1,55 mg/g for O-S1, 2,28 mg/g for O-S2, and 1,36 mg/g for O-S3. Mycorrhization in control areas decreased proportionally, while in treated areas, in contrast to phosphorus, increased.

The correlation between the two measured parameters in the Conventional system was observed on both times. At the first measurement, the average P content in Z-S1 were 5,77 mg/g, 6,54 mg/g in the Z-S3 and 6,67 mg/g in the Z-S2. The percentage of colonization showed the same order. For the second measurement, the P content of the control plants increased to an average of 6 mg/g, while the alfalfa and rye straw treated lettuces decreased to 6,26 mg/g and 5,81 mg/g. Although mycorrhization increased in all three treatments, Z-S3 treatment showed the slightest increase, with the highest decrease in P content. The P content in Z-S1 areas increased the most, and colonization also showed the biggest growth (Figure 3.). The difference in phosphorus content in different treatments was noticeable at the level of root colonization. In most cases, the highest phosphorus content was measured in alfalfa mulched plants and colonization on these plots was also slightly higher.

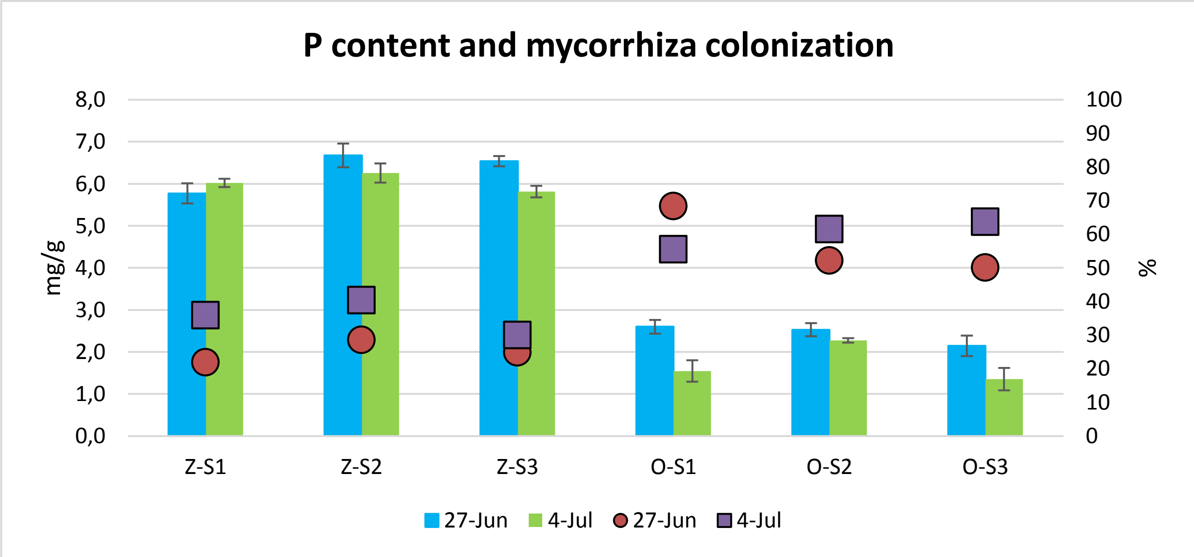

Figure 3. Correlation between phosphorous content and mycorrhizal colonization at both times

Conclusion

For head diameter in the Conventional system, in most cases, the highest values were measured on the control (Z-S1) and alfalfa (Z-S2) mulched plants, the rye straw mulched (Z-S3) plants showed the lowest results. In the Organic system the lowest results were also measured on rye straw mulched plants (O-S3), but in this system, alfalfa treatment (O-S2) showed the highest values. Based on these, may the allelopathic effect of rye straw was present in both areas (Jabran, 2017). A kind of 'good fertilizer effect' of alfalfa mulch was well observed in the Organic system, but this effect was not observed in the Conventional system (Hatwig and Ammon, 2002). This could be the effect of fertilizers used in conventional cultivation, which resulted a better nutrient supply in unmulched areas.

In the Conventional system there were no significant difference between treatments neither in the nitrogen content nor in the chlorophyll content. Due to small differences, no definite conclusions can be drawn. In the Organic system, the highest values for both N and SPAD were measured on treatment O-S2, which can be deduced from the positive effect of alfalfa mulch. Data from the other two treatments showed no correlation between nitrogen and chlorophyll content, however in other cases we verified the results of Sharaf-Eldin et al (2015). Mycorrhiza fungi were more present in the Organic system than in the Conventional system. The ratio of colonization can be associated with the phosphorus supply of plants. The results of the phosphorus measurement in the Conventional system showed the same tendency that we experienced with mycorrhization. In this system, the phosphorus content of the soil was almost twice as the value measured in Organic system (1. table). There was as high amount of phosphorus available in the soil, that the plants did not need the help of mycorrhizas. This also could contribute to the lower colonization ratio, because if the soil phosphorus content is high or increases, a decrease in colonization occurs (Guttay et al., 1989). Comparing the different plots, it was observed that the two measured parameters were related. Although at the time of the second sampling, in most cases the phosphorus content was reduced, while the number of mycorrhizas increased, the differences between the plots showed similar differences in both measured parameters. Mosse et al. (1973) studies proved there is correlation between phosphorus content of soil and mycorrhiza colonization.

Altogether, mulching has an impact on the morphological and inner content parameters of lettuce and on root colonization. Also, mycorrhiza fungi influence phosphorus uptake. However, due to the nature of conventional cultivation, these differences were less pronounced. It can be stated that cultivation method, which is less burdensome to the environment, has a positive effect on the mycorrhizal ratio. Although several correlations can be observed between the measured parameters in present experiment, for more definite conclusions further experiments should have been carried out.

KNOWLEDGE OF THE ECOMOMIC EFFECT OF BIOLOGICAL METHODS APPLICATION IN AGRICULTURE

Angel SAROV*

Institute of Agricultural Economics, Sofia, Bulgaria
*Corresponding author: angelsarov@abv.bg

Abstract

During the past few decades investigations have been conducted on the impact of different biological methods on yields, production quality and early maturity in agriculture. The benefits of their application have been established. From a theoretical point of view, the isolated established economic effect of a factor would be confirmed if there is no a deficit of resources. The effect of the application of biologically active substances may be economically beneficial for one agricultural holding and proven as useless for another farm. The economic efficiency of the various factors must be assessed in the context of the whole set of conditions under which an agricultural enterprise operates. The aim of this study is to test the mathematical model for assessment of the economic effect of biological methods application in optimizing the structure of production. The elaboration of the production structure is one of the most important and complex agro-economic tasks in the management of the farm. The assessment of the economic effectiveness of the different biological methods will be done through an optimization model to improve the farm production structure. The results of the preliminary studies show that in assessing the impact of biological substances it is necessary to take into account not only the increase in profitability and the profit per unit area of agricultural crops, but also whether the profit of the holding has increased as a whole.

Keywords: *knowledge, agriculture, economic effect, biological methods, optimizing of production structure.*

Introduction

The growth of the planet's population in line with the objectives of sustainable governance and environmental protection, required the introduction of innovations in agriculture. Besides the way of selection and mechanization in plant production, there is also a relatively new direction in the field of agricultural science. These are the biological production methods - growth regulators (Belcheva, S., 1989; Ankita, M., Debasish, P., 2017) or biologically active substances (BAS) (Brown P. and Saa S., 2015). The natural growth regulates include auxins, gibberellins (Rademacher, W., 2015, 2018), cytokinins, defoliants, femininizers, retardins (Izumi, K., Yamaguchi, I., Wada, A., Oshio, H. & Takahashi, N, 1984), abscissic acid, ethylene, etc. All of these are natural or synthetic substances and some of them are even extracted from the plants themselves (leaves, stems, fruits), i.e. they are completely harmless to human and animal health when applied in a certain ratio. They regulate plant growth, reveal and increase their biological potential (Looney, N. & Jackson, D., 2011; Fridlender M., Kapulnik Y. and Koltai H., 2015).

However, there is still a shortage of knowledge and research in Bulgaria for the economic benefits of their application. It is known that they contribute to increased yields in plant growing, early maturity and production quality. They reduce the fall of the flowers, seeds, and fruits, and they can regulate the maturation time of the fruits. The growth regulators are applicable to different crops such as wheat, legumes, vegetables, orchards, etc.

To determine the practical effectiveness of different growth regulators, all costs (not just the price of regulators) and absolutely all positive effects must be taken into account. At this stage, this has not been done by the BAS's developers and distributors. Normally, when analyzing the economic effects of a given method, the complex set of factors, interrelationships and interdependencies among all factors of production are not taken into account.

Typically, the same economic effect from the application of a factor (when identified in isolation from the specifics of the conditions in which the farm operates) may be beneficial to one enterprise and otherwise proven to be useless. From a theoretical point of view, the isolated established economic effect of a factor would be confirmed if there was no deficit of resources. The effect of the application of the biologically active substance may be economically beneficial to one agricultural holding and proven to be useless for another farm. The economic efficiency of the various factors must be assessed in the context of the whole set of conditions under which an agricultural enterprise operates. Therefore, knowledge about the economic impact of BAS is needed. In other words, the economic efficiency of a factor must be judged not only on whether the profit per unit area of the crop in question is significant, but rather on whether it increases the profits of the enterprise in general.

The usefulness of the factors of production should be established by the elaboration of the farm business plan. The basis of the business plan of an enterprise is the production structure. Therefore, I will evaluate the economic efficiency of different BASs by optimizing the farm structure by using linear programming.

The aim of this study is to test the mathematical model for the assessment of the economic effect of the biological methods in optimizing the structure of production.

Material and Methods

The necessary information was gathered with the assistance of specialists from the studied farm. The farm is a legal entity registered under the Cooperative Law as agricultural production cooperative. Its activities are in a flat and hilly terrains of Veliko Tarnovo region, Bulgaria. Climate conditions create prerequisites for growing the following crops of wheat, barley, maize, silage maize, sunflower, Burley tobacco, vineyards, fruit trees (apples, peaches, cherries), vegetables (tomato, pepper), lucerne (for seed and hay) and dairy cows. The agricultural cooperative cultivated land area: 8059 decares[1]

A detailed description of the linear programming is available in Dantzig, (1987); Nikolov, N., Ivanov, G., Stefanov, L., (1994); Vanderbei, (2015); Piryonesi, & Tavakolan, (2017), etc.

For the creation of the model, the study is based on Nikolov, N., Ivanov, G., Stefanov, L., (1994). Solving a particular economic problem with mathematical methods means creating an economically-mathematical task. Economic modeling is a mathematical task, which reflects with satisfactory precision the most important relations and characteristics of the economic problem. These tasks are constructed in a system of linear dependencies. They should reflect the conditions to be taken into account when solving the task. The objective function expresses the optimality criteria (min, max):

$$
\begin{array}{l}
A_{11}X_1 + A_{12}X_2 + \cdots + A_{1n}X_n \leq B_1 \\
A_{21}X_1 + A_{22}X_2 + \cdots + A_{2n}X_n \geq B_2 \\
. \\
\\
A_{m1}X_1 + A_{m2}X_2 + \cdots + A_{mn}X_n = B_1 \\
\hline
F = C_1X_1 + C_2X_2 + \cdots + C_nX_n \rightarrow \max\ (min),
\end{array}
\qquad (1)
$$

Where:

- X_j – indicates the size (magnitude) of the activities or metrics,
- A_{ij} and Cj – indicates the activities that will be done,

[1] 1 ha=10 decares

- B_i – means the amount of available resources or the amount of activities (restrictions).
- The objective function F gives the optimality criteria.

Objective function:

$$F_{max} \text{ (gross margin/profit)} = \sum_{j \in T}^{n} C_j X_j, \qquad (2)$$

where:

- C_j is (gross margin/profit) from j-th unknowns;
- T is the aggregate of the indices of the unknowns from which the gross margin / profit is obtained.

The solution of the model will answer the following questions:

1. Establishing the optimum production structure according to the constrains and the optimality criteria;
2. Establishing the impact of the BAS on efficiency and production structure, depending on the chosen optimal criteria;

In order to establish the production structure of the selected agricultural holding, it is necessary to determine: a crops area; a number of animals; a feed balance, labor resources and other activities. When developing the model, the optimality criteria will be max gross margin. Additionally, we will set another criterion for optimality - max profit.
The argument for choosing this agricultural cooperative is based on the fact that experts and researchers in agri-economic science find that farms in this areas have a mixed specialization - plant growing and livestock breeding. In order to determine the production structure of the selected cooperative, it is necessary to determine the area of the crops, the number of animals and other activities to achieve maximum economic impact. During the developing of the model, the criterion is to achieve the maximum gross margin with the inclusion of BAS and without applying them. The solution of the problem will also answer the questions regarding the most cost-effective production processes for crop production (for feed and commodities) and for livestock breeding (cows, feeding for 4 000 l milk, ration). On the other hand, the model provides the opportunity to quickly and easily develop different options for optimizing the production structure in case of a change of production or some of the limiting conditions. Additionally, the decision will present the impact of BAS on the production structure and, accordingly, on the economic outcome. The production structure in the case at hand depends on the specifics of natural conditions and limiting factors. On the chosen farm, the organizational conditions are as follows:

1. The quantity and quality of the land, irrigated conditions.
2. The amount of grazing meadows.
3. The quantity and quality of the main productions (breeds of selected animals, milking, presence of cowshed, warehouses, etc.).
4. Labor resources (number of permanently employed workers, plant breeders, livestock-breeders, mechanics, zootechnics, agronomist.
5. Agrotechnical crop rotation requirements (minimum / maximum limits in which they may vary, green / dry weight ratio).
6. Zootechnical conditions regarding the feeding of animals according to the milking (ration, green, dry, concentrated, fodder).
7. Contracts to buy milk, sale of commodity crops.
8. Ability to purchase concentrated fodder.
9. Prices of marketed production and means of production.

For all activities with and without application of BAS develop technical and economic norms of 1 decar or 1 t. production - for an average yield, selling price, incoming, material costs, labor costs, production costs, income, profit, business days, etc. I use the Solver application in MS Excel, for the purpose of optimization, the objective function, Solver is an application that can be used to find an optimal solution (minimum or maximum) of an equation that is subject to various constraints. The optimal solution should be located in one cell and to be the result of the mathematical calculation of the variables of the objective function. The article presents one case from which no conclusions can be drawn about the effects of the biological methods under farms. This is due to the fact that the more criteria from different groups (land, plant, livestock, labor) are included in the optimization, the more the model strikes for a balance between the created organizational conditions, which is often a prerequisite for compromise solutions to the task.

Results and Discussion

The results make it possible to assess to what extent and how the resources in the cooperative are used and, accordingly, the economic effect. Linear optimization allows to take into account changes in the production structure under the influence of a BAS, taking into account the whole complex of factors and their relationships.

Table 1 show the solution of the task of optimizing the production structure of the agricultural cooperative under different criteria of optimality: maximum income and maximum profit respectively with / without use of growth regulators (BAS). In the criterion of optimality of maximum income, using wheat and barley BAS occupies 41.9% of the arable land and the maize - 40.3%. Without BAS, wheat and barley occupy 50% and maize is reduced to 27.3%. Attention is paid to the fact that the pepper is inefficient production and does not enter the production structure when using BAS. The same applies to tobacco, which however disappears from the farm's production.

Table 1. Results of the optimization model, decares/n.

Products, decares	F max gross margin with biological activity substance	F max gross margin without biological activity substance	F max profit with biological activity substance	F max profit without biological activity substance
Wheat	991	991	991	1239
Barley	2179	2665	2116	2614
Maize	3046	1980	3047	793

Total decares	8059	8059	8059	8059

Source: Author's elaboration based on survey result.

Table 2 show the economic efficiency again at maximum income and maximum profit, respectively with / without using growth regulators (BAS).
The results show that the application of BAS is economically efficient. In the optimum criterion in the maximum income function, the optimal use of BAS gives 47% more incoming. At the same time, the production costs with BAS increased by 9.9%. This has an impact on income, which as a result of the application of BAS has increased by 52% and the profit by over 91%.
The results change with optimal maximal profit criterion, i.e. incoming with application of BAS gives an increase - 50%; production costs - 13%, income - 57% and profit 94.4%.

Source: Author's elaboration based on survey result.

More than 200 biological methods for regulating the physiological processes of plants are currently used worldwide with the help of BAS. Production and sales of growth regulators on international markets are steadily increasing. In Bulgaria, the application of growth regulators is still limited mainly due to the lack of knowledge and information on the positive economic effect. The main reasons for this lag are the insufficient scientific potential, the poor relationship with agribusiness and the lack of marketing.

Conclusions

Increasing plant productivity can be achieved on the one hand by genetics and selection, as well as by managing physiological and biochemical processes through the use of growth regulators, on the other hand. Great hopes have been addressed to growth regulators to increase the absorption of solar energy from plants. New groups of natural BAS will be discovered in the near future. They will refine existing growth regulators to achieve high physiological activity combined with highly selective action and safety for human health and the environment. At the same time, there is a need for more knowledge about the economic efficiency of applied biological methods in agriculture.

[2] Not included CAP subsidies
[3] Not included fixed costs
[4] 1 lev= Euro 1,95583 (2019).

The assessment of the economic efficiency of different biological methods was done through an optimization model for the structure of agricultural production. The results showed that when assessing the impact of biological substances, it is necessary to take into account not only the increase in the profitability and the profit per unit area of the crops, but also whether the profit of the holding is increasing in general.

Abstract

The paper aims at analyzing organic food market in Serbia with a particular focus on structural characteristics on production units and organic food distribution channels. Secondary data were collected mainly from Serbia Organica's database and includes 102 registered domestic producers/processors. Our research showed that the organic market in Serbia was still immature, as it was not well-organized and the products were not readily available on the market. The overall market share for organic food was extremely low as well as share of utilized area under organic production in total agricultural land. Research results indicate that the majority of farms are small, with fruit growing being the most prevalent activity. Majority of producers sold their products to wholesalers and to processing companies. The size of farm is not the main obstacle for further development of the organic food market since there is no statistically significant correlation between distribution channels and the utilized land for organic production. Despite that, the sector showed positive tendencies - domestic growers were increasingly turning to certified organic farming systems; large retails chains upped their offer of organic imported products; a large companies getting involved in primary agricultural production on larger land areas; and promotion of organic products was intensified in the past years. Taking into consideration that the majority of organic producers in Serbia are small farmers, in order to increase the supply, an improved framework for business development should be applied. In order to develop the local organic market, a complex measures must be adopted.

Key words: *Distribution channels, organic agriculture, organic market, Serbia*.

Introduction

The year 2017 was a record year for global organic agriculture: 69.8 million hectares or 1.4% of the world's agricultural land were dedicated to organic production (including in-conversion areas); about 2.9 million farmers from 181 countries/territories were engaged in this production; 93 countries had adopted organic legislation; global sales of organic products reached 97 billion US dollars with an average per capita spending of 12.8 billion US dollars (Willer *et al*., 2019). Thanks to a shift from natural shops to mass retail sales the organic agro-food system has been transformed from a local network to a globalized system. As a result of this process that lasts more than three decades over half of organic sales is done through supermarkets (Sahota, 2016). Many mergers, acquisition, and investments were announced over the past years. Among other, the world's largest organic food retailer Whole Foods Market was bought by Amazon, who is now actively promoting organic food on its online platform (Sahota, 2019).

Despite the overall positive outlook there are a few potential threats that may hinder the future growth of the organic sector: rising number of standards, supply shortfalls, competing labels, trade agreements, and demand concentration (Sahota, 2019). Regarding demand concentration it is important to emphasize that although approximately 87% of organic producers and a quarter of organic agricultural land were in developing countries (Willer *et al*., 2019), North America and Europe comprised almost 90% of global revenues (Sahota, 2019). The absolute leader - the US - worth US $45.2 billion, while the Europe worth US $39.6 billion in 2017. The highest per capita consumption in 2017, with more than 300 US dollars were found in

Switzerland and Denmark (Willer *et al*., 2019). In the same time, in India - home to the highest number of organic producers in the world (835,000)- *per capita* spending on organic packaged food and beverages was just about 0.04 US dollars (Organic Trade Association, 2019). Similar problem can be found in many other Asian as well as African and Latin American countries. In addition, internal market of organic food in Central & Eastern (CEE) countries, including Serbia is also slowly developing. Also, there is *a lack of* reliable data on the *organic market* in Serbia. Several articles describe the general tendencies of the sector (*e.g.* Brankov *et al*., 2014; Grubor and Djokic, 2016; Lukic, 2011).
That's why the objective of the present paper is to provide an overview of organic food market in Serbia with a particular focus on the structure of producers and processors in relation to activity, and the distribution channels.

Material and Methods

The paper is based on an extended review of secondary data provided by International Federation of Organic Agriculture Movements (IFOAM) and the National association for development of organic production *Serbia Organica.*
In 2015, there were 334 organic producers and they had a certificate issued by internationally recognized organizations, as well as around 2.000 producers-cooperants whose production is subjected to group certification (Serbia Organica, 2017). With the support of the USAID Project for Competitive economy, in 2019 Serbia Organica placed under its website, unified producers and processors with data on the types of primary and processed organic products, their quantities, the standards for which they are certified, and other important information. So far, 102 producers/processors out of 334 have been registered. The sampling frame for this study included those producers registered in the database. After the introduction, the paper gives an overview of organic agriculture in Serbia. In the next part of the paper structural characteristics of production units are described. Finally, organic food distribution channels are described. For the purpose of the analysis, the distribution channels of organic food in Serbia have been classified into: (1) *direct*: on-farm sales, farmers markets and door-to-door-sales*;* (2) *indirect:* specialized shops and retail chains. Furthermore, some suggestions for further development of the organic food market in Serbia are highlighted.

Results and Discussion

Organic agriculture in Serbia

Organic production in Serbia concerning the area of utilized land significantly increased in the period 2012-2015: from 6.340 ha to 15.298 ha. Total utilized land under organic production includes areas in conversion and those with organic status as well as meadows and pastures. However, the share of organic production in overall arable land remains extremely law - just 0,44% in overall arable land (Serbia Organica, 2017). A significant increase is noted also in number of heads of animals included in this production. But, in the context of the total number of heads of animals, participation of organic production is very infirm. For example, the share of organic sheep is accounted for 0.27% of the entire population.
Consequently, domestic market of organic products is still underdeveloped despite significant positive changes in the recent years. The major cities in Serbia – Belgrade and Novi Sad – are the major markets for organic food. It is quite expected and correlated with purchasing power of the citizens. Generally speaking, organic market in Serbia is still immature: first specialized market of organic products started to work in mid-2011 in New Belgrade; the first organic meat appeared in 2015; promotion of organic products has been intensified in the past years, but national logo of organic products is still not enough promoted (Serbia Organica, 2017). Regardless, there are some improvements: imported organic products are more present on the market, especially processed fruits with lower prices than domestic one; online shopping

becomes available; retail chains showed interest and demanded bigger quantities of organic food (Serbia Organica, 2017). Unfortunately, domestic producers are not capable to provide continuity and quantity to increase supply and organic products are not enough visible on domestic market.

Structural characteristics of production units

According to their status, the majority of farms are organic (n=84), while 18 of them are in conversion. Organic food producers from almost all Districts in Serbia, except Sumadijski and Borski District were included in the research. The number of organic food producers who participated in research is as follows: Grad Beograd (n=14), Severno-Backi (n=8), Srednje-Banatski (n=6), Severno-Banatski (n=2), Juzno-Banatski (n=5), Zapadno-Backi (n=2), Juzno-Backi (n=13), Sremski (n=7), Macvanski (n=1), Podunavski (n=1), Kolubarski (n=3), Branicevski (n=2), Pomoravski (n=1), Zajecarski (n=2), Zlatiborski (n=11), Moravicki (n=3), Raski (n=1), Rasinski (n=8), Nisavski (n=5), Toplicki (n=1), Pirotski (n=4), Jablanicki (n=1), and Pcinjski (n=1). According to the type of the registered subject[5], a majority of the producers (n=96, or 94.1% out of 102 who are registered in the Serbia Organica database) are registered as producers- family farm, trade or limited liability company, sole proprietorship and cooperative. As mixed units for production and processing, 4.9% producers are registered, while 5.9% producers are a registered processors. Majority of producers have up to 5 ha of agricultural land (60.5%), and 12.7% of these less than 1 ha. These farms are followed by those managing 2 to 5 ha (26.5%). Larger farms are few; those exceeding 50 or 100 ha are only 11, 4 of which account from 100 to 200 ha and three exceeding 2,000 ha. 38.7% of producers are controlled and certified by Organic Control System, 32.1% by Ecocert Balkan, 14.1% by TM CEE, 10.4% by Centar za ispitivanje namirnica and 4.7% by Ecovivendi. Serbian National Organic logo was awarded to 91.2% of all producers, EU logo to 50% of all producers, and BioSuisse logo to 2.9% of producers.

Fruit growing is the most dominant activity in which 52.9% of producers are engaged, whereas the least represented activities are mushroom growing and bee keeping. However, not all producers engage in only one activity, e. g. besides fruit growing they also grow vegetables. Table 1shows the structure of producers in relation to the activity.

Table 1. Structure of producers and processors in relation to activity

Activity	n	%
Producers		
crop production	23	22.5
vegetables growing	27	26.5
fruit growing	54	52.9
wine growing	7	6.8
medicinal, aromatic and spicy herbs – growing and wild collection	15	14.7
mushroom growing and wild collection	2	2.0
livestock breeding	5	4.9
bee keeping	1	1.0
Processors		
forest products	7	6.9
plant products	3	2.9
animal products	2	1.6

Source: Authors' calculation based on Serbia Organica's database

[5]A– registered producer; family farm, trade, limited liability company; sole proprietorship, cooperative; B – other type of registered units; C - registered processor; ABC – mixed unit - production/processing.

Organic food is exported by 24.5% of producers registered in Serbia Organica's database and mainly to the following countries: the US, Switzerland, and the EU countries.

Distribution channels of organic food produced by domestic producers

According to Renko (2010) retail is an important distribution channel for organic food market supply in Serbia and the *objective of the research was to check the hypothesis that retail is a significant distribution channel for domestic producers.*The structure and frequency of organic food sales are shown in Table 2.

Table 2.Th**e** structure and frequency of organic food sales through intermediaries

Organic food retail	n	%
specialized shops	6	5.9
retail chains (supermarkets, hypermarkets)	7	6.9
retail chains (supermarkets, hypermarkets) + specialized shops	6	5.9
total	19	**18.6**
Direct distribution channels		
on-farm sales	2	2.0
farmers markets	2	2.0
door-to-door-sales + farmers markets	5	4.9
total	9	**8.8**
Direct sales and sales through intermediaries	4	**3.9**

Source: Authors' calculation based on Serbia Organica's database

As could be seen from the Table 2, organic retail sales is practiced by 18.6% of producers, while direct sales e.g. on-farms sales, on green markets or door-to-door sales is practiced by less than 9% of the individual farmers. In addition, 3.9% of producers use both distribution channels (direct and through intermediaries). Most probably, the rest (68.7%) of producers sold their products to wholesalers and to processing companies. This is in line with finding that "the mark up in price they obtain for their organic produce is very moderate (with 10-20% on the average) and confirms that added value is not generated on the farm level" (Serbia Organica, 2017).

Considering that majority of organic producers are small producers (have up to 5 ha of agricultural land) *the second objective of the research was to determine whether small producers are in the position to reach certain distribution channels.* In order to examine the statistically significant correlation between distribution channels and the size of the area under organic production, chi-square ($\chi 2$) test was calculated (Table 3). The obtained results ($\chi 2$=23.870; $p>0.05$) show that there is no statistically significant correlation between distribution channels and the area of agricultural land under organic production.

Table 3. Cross tabulation of utilized land (in ha) under organic production and the distribution channels in Serbia

Area under organic production		Distribution channels through which the organic food is marketed

Source*: Authors' research*

Producers operating in *less* than 5 *hectares use both distribution channels equally. The products are sold directly to consumers (n=8) and through intermediaries (n=8). 2 of small-scale producers claim they have sold their products through both channels. Producers* with *20-50ha also use both distribution channels equally, while producers with 5 to 10 ha, and more than 50 ha sales through intermediaries.* This finding was confirmed by the chi-square test, which showed that there was no statistically significant correlation between small and big producers regarding the distribution channels.

Conclusions

This paper provides a short overview of organic production and marketing in Serbia. It investigates distribution channels of organic food by domestic producers based on the analyses of the available literature and presents the results of the research conducted on the Serbia Organica's sample of domestic organic food producers. Research results indicate that the majority of farms are small (60.5%), with fruit growing being the most prevalent activity (52.9%). The aim of the research was to assess the role of retail chains in organic food distribution and to determine whether small producers distribute their organic food exclusively through direct channels of distribution. The importance of retail sales cannot be denied since 18.6% of producers sold their products through this distribution channel. However, majority of producers sold their products to wholesalers and to processing companies. This is one of the most important reasons for the "invisibility" of organic products on the market. Considering that a statistically significant correlation between distribution channels and the utilized land for organic production has not been determined, it can be concluded that the size of farm is not the main obstacle for further development of the organic food market. For further development of the local organic market, a wide range of *measures must be adopted.* A stable *government support* is crucial for boosting growth and improving the sector of *organic* agriculture. *In addition, it is necessary to* improve the political and economic framework in the country; to facilitate access to finance and or operation of special credit lines, to implement strong and intensive campaigns with clear communication strategy etc.

AGRICULTURAL UTILISATION OF BIOWASTES AND BIODEGRADABLE WASTES

Monika JAKUBUS

Department of Soil Science and Land Protection, Poznan University of Life Sciences, ul. Szydłowska 50, 60-656 Poznań, Poland

Abstract

Due to rapid urbanisation and an increasing global population huge amounts of diverse wastes are produced. In this group a particularly important role is played by biowastes and biodegradable wastes. Presently in most European countries landfill disposal of these substances is banned, which makes them a potentially very attractive alternative for organic agriculture, after appropriate preparation such as stabilisation and/or composting. It is well known that the chemical composition of individual waste groups varies and consequently it will influence their agricultural quality. Therefore this study is focused on the verification of the above assumption. For this purpose 3 different composts (prepared from sewage sludge, garden and park wastes and a mixture of kitchen and garden wastes) and 2 municipal sewage sludge samples originating from one small and one bigger municipal wastewater treatment plant were evaluated in terms of their chemical properties (contents of macro- and micronutrients, the quality and quantity of humic compounds). Additionally, phytotoxicity of the composts and sewage sludges was analysed using phytotests. The study clearly demonstrated that the sewage sludges, independently of their origin, were more abundant in most macronutrients (e.g. C, N, P, S, Mg and Na) and micronutrients (Fe, Zn, Cu, Ni) in comparison to composts. At the same time it should be underlined that regardless of compost compositions they were richer in organic matter and Ca, K and Mn contents. Moreover, the composts were characterised by more favourable properties of humic substances and their influence on plants manifested in phytotests was more advantageous than that of the sewage sludges. The obtained showed both the analysed composts and sewage sludge to be promising organic substances as potential substitutes of mineral fertilisers according to the principles of sustainable agriculture, which becomes the predominant trend in agronomy.

Keywords: *Compost, Biowaste, Sewage sludge, Nutrients, Humic compounds.*

Introduction

Modern farming practices, such as intensive cropping, tillage and removal of crop residues, contribute to the depletion of soil organic matter reserves and low nutrient availability in arable land. At the same time the decline of soil organic matter has been identified as one of the most important threats to soil quality, as underlined in the document named Thematic Strategy for Soil Protection (2006) passed by the European Commission. Thus, to enhance productivity and restore degraded soils, organic fertiliser application is often required. Moreover, nowadays application of organic amendments has been employed as a fundamental principle of sustainable agriculture. Simultaneously, in view of the decreasing population of farm animals and the related limited availability of manure and slurry, a highly promising alternative may be provided by biowastes (garden and park wastes, food and kitchen wastes from households and restaurants) and biodegradable wastes (wood, paper, cardboard, sewage sludge, forestry and agricultural residue) utilised for agricultural purposes. It is very to implement thanks to an increasing generation of organic waste as a result of rapid urbanisation at the simultaneous trend to follow circular economy principles. Among the huge group of various wastes those above-mentioned constitute a very important and significant part. Presently according to the European Council Directive (1999) as well as Polish legal regulations landfilling of these types of wastes is forbidden. At the same time, biowastes and biodegradable wastes represent a valuable resource thanks to their chemical composition. For this reason, organic fertilisation using these wastes could be an alternative method substituting inorganic fertilisers, improving general soil fertility and maintaining soil macro- and micronutrients at appropriate levels (Jakubus, 2013, Sharma *et al.*, 2017). Obviously, first of all the applied wastes must be properly prepared and stabilised to meet criteria of environmental safety imposed by legal regulations. Composting is one of the methods of biowaste and biodegradable waste preparation. This process has been presented as an environmentally friendly alternative applied to manage and recycle organic waste with the aim to produce products used as amendments in agriculture (Gu *et al.*, 2011, Deepesh *et al.*, 2016).

Therefore, the main aim of this study was to evaluate applicability of various organic wastes such as sewage sludge and composts in agriculture.

Material and Methods

Chemical analysis of composts and sewage sludges

The composts were commercially prepared from a mixture of green plant residues and kitchen wastes (C1), a mixture of sewage sludge, green plants and straw (C2), and a mixture of green plant residues, chopped wood and park wastes (C3). The sewage sludges (SS1 and SS2) originated from municipal wastewater treatment plants located in the Wielkopolska region, SS1 from a small, local installation and SS2 from a big sewage treatment plant, respectively. The samples of the composts and sewage sludges were collected at the end of autumn and then they were undergone to analyses.

The chemical analyses were conducted on dried samples. Total organic carbon (TOC), nitrogen (N) and sulphur (S) contents were determined using Vario Max CNS. The composts and sewage sludges were ground and ashed in a furnace at 450^oC for 6 h. The ash was dissolved in 5 mL of 6 mol· dm^3 HCl (Ostrowska *et al.*, 1991) and diluted to a constant volume with distilled water. The obtained extracts were analysed to determine the levels of macronutrients (K, Ca, Mg, Na), micronutrients (Fe, Mn, Zn, Cu, Ni) and heavy metals (Pb, Cd) using atomic absorption spectrophotometry in a Varian Spectra AA 220 FS apparatus. Total phosphorus (P) content was measured colorimetrically by the vanadium–molybdenum method. All the assays determining the amounts of individual elements in the tested samples were performed in three replications and the presented results are their mean values.

Humus fractionation was determined according to the method proposed by Kononova and Bielczikova (Dziadowiec and Gonet, 1999), in which humic substances were determined in a mixture of 0.1 mol·dm^{-3} $Na_4P_2O_7$ + 0.1 mol·dm^{-3} NaOH solution. The fulvic acid fraction (FA) was separated after precipitation of humic acids at pH 1.5 (HA). Carbon in the obtained fractions (C_{HS} and C_{FA}) was oxidised by 0.1 mol·dm^{-3} $KMnO_4$ in the H_2SO_4 medium. Humic acid carbon (C_{HA}) was calculated by subtracting C_{FA} from C_{HS}. Optical density ($Q_{4/6}$) of the obtained fractions was determined at 465 nm and 665 nm.

The germination index (GI) and the Phytotoxkit (seed germination and early growth test) were used to determine phytotoxicity of composts. The tests were performed using seeds of cress (*Lepidium sativumm* L.). The germination index (GI) was calculated according to the formula given by Miaomaio et al. (2009), while seed germination and early growth tests followed the Phytotoxkit procedure (ISO 11269-1).

Statistical analysis

Analyses of mean samples were carried out in three replicates. The obtained results were subjected to formal evaluation by the analysis of variance using the F test at the significance level $p \leq 0.95$. The least significant differences were calculated using the Tukey test at the significance level $\alpha \leq 0.05$ and then uniform groups within the factor level were established. Simple correlation coefficients were computed to show the relationship between evaluated parameters of compost maturity and stability.

Results and Discussion

Differences in the chemical composition of tested organic amendments were noticeable and statistically confirmed (Tables 1 and 2). The data in Table 1 clearly show that sewage sludges contain considerably greater amounts of N, P, S and Na than the composts. The same disparity between sewage sludge and compost was indicated by Alvarenga *et al.* (2015). The composts were characterized by higher Ca contents. The Mg amounts determined for both composts and sewage sludges were very similar, although they differed statistically. Levels of potassium, an essential nutrient for plants, were highly variable, with the highest value recorded for C3 (4.03 $g \cdot kg^{-1}$) and the lowest for C1 (0.85 $g \cdot kg^{-1}$). Simultaneously the amounts determined in C1 and SS2 were comparable, similarly as for C2 and SS1 (Table 1). Generally compost C2 prepared from sewage sludge, green plants and straw was far more abundant in N, P, Mg, S and Na, whereas C1 was very poor in all the analysed macronutrients except for Ca. Similar levels of macronutrients in composts produced from municipal waste were presented by Becher *et al.* (2018).

Table 1 The mean content of macronutrients in analysed organic amendments ($g \cdot kg^{-1}$)

Amendment	N	P	K	Ca	Mg	S	Na
C1	5.46 e	1.63 d	0.85 c	7.49 a	1.0 c	0.40 d	0.17 d
C2	14.29 c	4.24 b	2.91 b	6.24 b	1.18 ab	0.77 c	0.54 c
C3	13.22 d	2.56 c	4.03 a	7.03 a	1.15 ab	0.75 c	0.50 c
SS1	88.33 a	9.14 a	3.02 b	1.85 d	1.10 b	2.13 b	1.31 a
SS2	52.62 b	9.90 a	1.02 c	3.45 c	1.20 a	2.86 a	0.98 b

The sewage sludge from the small installation (SS1) was more abundant in N, K and Na, whereas SS2 from the big sewage treatment plant contained significantly greater amounts of Ca. Simultaneously, the discussed sewage sludge was very rich in microelements (Fe, Mn, Cu, Ni). Also this waste showed a 9-fold higher amount of Pb than SS1, while Cd amounts were comparable for these sewage sludges, ranging from 1.47 $mg \cdot kg^{-1}$ to 1.91 $mg \cdot kg^{-1}$ (Table 2). It should be underlined that neither SS1 nor SS2 exceeded the thresholds of heavy metal contents indicated in the Polish regulations for sewage sludge recommended for application as natural fertilisers.

Table 2 The mean content of metals in analysed organic amendments ($mg \cdot kg^{-1}$)

Amendment	Fe	Mn	Zn	Cu	Ni	Pb	Cd
C1	3801.5 c	175.3b	41.5 d	24.8 d a	2.5 c	14.3 c	0.07 d
C2	5059.1 b	196.4a	308.0 b	160.7 c	21.6 b	19.2 c	0.31 c
C3	3760.1 c	198.3a	243.6 c	22.1 d	3.4 c	64.1 b	0.08 d
SS1	998.2 d	134.6c	312.8 b	375.3 b	7.4 b	10.8 cd	1.91 a
SS2	16886.6 a	176.6b	430.6 a	421.2 a	54.4 a	101.3 a	1.47 b

The sewage sludge originating from the big wastewater treatment plant was characterised by higher contents of metals than sewage sludge from the small treatment plant. Comparing obtained data with literature sources (Turek *et al.*, 2019) it may be noted that amounts of Cu, Ni and Pb were higher, while those for Zn and Cd were lower. Similarly as it was presented above, among the tested composts C2 was richest in all the analysed micronutrients, while levels of micronutrients determined for C1 and C3 were very comparable and significantly lower in relation to the values presented for C2 (Table 2). Generally the sewage sludges were richer in microelements than composts. Irrespective of compost mixture composition the amounts of nutrients increase as follows N> Ca> P > K > Mg > S > Na for macronutrients and Fe > Zn > Mn > Cu > Ni for micronutrients. Regardless of the size of the wastewater treatment plant the macronutrient contents in sewage sludge increased in the following order: N> P > Ca > K > S > Mg > Na, while for micronutrients it was Fe > Zn > Cu > Mn > Ni.

Taking under consideration the potential agricultural utilisation of both sewage sludges and composts, the organic matter and organic carbon contents are especially important. The data given in Figure 1 show that composts, particularly C1 and C2, are highly abundant in organic matter, which amount ranged from 920 to 940 $g \cdot kg^{-1}$. Organic carbon contents in composts were determined between 256.2 $g \cdot kg^{-1}$ to 424.2 $g \cdot kg^{-1}$ at the percentage share in organic matter of 33 – 46%. In turn, the sewage sludges were characterized by huge organic carbon contents ranging from 540 $g \cdot kg^{-1}$ to 780 $g \cdot kg^{-1}$ and relatively smaller amounts of organic matter (653 $g \cdot kg^{-1}$ and 780 $g \cdot kg^{-1}$) in relation to the data shown for the composts (Figure 1). Regardless of the above, the percentage share of organic carbon in organic matter was 82%. One of the most commonly used methods of stabilising sludge consists in the addition of lime. Calcium oxide promotes both immobilisation of metals and reduction of organic matter content, so that explains its small amounts and it is consistent with literature data (Turek *et al.*, 2019).

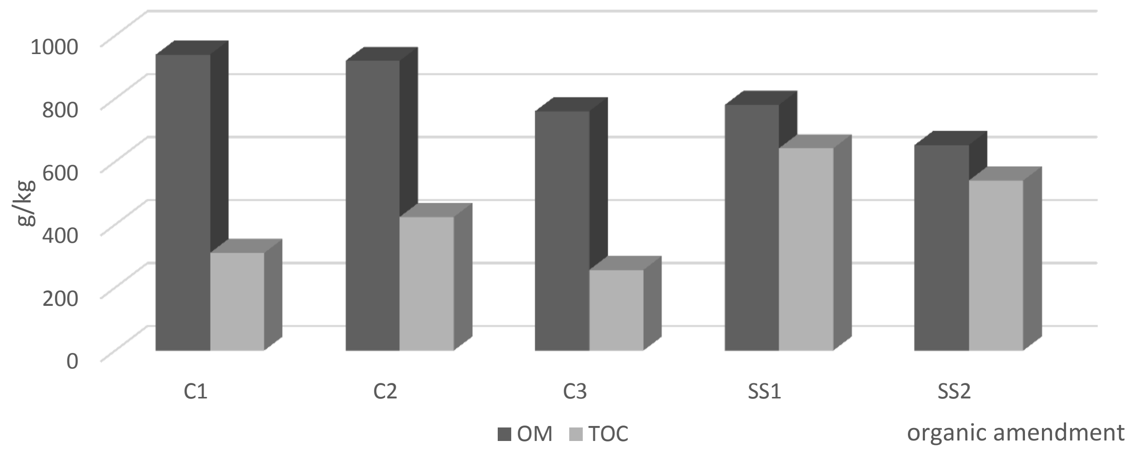

Fig. 1 The organic matter and organic carbon amounts in analysed organic amendments

Contents of nitrogen, organic carbon and organic matter determined for compost prepared from sewage sludge are very similar to those cited by Jakubus (2013).

Not only the quantity, but also quality of organic matter is very important, especially when we consider soil fertility improvement in the term of increasing soil humus levels. The sewage sludges contained significantly bigger amounts of humic substances (59 – 120 $g \cdot kg^{-1}$) in relation to composts (30.8 – 48.6 $g \cdot kg^{-1}$) (Figure 2). Regardless of the above, the quality of sewage sludge humic substances was lower because they were mainly composed of the fulvic acid fraction (45 – 90 $g \cdot kg^{-1}$). In contrast, the compost humic substances consisted primarily of humic acids (24 – 42 $g \cdot kg^{-1}$), i.e. more valuable and more polymerised compounds. These differences were also reflected in the values of $Q_{4/6}$ presented in Table 3. The values of optical density for the mixture of FA and HA as well as for FA were significantly higher in relation to the data obtained for the composts. The lower values of $Q_{4/6}$ indicate greater maturity of humic substances, their more advanced humification stage and aromatisation, which is more desirable. The noticeable differences in the composition of humic substances between sewage sludges and composts are related to the composting process, which accelerated the humification transformation of organic compounds into humic acids. This phenomenon is well documented in literature (Li *et al.*, 2017, Becher *et al.*, 2018).

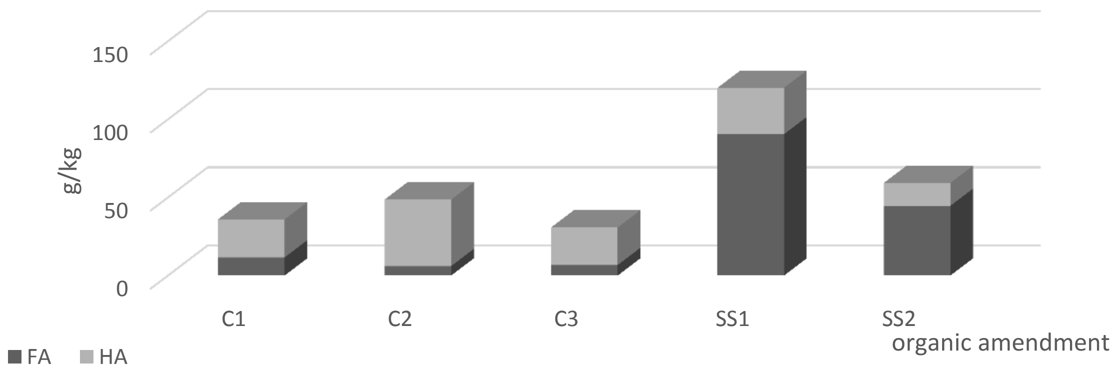

Fig. 2 The content of organic carbon of humic acid (HA) and fulvic acid (FA) in analysed organic amendments

Table 3 The values of $Q_{4/6}$ obtained for humic substances of analysed organic amendments

Amendment	Mixture of FA and HA	FA
C1	5.62	4.34
C2	6.06	5.27
C3	6.15	2.69
SS1	17.28	8.34
SS2	13.88	5.08

Application of the composts or sewage sludges not only influences soil properties, but also vigor of seed germination, therefore analysis of such an effect is fundamental. The organic amendments analysed in this study were subjected to this type of assessment using the obligatory biotests such as the germination index and the phytotoxkit and the final results are presented in Table 4. The application of bioassays is considered a sophisticated method to evaluate environmental threats, supplementing chemical methods. Generally the best conditions for germination of cress seeds were observed in the case of C2 and SS1, because the values of GI were the highest (78.2% for C2 and 87.1% for SS1). According to Jakubus and Bakinowska (2018), the range of GIs between 80 and 160% reliably indicates a low phytotoxic effect of the tested organic amendments. Moreover, inhibition of both seed germination and root elongation was the lowest in the case of C2 and SS1, amounting to 3.6 % and 0%, respectively (for seed germination inhibition) and 22.1 % and 9.3 % (for root elongation inhibition) (Table 4).

Table 4 The values of GI, inhibition of seed germination and root elongation (%)

Amendment	GI	inhibition of seed germination	inhibition of root elongation
C1	68.2	25	36.6
C2	78.2	3.6	-22.1
C3	64.4	28.6	51.2
SS1	87.1	0	9.3
SS2	70.2	14.3	30.2

Conclusions

The presented study confirmed that sewage sludge is a highly valuable organic amendment, which can serve as a source of both organic matter and nutrients essential for plants. Additionally, various composts apart from nutrients provide significant amounts of quality organic matter. Generally it should be underlined that regardless of the organic amendments tested in this study, their chemical composition shows considerable abundance in macro- and micronutrients as well as organic matter exceeding the typical composition of manure. Thanks to such favourable properties both composts and sewage sludges fit perfectly into the concept of circular economy and provide a promising alternative to commercial fertilisers in modern agriculture.

THE USE OF FUNGI OF THE GENUS TRICHODERMA TO REDUCE THE INFECTIOUS BACKGROUND OF THE SOIL

Abstract

Fungi of the genus *Trichoderma* and preparations based on them have long been used as effective antagonists to suppress a wide spectrum of phytopathogenic microflora and to induce soil improvement. The effect of seven strains of fungus of the genus *Trichoderma*, isolated from the soils of different climate zones, were studied for 1) their ability to inhibit the growth and activity of pathogens, 2) their effect on the biodiversity of the soil microbiota and the increase in associative nitrogen fixation, and 3) their stimulation of growth and development of *Brassica oleracea*. It has been shown that *Trichoderma* strains isolated from the soil of agrophytocenoses, where organic fertilizers have been used for a long time, have the greatest impact in suppressing the growth and development of pathogenic microflora. These strains differ from those that are isolated from badlands due to a steady nitrogen-fixing effect and the high destruction rate of plant residues. They are characterized by a low growth rate and insignificant sporulation when compared to other strains of the same kind. However, a positive impact has been noted in the increase of the number of non-pathogenic soil microflora, and the approximation of this indicator on fertile soils. This would suggest that the search and selection of products for the development of biological preparation, potentially effective for organic farming and bio- vegetable production, should be carried out in resistant agrophytocenosis soils, as they accumulate a genetic memory for maintaining the sustainability of the soil ecosystem and for the conservation of biodiversity.

Keywords: *Trichoderma, soil fertility, organic agriculture*

Introduction

Preparations based on the fungi of the genus *Trichoderma* are known as effective biofungicides and are used to reduce the infection of vegetable crops (Gromovs *et al*., 2010; Sadykova *et al*., 2007; Sternshis *et al*., 2007). Currently, the choice of biological products that can replace toxic chemical fungicides is quite extensive, their potential is not limited to suppressing the growth of phytopathogenic fungi and bacteria. The use of *Trichoderma*-based biologics for improving fertility and natural nitrogen fixation of soils is known (Inuwa, 2013; Triveni, 2012; Sternshis *et al*., 2007).

We have created our own collection of potential biofungicides, including representatives of the genus *Trichoderma*, isolated from the soil of agrocenoses of different natural zones of Russia, and we assessed the activity of strains in relation to the most common pathogens of diseases of vegetable crops found in the Nonchernozem zone of Russia. These include numerous *Fusarium*, bacteriosis , *Alternaria*, *Cladosporium.*

Material and Methods

Collection strains of fungi of the genus *Trichoderma*:

The *Trichoderma* TS, TT, K-15, AV strains were isolated from the soils of the experimental field of the FSBSI FSVC (Nonchernozem Zone of Russia, Moscow Region);

Strains 9B and 19B were isolated from soils of many years of experience using organic fertilizers in Western Siberia (West Siberian Station, Barnaul);

Strain U-9 isolated from natural soils of the north of the Komi Republic (Usinsk district).
Collectible strains of pathogenic fungi of the genus *Fuzarium*, provided by the Laboratory of Immunity and Plant Protection of the FSBSI FSVC, were isolated from the surface of diseased carrot and tomato plants. In addition, strains of *Fuzarium, Alternaria, Cladosporium* genera and *Xanthomonas* genus bacteria isolated from the soil after the cultivation of tomato and cabbage were used. All pathogenic strains were highly aggressive towards vegetable crops.
Traditionally, chemical fungicides, such as Ridomil, have been used to reduce disease. Ridomil is known as a potent fungicide against fungal diseases, manufacturer Syngenta Crop Protection, Switzerland. The active ingredients of the preparation dithiocarbamate and phenylamide mefenoxam. The preparation is toxic to humans, warm-blooded animals, insects, including bees, can accumulate in the soil and vegetables (https://udobreniya.info). In experiments, we considered the use of strains based on fungi of the genus *Trichoderma* as a possible alternative to chemical methods of plant protection.
The strains of *Trichoderma* and pathogens of fungal diseases were grown on the Czapek agar medium; for experiments with vegetable cultures, the biomass of fungi was produced under conditions of intensive aeration on a sterile grain medium containing water (1000 ml); grain of wheat or oats (15 g); $NaNO_3$ (3 g); K_2SO_4 (1 g); K_2HPO_4 (1.5 g). After 5 days of production, the preparations were left at rest for 7 days, then they were filtered through sterile gauze and soil was infused at the rate of 10 ml of preparations per 100 g of soil. Concentrate preparations based on fungi of the genus *Trichoderma* contained spores in the amount of 250-350 million / ml. This concentrate was diluted 100 times before the experiment.
Bacteria of the genus *Xanthomonas*, causing vascular bacteriosis on cabbage cultures were grown on the liquid medium of Czapek. The titer of the preparation after 3-4 days under the conditions of liquid phase fermentation was 1.0-1.5 billion cells / ml. For the experiments, the concentrate of the preparation was diluted 100 times and inoculated the soil at the rate of 10 ml per 100 g of soil. As a test culture was taken the *Brassica oleracea* variety "Severyanka" collection of the FSBSI FSVC. As a test soil was taken soil for growing seedlings "Agrobalt" on the basis of peat. pH (H_2O) – 5.5-6.6; pH (KCl) – 5.0-6.2; N 180 mg/l; P 210 mg/l; K – 360 mg/l; Mg – 40 mg/l; Ca – 120-160 mg/l.

Results and Discussion

The evaluation of the fungicidal potential of the studied *Trichoderma* strains was carried out in experiment with pure pathogen cultures. Express experiment was carried out in Petri dishes. The seeding of the tested *Trichoderma* strains was carried out on the edges of the cup on the Czapek agar medium, fixing the spores of fungi from a tube with a pure culture at the tip of the dissecting needle. Pathogens were sown in the center of the cup with a piece of agar medium from a tube with a pure culture of the pathogen. As the fungi grew, a description was made of the intensity of the growth of pathogens depending on the presence of different *Trichoderma* strains. The results of the observations are given in table 1. Against the tested *Fusarium* strains, the most effective were *Trichoderma* TT, K-15, 9B and 19B strains.

Table 1. Effect of different strains of *Trichoderma* on the growth and development of pathogenic microflora.

	The growth pattern of pathogens in the presence of *Trichoderma* strains					
Pathogen strain	Tr TC	Tr TT	Tr K-15	Tr 9B	Tr 19B	Tr У-6
Fusarium 1M	±	±	±	±	±	±
Fusarium 2M	-	+	+	+	+	±
Fusarium 3M	+	±	±	±	±	±

Xanthomonas K10	++	+	++	±	±	+

- does not prevent the development of the pathogen
+ competes with the pathogen, a clear border is visible in the development of mycelium
+ inhibits pathogen growth
++ destroys the pathogen

Fusarium differ in significant diversity and are capable of infecting almost all vegetable crops. In this regard, it is necessary to evaluate the potential of biofungicides for further development of biological preparation based on them, taking into account the characteristics of each specific disease and type of vegetable crops. From our experience, we selected strains 9B and 19B for the next phase of testing in vegetable crops.
All tested strains of biofungicides were effective against *Alternaria* K6-1 and *Cladosporium* K15-2, the suppression of the growth and development of *Xanthomonas* K10 was most pronounced in the presence of strains TC and K-15. This was also taken into account by us later in the development of biofungicides of directional action.
The effect of biofungicides on the reduction of the infectious background was evaluated when growing *Brassica oleracea* seedlings. *Brassica oleracea* often suffers from vascular bacteriosis caused by bacteria of the genus *Xanthomonas.* The disease can reduce the yield by 20-50%, and in adverse years (significant temperature drops, cold and rainy summer) yield losses can reach 100% (Ignatov, 2006). *Fusarium* on *Brassica oleracea* can lead to crop loss up to 25%, the risk of damage increases in hot and dry years (https://agroflora.ru/fuzarioznoe-uvyadanie-kapusty). Diseases can infect plants through the soil, so it is necessary to carry out timely treatment to prevent infections.
The growing season for growing *Brassica oleracea* seedlings was carried out in stationary conditions, the soil was infected with inocula of pathogens *Fusarium* 5M and *Fusarium* 9M,

Alternaria K6-1, *Cladosporium* K15-2, *Xanthomonas* K10. The control was non-inoculated soil. The treatment with biofungicides from *Trichoderma* 9B and 19B strains was carried out in two ways: soaking *Brassica oleracea* seeds for 1 hour in a working solution of biofungicide and tilling the soil before planting seeds. The character of seed germination, the intensity of plant development and the quality of seedlings were tracked. The duration of the experience - 1 month. The biometric characteristics of seedlings at the end of the experiment are shown in Table 2.

Table 2. Biometric characteristics of seedlings a month after planting seeds into the soil.

As experience has shown, the tested pathogenic microorganisms reduce seed germination and seedling survival, slow down the growth and development of plants, and are capable of causing mutations in the form of leaf deformation. Ultimately, the seedlings become weak and poor quality. Seed and soil treatment with biofungicides enhances germination energy and increases survival in the presence of various pathogens. Of the strains tested, biofungicide 9B was the best. The seedlings prepared during the treatment of seeds and soil with this biofungicide were distinguished by the highest biomass and survival. Seed treatment had a slightly better effect than tillage.

The effect of fungicides on the biodiversity of soil microflora is the most important criterion for the safety and preservation of the natural balance of agrobiocenoses. The balance of soil microbiological processes reflects the resistance of the ecosystem to adverse factors and will largely determine the immune potential of vegetable crops (MSU, 1989). It can be disturbed by changing substrate conditions, such as acidity, organic matter content, excess or deficiency of basic nutrients, fluctuations of humidity and temperature, as well as the introduction of agrochemicals, pesticides and fungicides. In technogenic soils, the balance is disturbed, and the ecosystem seeks to eliminate the cause of the disturbance and mobilizes the microbial potential. The microbiocenosis is rebuilt in a short time, the ratio of the number of main groups of soil microorganisms changes (MSU, 1989). The introduction of biofungicides into the soil can also disrupt the microbial balance of the soil and lead to the dominance of invasive species, which is highly undesirable. We evaluated the soil microbial state after treatment with the studied *Trichoderma* strains and established the following.

In the presence of all the studied strains in the soil, the total number of pathogenic fungi of the genus *Fusarium* decreased. At the same time, a month after tillage with biofungicides 9B and 19B, representatives of the genus *Fusarium* were found in the soil in insignificant amounts. These strains did not affect the overall microbial pattern of the soil, the ratio of the number of bacteria and micromycetes determined on the Czapek medium and bacteria on the MPA was close to the soil without biofungicide treatment. At the same time, an increase in the number of bacteria was observed on the Ashby nitrogen-free medium. The studied strains also grew on the Ashby medium, which indicates that they belong to the group of nitrogen fixers, while they did not inhibit the growth of nitrogen fixation bacteria. *Trichoderma* 9B and 19B strains were isolated from soil experience with long-term use of organic fertilizers and, obviously, genetic information on the sustainable functioning of the ecosystem and the preservation of biodiversity was accumulated in the microbiocenoses of such soils. These strains can be considered as significant for reducing the infectious background and as a bio-fertilizer with a high natural nitrogen-fixing potential.

The strains of Trichoderma 9B and K-15 also reduced the infectious background, but in addition they had a pronounced cellulolytic effect. They were isolated from natural soils, and, naturally adapted to the destruction of plant residues, therefore, may be promising in the development of biological products intended to increase soil fertility.

The TT and TS strains significantly suppressed the total number of soil micromycetes and significantly reduced the biodiversity of bacterial microflora. Sowing from the soil treated with these strains was distinguished by the uniformity of the colonies represented by small non-pigmented mucous forms. At the same time, on a high initial infectious background, these strains gave a significant effect of its reduction.

This suggests that the search and selection of products for the development of biological preparation of directional action and potentially effective for organic farming and biological vegetable growing should be carried out taking into account the peculiarities of the soils from which the strains are isolated, and the properties of the soils on which the biopreparations will be used in the future.

Conclusions

Biological preparations based on *Trichoderma* strains are distinguished by a high fungicidal effect and inhibit the development of *Fusarium*, vascular bacteriosis, *Alternaria*, *Cladosporium*. The use of biofungicides based on *Trichoderma* strains in the form of seed and soil treatment before planting seedlings is an effective prevention of diseases of *Brassica oleracea* and reduces the infectious background of the soil. Selection of optimal combinations of *Trichoderma* strains depends on the characteristics of the soil from which the products are isolated, and the soil for which they will be used. Biofungicides have been and remain the most important element of organic farming, because with proper selection they allow to get ecologically pure vegetable products and preserve soil fertility.

Abstract

As a critical nutrient, phosphorus plays an important role in controlling primary productivity in warm-water fishponds. Concentration of water-soluble phosphate is often very low, since a large portion of soluble phosphate in fish ponds often bonds and forms insoluble complexes with calcium (Ca^{2+}) and magnesium (Mg^{2+}) in calcareous soils and with iron (Fe^{3+}) and aluminum (Al^{3+}) in acidic soils. Application of phosphate solubilizing bacteria (PSB) is one of the most important new approaches for increasing water-soluble phosphate that are consistent with the principles of sustainable aquaculture. For this purpose, sediment sampling from 30 warm-water fishponds in Mazandaran province was carried out. A total of 64 PSB strains were isolated using National Botanical Research Institute medium (NBRIP) that contained tricalcium phosphate (TCP). In this study, 11 stronger PSBs, identified by 16s rRNA gene sequence, showed good ability in solubilizing TCP, including *Acinetobacter lactucae* (Persian$_{11}$), *Pseudomonas frederiksbergensis* (Persian$_7$, Persian$_8$ and Persian$_9$), *Pseudomonas deceptionensis* (Persian$_9$), *Pseudomonas kilonensis* (Persian$_6$), *Pseudomonas putida* (Persian$_3$), *Pseudomonas taiwanensis* (Persian$_1$ and Persian$_2$) and *Pseudomonas umsongensis* (Persian$_4$ and Persian$_5$). Based on the ability to dissolve TCP in liquid medium as well as growth in the range of environmental parameters of warm-water fishponds (temperature, pH and salinity), the Persian$_{10}$ was selected as the strongest PSB strain, with an ability to release 80.52 mg/l of phosphorus. According to the results of this study, the Persian$_{10}$ strain can be used as an effective bio-fertilizer in warm-water fishponds.

Keywords: *Phosphate solubilizing Bacteria, Bio-fertilizer, Fishpond, Sustainable aquaculture, Sediment*

Introduction

Phosphorus (P) is an essential macronutrient for phytoplankton that plays a pivotal role in biological productivity of earthen ponds for freshwater fish culture, especially filter-feeding carp species. Organic and chemical fertilizers are commonly used in fish farms to increase the level of phosphorus in the water. However, phosphorus tends to bind with bivalent cations such as calcium, iron, and aluminum forming insoluble complexes in sediment (Mahanty *et al*., 2017). It also remains bound as a part of organic matter, remains biologically non-available and may even be refractory. It is estimated that in freshwater sediment about 8–82% of total P remains mineral-bound, only part of which is easily exchangeable and biologically available in short- and long-term (Maitra *et al*., 2015). Jana (2007) also reported that about 10% of the fertilizer applied caused phosphorus increase in the water phase, whereas the rest is rapidly precipitated and settled at the bottom and converted into insoluble compounds. Phosphorus deficiency is also more critical in fishponds due to the alkaline conditions and the effects of liming. Under such conditions, phosphatic fertilizers are extensively used to augment fish production in most of the ponds (Sahu and Jana, 2000). These chemicals adversely affect soil in terms of depletion of water holding capacity, soil fertility, trophic state, biodiversity, increased salinity, and disparity in soil nutrients (Maitra *et al*., 2015; Wang *et al*., 2016). Global assessments showed that non-renewable resources of high quality phosphates are rapidly depleted and expected to be exhausted in less than 100 years (Cooper *et al*., 2011).

Nowadays, the demand for more environmentally friendly alternatives is higher than ever. Exploitation of microbes as bio-fertilizers is considered to some extent an alternative to chemical fertilizers in agricultural sector due to their extensive potentiality in enhancing crop production (Mahanty *et al*., 2017). Increasing the bioavailability of immobilized phosphorus (P) in soil by phosphate solubilizing bacteria (PSB) is an effective strategy for sustainable agronomic use of P and for mitigating the P crisis (Maitra *et al*., 2015). PSB can increase soil available P through the release of organic acids and enzymes (Behera *et al*., 2014; Zhang *et al*., 2014). Unlike in agricultural system where PSB have been intensively studied and are commercially exploited, few works (Jana, 2007; Hu *et al*., 2010) have been conducted regarding P release potential of PSB in freshwater aquaculture systems.

The aims of this study were, therefore, to isolate and identify endemic PSB strains from fishpond, and evaluate their performance in culture media.

Material and Methods

Sediment samples were collected in aquaculture earthen ponds (30 warm-water fishponds) using a Van-Veen grab sampler in Mazandaran province, Iran. The samples were stored at 4°C in the sterile containers until further analysis. For each soil sample, several sub-samples were taken, homogenized in sterile MilliQ water containing 0.85% NaCl (wt/vol) and serially diluted. Aliquots of each dilution were spread on NBRIP (National botanical research institute's phosphate growth medium) medium containing D-glucose (10 g l^{-1}), $Ca_3(PO_4)_2$ (5 g l^{-1}), $MgCl_2.6H_2O$ (5 g l^{-1}), $MgSO_4.7H_2O$ (0.25 g l^{-1}), KCl (0.2 g $l^{-})^{1}$, $(NH_4)2SO_4$ (0.1 g l^{-1}), with 15 g agar and pH 6.8 to 7.0 (Nautiyal, 1999). The plates were incubated at 28-30°C for 7 days. Colonies were selected from the plates based on the appearance of a solubilization zone. The colonies were purified on nutrient agar for further study.

In order to screen an efficient PSB, the phosphate solubilization was tested in plate assay using NBRIP medium. Briefly, bacteria were inoculated onto solidified NBRIP medium, incubated at 28-30°C for 10 days and examined for any visible bacterial growth with surrounding clear zones. The experiment was repeated three times and results are expressed as solubilization efficiency = (solubilization diameter/colony diameter) × 100 (Nguyen *et al*. 1992).

Quantitative estimation of phosphate solubilization was performed using NBRIP liquid medium carried out (Mehta and Nautiyal, 2001). Briefly, Erlenmeyer flasks (250 ml) containing 80 ml of freshly prepared NBRIP medium containing 5g l^{-1} TCP were prepared. After 48h, broth culture grown in NBRIP medium was inoculated into Erlenmeyer flasks in triplicate. Autoclaved uninoculated medium served as control. The flasks were incubated for one week at 26-28°C in a shaking incubator at 100 rpm. The cultures were harvested by centrifugation at 10,000 rpm for 10 min. Soluble phosphate in culture supernatant was determined by the molybdenum-blue method (Murphy and Riley, 1962).

Based on culture conditions on northern Iran, the effect of environmental effect on strains were carried out in three cluster. The first group of study was examined the tolerance of strains to different temperatures (4, 18, 26, 34°C) by use of shaking incubator at 150 rpm. The second study was to evaluate tolerance to different pH (6.4, 7.4, 8.4, and 9.4) with HCl-tris and acid acetic buffer-tris and the third dealt of experiment was carried out to examine the ability of strains to growth in different salinities (0, 1.5, 3, 5, 10 ppt). In all the experiments, Erlenmeyer flasks (250 ml) containing 100 ml of the freshly prepared Nutrient broth (NB) medium were inoculated in triplicate with a 1% (v/v) 48 hours culture inoculum. Bacterial population was estimated using OD600 by spectrophotometry technique at 24h of incubation (Koch, 1970).

In this study, strains were identified by 16s rRNA gene sequence. Bacterial DNA was extracted using using CinnaPure DNA kit (SinaClon CO., LTD). Amplification of 16S rDNA was performed in a 50 microliter final volume containing 2 µl of total DNA, 1 µl of 27F primer (AGAGTTTGATCMTGGCTCAG), 1 µl of 1492R primer (5′-GGTTACCTTGTTACGACTT-3′), 4 µl of each dNTP, 5 µl of $MgCl_2$, and 1 µl of Taq DNA polymerase (Weisburg *et al*. 1991). The reaction conditions were as follows: 95°C for 1 minute (min) followed by 30 cycles of denaturation at 95°C for 1 min, annealing at 52°C for 1 min and primer extension at 72°C for 2 min; followed by a final extension at 72°C for 7 min. The reaction products were separated by running 4 µl of the PCR reaction mixture in 1.0% (w/v) agarose gel and staining the bands with simplySafe (EURx® LTD). Sequences data were aligned and similarities were analyzed using available standard sequences of GenBank database for of bacterial lineage and BLAST-in software at http://www.ncbi.nih.gov/. A phylogenetic tree was constructed by the neighbor-joining method using the software MEGA 6.00. Statistical analysis of the data was carried out using ANOVA, SPSS 13.0 software.

Results and Discussion

About 64 isolates were selected from the soil samples. However, based on solubility index in solid media, only 11 strains were able to highly solubilize actively phosphate in vitro, which showed persistence of this capability after five or more subcultures (Table 1, Fig 1). The phylogenetic tree of 11 strains showed that the strains belonged to the genus of *Pseudomonas* and *Acinetobacter* (Fig 2). The development of molecular biology makes the identification of microorganisms had an enhancement of research ideas. 16S rDNA sequencing analysis as an important research method is widely used (Weisburg *et al*. 1991). In present study, strains were identified using 16S rDNA sequencing analysis.

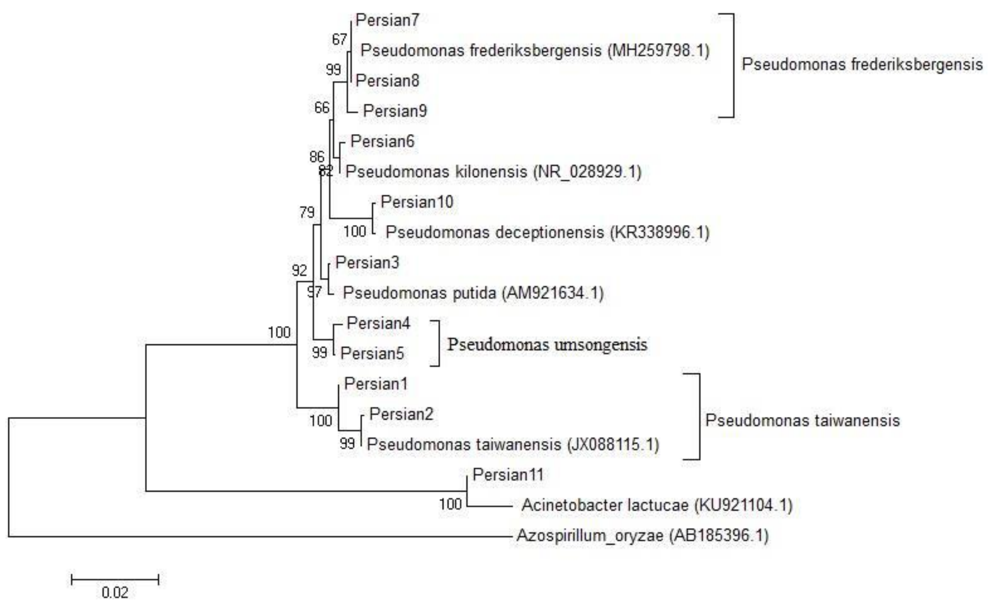

Fig 2. Phylogenetic tree based on 16s rRNA gene sequence showing the evolutionary position and relationship of strain with other bacteria

The range of phosphorus release from strains was between 20.93 and 142.20 mg l-1 in liquid medium (Table 1). It was approximately similar to the results of Maitra *et al*. (2015). Many considered that contrary to indirect measurement of phosphate solubilization by plate assay, the direct measurement of phosphate solubilization in NBRIP broth assay always resulted in reliable results (Hu *et al*., 2010).

In the temperature resistance test, growth and proliferation of Persian1, Persian 2, Persian10 and Persian11 strains were higher than others. In addition, only the Persian10 strain has the ability to grow at 4°C (Fig 3.) Results of pH effect showed that at pH 8.4, Persian3, Persian8, Persian10 and Persian11 strains had higher ability to grow and proliferate. However, at pH 4.9 only the Persian11 and Persian10 strains showed favorable growth (Fig 4.). The results of salinity effect showed that all strains were able to grow and reproduce at 0-10 ppt except

Persian 5 strain, which decreased at 10 ppt salinity (Fig 5.). Among the water quality factors, temperatures, salinity, and pH are the key ones in choosing more efficient strains, which affect the growth of bacteria. Many researchers in agriculture pay much attention to these factors (Malboobi *et al*., 2009; Hu *et al*., 2010).

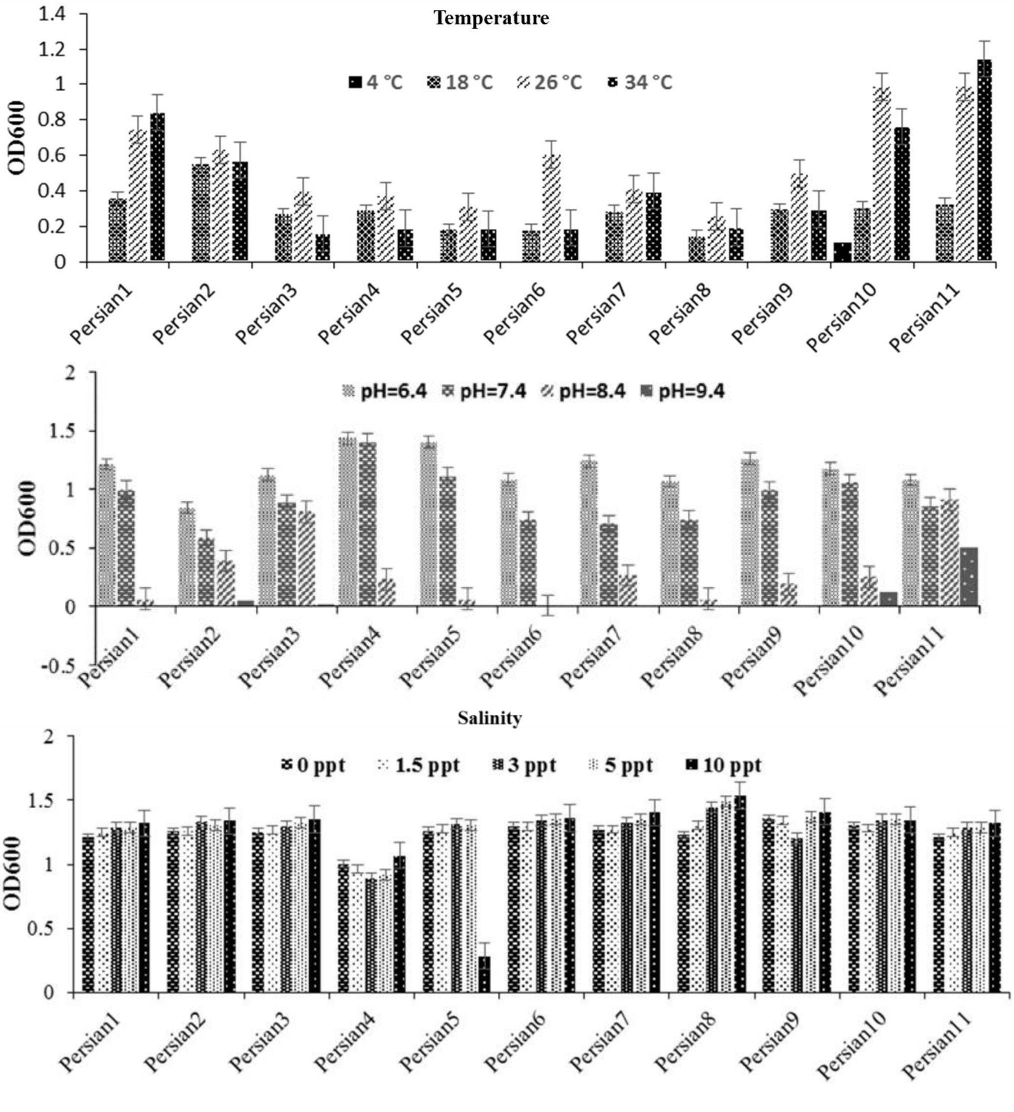

Fig. 3. Growth of strains under different temperatures, pH and salinity

Conclusions

In this study, considering all criteria (solubility, growth and proliferation ability in different environmental parameters, Persian 10 strain was selected as the most efficient strain. This strain was selected as the most efficient strain for the following reasons: Optimum phosphorus solubility, optimum growth at different temperatures especially at 4°C, optimum growth at pH above 8. Optimum growth at 4°C increases the assurance of winter survival of this strain as well as stabilization and effectiveness of bio-fertilizers in the fishpond throughout the year. In addition, Optimum growth at pH above 8 increase the probability of phosphorus release under alkaline conditions.

ORGANIC BEEKEEPING DEVELOPMENT IN LATVIA

Ligita MELECE*, Ilze SHENA

Institute of Agricultural Resources and Economics, Latvia
*Corresponding author: ligita.melece@arei.lv

Abstract

Organic farming as the more sustainable agriculture system shows considerable growth on the global and EU level, including Latvia. The paper discusses the achievements of organic beekeeping, as well as perspectives and some threats. Organic beekeeping is an important sector, which produce more than 27% from total honey production in 2017. The paper discusses achievements of organic beekeeping, as well as perspectives and some threats. The aim of the paper is twofold: 1) to assess the role of organic beekeeping (i.e., production of bee products and related services), as well as the latest development trends and issues of sector; 2) to evaluate the role and impact of CAP or RDP 2017-2020 measures on the further development of the sector. Beekeeping is an important organic sector, which produce more than 27% of honey from total national production in 2017. There is growing trend to diversify of or bee products and related services (i.e., heritage or agritourism, apitherapy etc.). Various activities, cooperation and collaboration forms support the distribution channels of organic bee products and services, and boost the added value and beekeepers' income. The main threat of further development of organic beekeeping is as follows: reduction of biodiversity (i.e., agrobiodiversity), increasing monoculture (i.e., rape) and usage of pesticides.

Keywords: *Organic beekeeping, bee products, Latvia.*

Introduction

There are many indications that pollination by a variety of species ensures optimal crop development and increased yield (Melece & Shena, 2018a). Diversified agriculture with a large number of crop types and small field sizes promote pollinator diversity, community stability and pollination success of crops and wild plants (Kovacs-Hostyanszki et al., 2017).

Intensification was aspect of agriculture modernisation, but it had the unforeseen side effect of increasing pressure on the environment. Recently biodiversity, especially in Central and Eastern European farmlands has decreased sharply, due to rapid economic transformations that are changing the agricultural landscape (Melece & Shena, 2018b). Nowadays agriculture faced with contradictory groups of requirements that could be fulfilled to provide a number of ecosystem services. So called provisioning services are aimed to supply a wide range of agricultural products as goods that requires intensifying production effectively, e.g., to increase application of mineral fertilizers, to replace less productive traditional breeds (i.e., decrease biodiversity), etc. (Melece & Shena, 2018b). However, supporting and regulating services (i.e., agro-ecosystem services) are provided interaction between humans and nature; and often are not monetary valued. One of the main regulating ecosystem service—pollination—provides direct and indirect benefits to nature and human well-being.

The economic value supplied by bees involves pollination and the production of honey and other bee products, as well as apitourism that also has great importance (EP, 2018).

It is expected that organic beekeeping will continue to grow worldwide thanks to the increasing demand for organic honey and bee products (Willer & Lernoud, 2019), particularly for medical and pharmacological purposes. The medical use of honey bee and bee products—apitherapy—such pollen, propolis, royal jelly and bee venom against disease and disorders (Ghosh & Satpute, 2016) became more important. For instance, propolis possesses a wide range of pharmacological potentials including antibacterial, antifungal, antiprotozoal,

hepatoprotective, antioxidant, anti-inflammatory, antiviral, anticancer and antitumor properties (Anjum et al., 2018). Kieliszek et al. (2018) argue that each bee product is pharmacologically active. Since the target audience include very vulnerable people or patients, also children (i.e., parental), seriously ill people (i.e., cancer, immunodeficiency), the bee products should be free of any contaminants, in particular residues of agro-chemicals (i.e., pesticides). Therefore, organic bee products is best source of medical and pharmacological preparations—drugs, dietary supplements and medicated cosmetics.
The aim of the paper is twofold: 1) to assess the role of organic beekeeping, as well as the latest development trends and issues of sector; 2) to evaluate the role and impact of CAP or RDP 2017-2020 measures on the further development of the sector.

Material and Methods

The principal materials used for the studies are as follows: different sources of literature, e.g., scholars' articles, research papers and the reports of institutions. Data have been obtained from various online databases: Eurostat, CSB, LDC – Agricultural Data Centre, and PVD – Food Veterinary Service. For comparison of organic beekeeping (i.e., beehives, honey production) development trends among neighbouring countries, the data of Baltic States were evaluated. Organic beehives' number was compared among the EU member states—Baltic Sea Region countries. The mixed methods, combining suitable qualitative and quantitative (correlation-regression analysis) research methods have been used. Significance levels are as follows ** - α<0.05; *** - α<0.01.

Results and Discussion

Comparing the organic beehives' number among the Baltic Sea countries, results show that Latvia has second highest number after Germany, but other countries has considerable less numbers (Fig. 1).

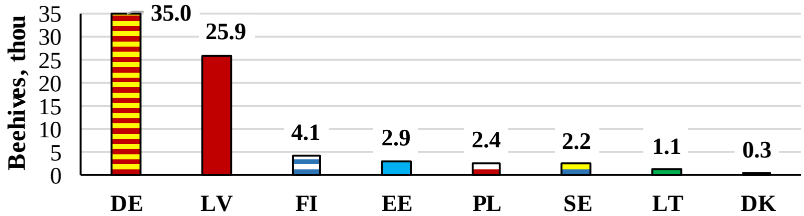

Figure 1. Number of organic beehives in the Baltic Sea countries, 2017
Source: authors' elaboration based on Willer & Lernoud, 2019

The volume of organic honey and number of organic beehives, and its trends among the Baltic States (Fig. 2 and 3) show that beehives have significantly increase in all countries, but production of honey has increased in Estonia and Latvia, but not in Lithuania.

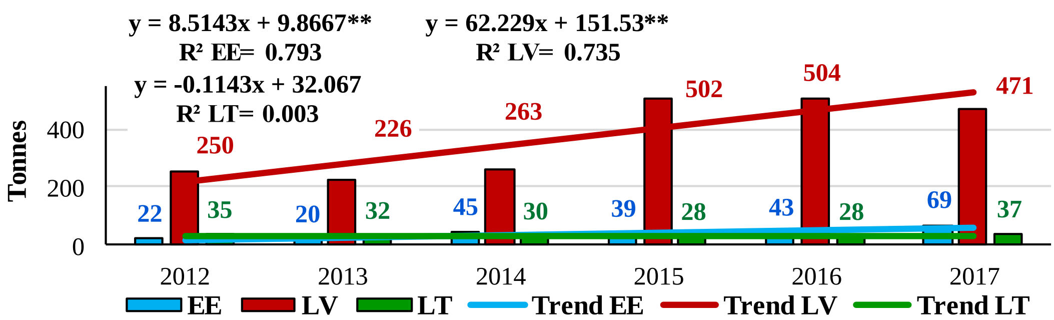

Figure 2. Organic honey production and it trends in the Baltic States, 2012-2017

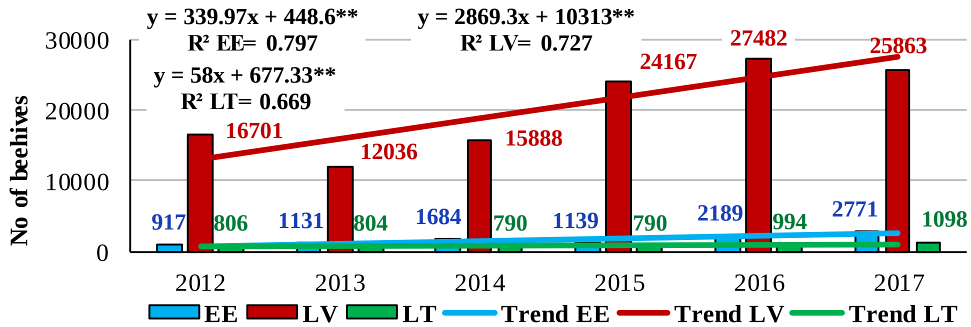

Figure 3. Number of organic beehives and it trends in the Baltic States, 2012-2017
Source: authors' calculation based on Eurostat (2019) data

In Latvia both number of conventional and organic beehives' number has significantly increased from 2012 to 2017, and the share of organic ones is 27% in 2017 (Fig. 4).

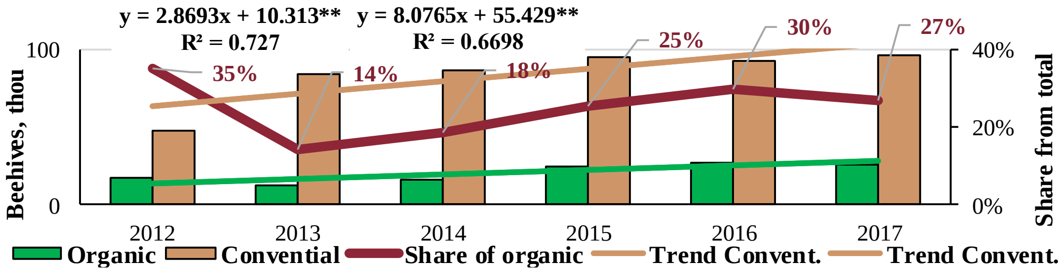

Figure 4. Organic and conventional beehives' number, and the share of organic beehives from total in Latvia, 2012-2017
Source: authors' calculation based on LDC (2019) data

Diversified agriculture with a large number of crop types and small field sizes promote pollinator (i.e., honey bee) community stability and pollination success of crops and wild plants (Kovacs-Hostyanszki et al., 2017). Controversially, in Latvia diversification of agricultural crops (esp. related to beekeeping), show decreasing tendency (Table 1).

Table 1. The changes of some crops' area from 2005 to 2017

Crop	Sown area, thou ha		Changes 2017/2005, %	
	2005	2017		
Wheat (winter & spring)	129.1	331.2	154%	↑
Rye	45.1	34.0	-25%	↓
Spring barley	145.9	78.2	-46%	↓
Oat	58.0	70.9	22%	↑
Buckwheat	10.4	30.9	**197%**	↑
Mixed cereals and pulses	8.1	5.3	**-35%**	↓
Field beans	0.4	42.5	**10525%**	↑
Winter rape	22.9	90.0	**293%**	↑
Potatoes	45.1	22.7	-50%	↓
Open field vegetables	12.9	8.0	-38%	↓
Forage crops	372.2	297.6	-20%	↓
Perennial grass	360.6	270.3	**-25%**	↓
Nectar crops	2.1	1.9	**-10%**	↓

Source: authors' calculations based on CSB (2019) data

Requier et al. (2015) argue that honey bees' demand very wide plants diversity for pollen needs over season; furthermore, the pollen resource diversity enhances resistance to fungal diseases, tolerance to pesticides, and immunity in honey bees to parasites, diseases, and pathogens. Oilseed rape, wheat and maize (for green mass) in Latvia is cultivated as energy crops in intensive agriculture, including several pesticide treatments. Crops' treatment also can spread to wild flowers around fields, and thus can cause the residues of pesticides in honey and bee products. The use of insecticides directly affect bees, but other pesticides has an indirect effect. Use of pesticides (active substances, kg) on 1 ha of several crops' sown area show that the highest doses of pesticides are used for field beans, winter wheat and rape (Fig. 5).

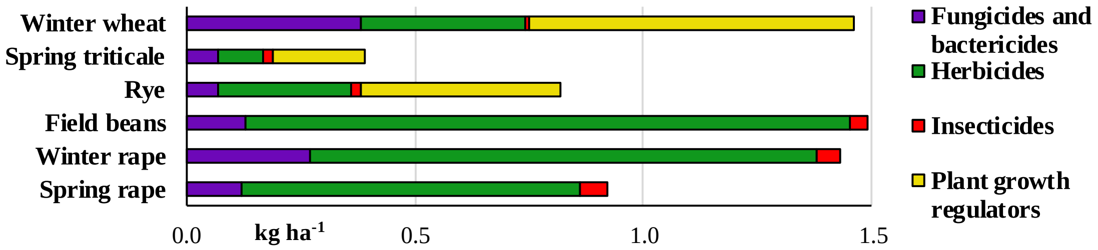

Figure 5. Use of pesticides (kg ha^{-1}) on crops, where insecticides were used in Latvia, 2017
Source: authors' elaboration based on CSB (2019) data

New organic EU Regulation—2018/848 was adopted, which will come into force in 2021 (European Parliament and…, 2018). For certification as organic apiary, its location must be within a radius of 3 km from the nectar and pollen sources (i.e., organic crops or spontaneous vegetation, or crops treated by low environmental impact methods). Since agricultural intensification (i.e., monocultures, mineral N fertilizers and pesticide use) is growing, this could be a main threat for further preservation and development of organic beekeeping.
Summary of some adverse agricultural practices and threats for pollination and honey bees, as well as beneficial agricultural practices influenced pollination and honey bees are reported in Table 2 and 3. Despite that practices mainly are aimed for beekeeping in general, they should be useful for organic beekeeping also, since the literature sources for it are very limited.

Table 2. Some adverse agricultural practices and threats for pollination and honey bees

Practice	Impact	Reference
Use high level of inorganic nitrogen fertilizers	decreased diversity of wild plant; significantly reduced worker bee longevity	IPBES, 2017; Melece & Shena, 2018b
Loss of biodiversity	destruction of habitat & lack of forage due to monocultures, and reduction of wild flora	IPBES, 2017; Kovacs-Hostyanszki et al., 2017; EP, 2018; Melece & Shena, 2018a
Changes in land-use and management intensity	agricultural intensification, i.e., land cover and spatial configurations	Kremen et al, 2002; Potts et al., 2016; IPBES, 2017; Melece & Shena, 2018b
Use of pesticides, esp. insecticides	have of lethal & sublethal effects on bees; destroy wild flowers near crop fields	Potts et al., 2016; IPBES, 2017; Kovacs-Hostyanszki et al., 2017; EP, 2018

Table 3. Some beneficial agricultural practices influenced pollination and honey bees

Practice	Impact	Reference
Organic or ecological farming	high biodiversity without any application of chemical pesticides or fertilisers	IPBES, 2017
Diversified farming systems & Diverse agricultural landscapes	organic, multifunctional, sustainable, and agroecological management approaches	Kremen & Miles, 2012; IPBES, 2017; Melece & Shena, 2018a
	crop rotations, cover cropping, fallowing; field margins, buffer strips, field edges, grass strips & hedgerows	
	semi-natural habitats, small landscapes & pastures	
	wild flowers left in crop fields can facilitate honey bee movement and therefore crop productivity	

There is strong evidence that the current CAP is inefficient regarding its environmental objectives. Pe'er et al. (2017) indicate that support is the highest for greening measures (Table 4), for agri-environment measures (i.e., organic farming) it is more than three times less, but payment for Natura 2000 territories is absolutely negligible.

Table 4. Area and potential average payment per ha under RDP 2014-2020 measures in EU

RDP measure	Area, mill. ha	EUR ha^{-1}
Greening: Ecological Focus Area	8	790
Agri-environment measures (i.e., area of organic farming)	13	247
Natura 2000 territories	12	25

Source: authors' elaboration based on Pe'er et al., 2017

In Latvia only support for organic beekeeping is EUR 40 per beehive in case if beekeeper has more than 21 beehives (LAD, 2019).

EP (2018) underlines that the financing of beekeeping for food production and therapeutic purposes must be structured in a more targeted and effective way, and appropriately increased in a future agricultural policy (expected from 2021).

For increase the income organic beekeepers via value added products and services, they are involved in several rural tourism activities, such as follows: Heritage Agritourism farms and Countryside goodies (Lauku ceļotājs…). Heritage Agritourism farms inform visitors about products or skills that relate to farming that has been inherited from at least one generation, and continues to exist and is developing in modern way. Owners offer tours, tastings of products, demonstrations of processes, a chance to take part in some of the work on the farm. For instance, organic beekeeping farm 'Lapegles farm' has 150 beehives, which are carefully tended by beekeepers. The farm also produces nectar plants such as buckwheat, clover and phacelia. Visitors can learn all about beekeeping, as well as to taste and purchase various bee products. Another organic farm 'Turaidas' is one of the smallest organic farms in Latvia, with 2.4 ha of land, produces and sale herbal teas, also has beehives to produce honey. Farm products are sold on website. For visitors among others owner offer an apiary tour with a demonstration of the beekeeper's work, tasting and sale of different sorts of honey. Countryside goodies—Bee— the tour may involve beehives, where visitors will learn about the structure of hives, about the lives and hierarchy of the bees, etc.; to taste various types of honey; to purchase the honey which they like the most; and some farms sell not just honey, but also other bee products. Besides, visitors are encouraged to take part in various processes, among which the most popular is the production of wax candles.

Conclusions

Further preservation and development of organic beekeeping mainly are threatened by intensification of agriculture (e.g., use of mineral nitrogen fertilizer, pesticides, reduction of

both agro-biodiversity and wild), as well as new EU requirements for certification (3 km radius claim).
There is necessary expanding supporting measures capabilities to organic beekeeping, especially in Latvia. For instance, to support cooperation initiatives, to cover certification payments, as well as expenses of honey and bee products analyses. Besides, to support short supply chains (i.e., direct sale) development, and include organic honey in green public procurement.

4. ENVIRONMENT PROTECTION AND NATURAL RESOURCES MANAGEMENT

ESTIMATION OF CLIMATE CHANGE IMPACTS ON EVAPOTRANSPIRATION BY USING DIFFERENT METHODS

Muhammet AZLAK[1,2,*], Levent ŞAYLAN[3]

[1]Directorate General of Water Management, Ankara, Turkey
[2]European Environment Agency, Copenhagen, Denmark
[3]İstanbul Technical University, Faculty of Aeronautics and Astronautics, Department of Meteorological Engineering, İstanbul, Turkey
*Corresponding author: m_azlak89@hotmail.com

Abstract

In recent years, environmental issues have come to the fore with their effects. Two of these important environmental issues are climate change and the water problems. Especially, the impact of climate change on water resources has been increasingly attracting attention as an important environmental issue. Therefore, the effects of climate change on water resources are needed to be known to manage water-related issues in the future. In this context, with this study, the impacts of climate change on evapotranspiration, which is one of the important components of water resources as a loss, were analyzed by using 18 different evapotranspiration equations (temperature-based, radiation-based, and mass transfer-based) for the three cities of Thrace part (Edirne, Kırklareli, Tekirdağ) of Turkey. The past situation was investigated by using actual data obtained from meteorological stations for the period of 1975-2010. The future projection was estimated for the period of 2015-2040 by using ECHAM-5 model data in the framework of the A1B scenario. As a result of the study, in the framework of 18 methods, it was estimated that evapotranspiration would increase in the Thrace part of Turkey from 13 to 17% as an average in the future.

Key words: *Climate change effects, evapotranspiration, evaporation, water resources.*

Introduction

Changing precipitation regime and increasing temperature are two of the main climate change effects, which have been predicted by many researches and are now being encountered worldwide. This situation will increase the importance of water even more in the future. Depending on temperature increase, it is undeniable fact that evaporation may increase especially for the open surface waters (Şaylan *et al*., 2011). In parallel to this, evapotranspiration (ET), which expresses transpiration from plants and evaporation from soil and open water surface, will also be affected significantly by climate change.

Evapotranspiration is an important component of the hydrological cycle and the knowledge of water loss from ET within the hydrological cycle is an important issue for the management and planning of water resources. Especially for the countries with an agriculture-based economy in which the majority of water demand arises from the agricultural sector, water management and planning is of great importance (Azlak, 2015). Therefore, in order to improve planning and to support the efficient use of water resources, accurate estimation of ET in irrigated lands is necessary (Tabari *et al*., 2011).

In practice, ET can be estimated either by using available climatic data or from the pan observation multiplied by a conversion factor (K_{pan}) (Xing *et al.* 2008). In the past half century, in order to estimate ET, numerous empirical and/or physically based equations, classified as temperature-based, radiation-based, pan evaporation-based, mass transfer-based and combination-type, have been developed for different climatic regimes (Alexandris *et al.* 2006). Although performances of the methods vary in different environments (Gocic and Trajkovic 2010), most of the study related to the planning and efficient use of water resources is based on these equations for the places where the actual measurement of ET is non-exist.

On the other hand, The Penman-Monteith FAO 56 (PM) equation has been reported to be able to provide consistent ET values in many regions and climates (Allen *et al.* 2005, 2006) within all these methods. Hence, it is accepted as a well-developed worldwide ET estimator (Cai *et al*. 2007) and is recommended by FAO.
In recent years, there has been a significant increase in the number of studies related to ET. In general, recent studies have focused on researches comparing ET methods and determining the effects of climate change on ET. In this scope, the study made by Şaylan *et al.* (2011) by using 6 methods for Edirne provinces and the study made by Kişi (2013) by using 8 methods for Mediterranean part of Turkey are two of the ET comparing study made for Turkey. Beyond this, the study made by Tabari *et al.* (2011) by using 31 methods and the study made by Bormann (2010) by using 18 methods are the other studies, which made ET comparison by using a large number of ET equations. In this study, in line with this concept, we focused on the comparison of 18 different ET methods. Using climate change model data for the 2015-2040 period, we estimated the possible ET changes that will occur in the future compared to the reference period 1975-2010.

Material and Methods

The study was conducted in three cities (Kırklareli, Edirne, Tekirdağ) locate in the Thrace part of Turkey. The Thrace region is located in the vicinity of Istanbul, one of the largest metropolitans in the world. Intensive agriculture is one of the main sources of water demand in the Thrace region. Most of the territory of the region is used as agricultural land.
In this study, the daily climatic data (1975-2010) of three weather stations, Edirne station (41°40' N, 26° 33' E, 51 msl), Kırklareli station (41°44' N, 27°13' E, 232 msl), and Tekirdağ station (40°59' N, 27°29' E, 4 msl) operated by the Turkish Meteorological Organization (TMO) in Turkey were used. The study was carried on by using the daily global solar radiation, wind speed, relative humidity, maximum and minimum temperatures and average temperature data of the stations.
For the period of 2015-2040, the model data obtained from the grids, which contain the coordinates of the selected meteorological stations, were used. The model data were obtained by running the results of ECHAM5 global climate model with the RegCm4 regional climate model within the framework of the A1B scenario. A1B scenario is similar to the second mid-level route RCP6 (RCP; Representative Concentration Routes) scenario, which is one of the new approaches in climate change studies and the new scenarios to be used in these studies within the framework of the decisions taken at the IPCC experts meeting (Moss *et al.*, 2008) in 2007 (Rogelj *et al.*, 2012). The data gap in the actual data was filled by using data obtained from the climate model.
In this study, the following 18 different evapotranspiration equations were used to estimate ET (Table 1).

CM	PM / FAO Penman–Monteith (Allen *et al.*, 1998)	$ET = \frac{0.408\Delta(R_n - G) + \gamma \frac{900}{T + 273} u_2(e_s - e_a)}{\Delta + \gamma\ (1 + 0.34\ u_2)}$
TB	SC / Schendel (1967)	$ET = 16 \frac{T}{RH}$
MT	TR / Trabert (1896)	$ET = 0.3075\sqrt{u}(e_s - e_a)$

*MT: Mass transfer, RB: Radiation-based, TB: Temperature-based, CM: Combination method.
**ET: Evapotranspirasyon in mm day^{-1}, in cm day^{-1} for MB; e_s: saturation vapour pressure (hPa), (kPa) for PM; e_a: actual vapour pressure (hPa); (kPa) for PM; RH: relative humidity (%); u: wind speed (m/s), α: empirical constant (−; 1.26 for humid conditions); λ: latent heat of vaporisation (MJ/kg), γ: psychrometer constant (kPa°C^{-1}), (mbar°C^{-1}) for MK; Δ: rate of change of vapour pressure with temperature (kPa°C^{-1}), (mbar°C^{-1}) for MK; R_n: net radiation ($MJm^{-2}day^{-1}$); R_s: global radiation ($MJm^{-2}day^{-1}$); (cal $cm^{-2}day^{-1}$) for TU and MB; R_a: external radiation ($MJm^{-2}day^{-1}$); T_{max}: daily maximum temperature (°C); T_{min}: daily minimum temperature (°C); T: daily average temperature (°C), (°F) for MB; T_{ma}: monthly average temperature (°C); G: soil heat flux ($MJm^{-2}day^{-1}$).

For this study, the PM method was used as a reference method for comparison. In this context, first, ET was calculated with the PM for three stations, and then the results of the other approaches were assessed according to the results of the PM method.

Results and Discussion

In the study conducted with 18 different ET equations, first, the long-term average of annual total ET values for the period of 1975-2010 were calculated. By using selected methods, ET values were estimated between 654 and 1703 mm for Edirne, 644 and 1702 mm for Kırklareli and 623 and 1708 mm for Tekirdağ. For Edirne province, the study has given similar results with the study made by Şaylan *et al*. (2011). The highest ET values for all stations were calculated by the dB method, whereas the lowest ET values were estimated by the MB (Table 2).

Table 4. Long-term average of annual total ET values (mm) for the period 1975-2010 (actual) and 2015-2040 (model)

dB	**1703.1**	1725.3	**1702.8**	1729.4	**1708.8**	**1847.4**
HS	1146.5	1131.3	1060.5	1100.9	912.3	941.2
IR	906.2	942.9	900.6	931.1	894.7	988.3
JH	1023.8	1096.4	1006.4	1070.2	972.1	1130.9
JR	1081.0	1113.4	1089.2	1096.0	1007.1	1085.9
PM	1077.4	1277.9	1002.5	1236.8	1040.2	1211.1
SC	1328.8	1663.5	1285.7	1655.3	1110.3	1419.1
TR	1358.1	1838.8	1136.4	1703.9	1177.5	1524.3

Comparing the long-term annual total ET results of the methods with the PM reference method showed that the DA, MH, MY, MY, dB, SC, and TR methods gave higher ET values than the PM method, whereas the MK, MB, PT, TW, TU, and IR methods gave lower ET values. These calculations gave different results when compared with the study, which made by Şaylan *et al.* (2011) for Edirne province and which the PT, HS, JH, TU, MK, and PM equations have been used in. This is because of the used time period differences between the studies. In this study, the calculation has been made for a long period (35 years), whereas it has been made for a year period in the other study.

Figure 1 shows the long-term averages of monthly total ET values of all methods. While the divergence between the methods, which have the same type (temperature-based, radiation-based, etc.), is lesser, a high level of divergence has seen between different method types mostly. As shown in the figure, the divergences between the methods increase during the summer period. On the other hand, the PM method and the average of the 18 methods gave close results to each other.

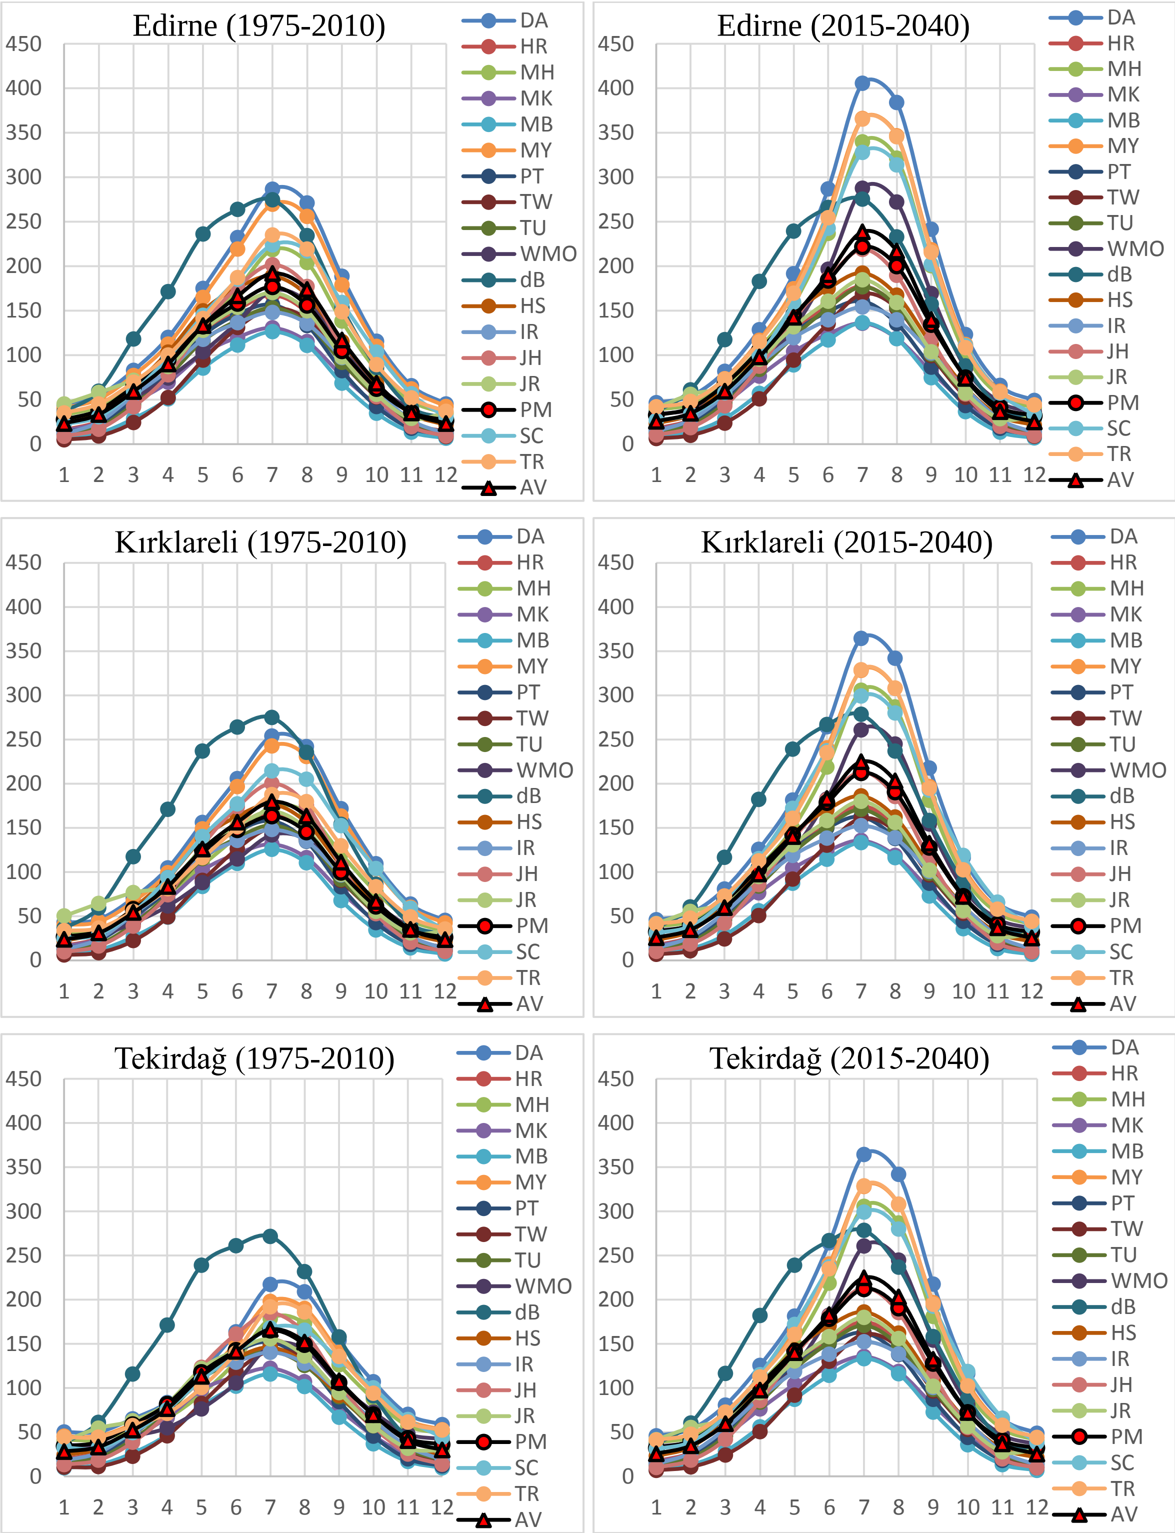

Figure 3. Long-term average of monthly total ET values for the period 1975-2010 (actual) and 2015-2040 (model)

As a next step, scatter plots diagram between the PM reference method and the other methods were drawn. Although the MB method gave the best determination coefficient for the stations as general (0.98 for Edirne, 0.96 for Kırklareli, and 0.98 for Tekirdağ), good determination coefficients, which are higher than 0.9, were obtained almost for all methods.

As the final step, in order to estimate the effect of climate change on ET, calculated results of long-term annual total ET values of all equations for the 1975-2010 reference period was compared with the calculated results for the period 2015-2040. The changes were presented as a percentage in Table 4. When the table is examined, it can be seen that the WMO method estimated the maximum changes for all provinces with the value that higher than 39%, which is more than twice the average of all methods. The minimum changes were estimated with the HS for Edirne and Tekirdağ, while estimated with the JR method for Kırklareli. Beyond this, as an interesting result, while all methods estimated increase in ET value for all provinces, the HS has come to the fore as the only method, which estimated the decrease in ET for Edirne province. As general, according to the average value of the 18 selected methods, it is estimated that ET would increases 13.7% for Edirne, 16.6% for Kırklareli, and 16,9% for Tekirdağ province in the future.

Table 5. Average ET changes (%) in the future (2015-2040) according to reference years (1975-2010)

Method	Method Type*	Edirne	Kırklareli	Tekirdağ
DA	MT	22.5	26.1	24.0

Conclusions

Within this comparison study of ET methods, which use different inputs and constants, calculated ET values have been analysed and compared with each other for the three provinces of Thrace region. As a reference method, the PM method was used to make comparison and assessments have been presented according to the PM method. Although the calculated ET amounts are different depending on equations, high determination coefficients were obtained between the methods and the PM method. Beyond this, by using model data for the period 2015-2040, the impact of climate change on ET has been estimated in the Thrace region. According to the analysis made, although the increase rates vary from method to method, it is seen that ET would increase in the future as a common result of all methods. The methods selected in the scope of the study depend on four different approaches as temperature-based, radiation-based, mass transfer, and combination. From these four approaches, methods, which depend on mass transfer approach, estimated the highest ET values and the highest percentage increase for the future. As average, it is estimated that ET would increase as 13.7% for Edirne, 16.6% for Kırklareli, and 16.9% for Tekirdağ. On the other hand, without using the results of methods, which depends on the mass transfer approach, these averages were calculated as 7% for Edirne, 7.5% for Kırklareli, and 12.4% for Tekirdağ. However, it should be remembered that climate change models continue to be developed and updated to include new approaches. In addition, as can also be seen from the ET methods used in the study, the methods give very different ET values as a result of calculations. Therefore, first, by comparing with actual measurements, the best methods must be determined to estimate ET accurately for the region. Then, by using data obtained from the new climate change scenarios, climate change effect on ET must be determined. In this way, the effect of climate change on ET can be estimated as more accurately and depending on accurate results water resources planning can be made better.

Abstract

Phosphorus, potassium and nitrogen are major macronutrients for plants which means that plants are using them in large amounts for their growth and survival. Due to their importance, those three are classified as necessary macroelements. The aim of this paper is to present soil condition of Doljevac municipality in Serbia regarding abundance of those macronutrients. The collecting of samples and testing was carried out in 2016. Precisely 116 samples were taken from 10 different villages of this municipality. The contents of readily available potassium and phosphorus were tested using the Egner-Riehm method, AL-method. The content of total amount of nitrogen was analysed using Kjeldahl method. The data processing was carried out in the IBM SPSS Statistics – Version 20 (trial version). It was found that 42,2% of the phosphorus samples belong to a class of soil badly supplied with readily available phosphorus while only 22,4% of samples were in class of well supplied or rich soil. On the other hand, the majority of samples (79,3%) were classified as well supplied and only 1,7% as badly supplied soil. Regarding nitrogen, almost all samples were classified as moderate supplied soil (>0,20% N) with 91,4% of total amount of samples.

Keywords: *phosphorus, potassium, nitrogen, Doljevac municipality, soil.*

Introduction

The availability of nutrients from the soil to plants is limited, and those nutrients can be lost from the soil by yield, erosion, rinsing, etc. (Varga, 2015). Soil nitrogen (N), phosphorus (P), and potassium (K) are important macronutrients (Tang et al., 2016) which can limit or co-limit plant growth and developement (Li et al., 2016; Tripler et al., 2006). Due to their importance, those three are classified as necessary macroelements along with other six elements: carbon (C), oxygen (O), hydrogen (H), calcium (Ca), magnesium (Mg) and sulfur (S) (Kastori & Maksimović, 2008). Nitrogen is essential for carbohydrate use within plants. A good supply of nitrogen stimulates root growth and development, as well as the uptake of other nutrients. Nitrogenous fertilizers play vital roles in different plant's growth and developmental processes. But, excessive use of nitrogen is no more beneficial to plants. Only 30 to 50% nitrogen use efficiency is recorded in plants, the remaining nitrogen is used by soil microbes, leached down in soil profile or volatilized (Haroon et al., 2019). The accessibility of phosphorous by plants from the soil depends on the pH of the soil and on the form in which the phosphorus is found. The poor availability of phosphorus in the soil is one of the limiting factors of growth and development of plants. Phosphorus is involved in the construction of structural components and the regulation of energy economy of the plant and can be found in soil in organic and inorganic form (Jurišić, 2017). Unlike nitrogen and potassium, phosphorus is found in small amount. In the earth's crust, it has about 0.28%, of which 0,02 - 0.15% is available (Komljenović and Kondić, 2011). Potassium is the only element that occurs in the plant exclusively in ionic form. Potassium is not embedded in organic compounds and has the highest content in metabolic tissues where cell division takes place (Ilić, 2016; Kastori et al. 2013). Problems related to the use of chemical fertilizers are long-term adverse effects on fertility and productivity of the soil, and environmental safety. That's why scientists look for alternative sources of fertilizers such as biological fertilizers or biofertilizers. Biofertilizers are microbiological preparations that contain living cells of bacteria, blue-green algae or fungi that effectively fix atmospheric nitrogen (*Azotobacter chroococcum*), improve the accessibility of phosphorus (*Bacillus polymyxa, B. circulens, ...*) and potassium (*B. mucilaginosus*) in soil (Dimitrijević, 2018). Aim of this paper was to determine abundance level of nitrogen, potassium and phosphorus in soil of Doljevac municipality in order to take appropriate measures of soil improvement if necessary.

Materials and methods

Doljevac is a municipality that borders in the north with the municipality of Merošina and the city municipality of Palilula of the city of Niš. With municipality of Gadžin Han in the east, the town of Leskovac in the south and the municipality of Žitorađa in the west. Municipality of Doljevac occupies an area of 121 km², of which 9161 ha are on the agricultural soil. Total number of collected samples was 116. Different amount of samples was taken from different villages which belong to Doljevac municipality (Table 1). The collecting of samples and testing was carried out in 2016. Average samples were taken by combining 20 to 25 individual samples (Gudžić, 2011) and sent to labaratory for chemical analysis.

Table 1. Number of samples per town / village in Doljevac municipality

Town / Village	**Number of samples**	**Percent (%)**
Doljevac	9	7,8
Pukovac	52	44,8
Kočane	10	8,6
Čečina	5	4,3
Orljane	14	12,1
Mekiš	3	2,6
Šainovac	6	5,2
Malošište	3	2,6
Belotinac	10	8,6
Šarlince	4	3,4
Total	**116**	**100**

The concentration of available forms of phosphorus and potassium in the soil is expressed in mg P_2O_5 or K_2O $100g^{-1}$ of the soil and in percentages for total amount of nitrogen (N). Available forms of phosporus and potassium were measured by using Egner-Reihrn method (AL-method). Potassium is determined by flame photometry way. Phosphorus is determined colorimetrically by spectrophotometer (Grčak et al., 2018). Nitrogen determination was performed by using Kjeldahl method (Bogdanović et al., 1966). The data processing was carried out in the IBM SPSS Statistics – Version 20 (trial version) and results are shown in the following chapters. The aim of this paper is to present soil condition of Doljevac municipality regarding abundance of macronutrients such as phosphorus, potassium and nitrogen.

Results and discussion

In 2016 samples were analized regarding the amount of available phosphorus (Table 2), available potassium (Table 3) and total amount of nitrogen in the soil (Table 4). Chemical analyses were conducted in a laboratory of the Agricultural Advisory Professional Service in Nis and the results of the given analyses are shown in following tables.

Table 2. Soil classification regarding the readily available phosphorus supply (classification by Jelić, 2012)

Types of soil	Content P_2O_5 (mg $100g^{-1}$soil)	Percent (%) of samples P_2O_5
Badly supplied - poor	< 10	42,2
Moderate supplied soil	10 - 20	35,3
Well supplied soil – rich	> 20	22,4
Total		100.0

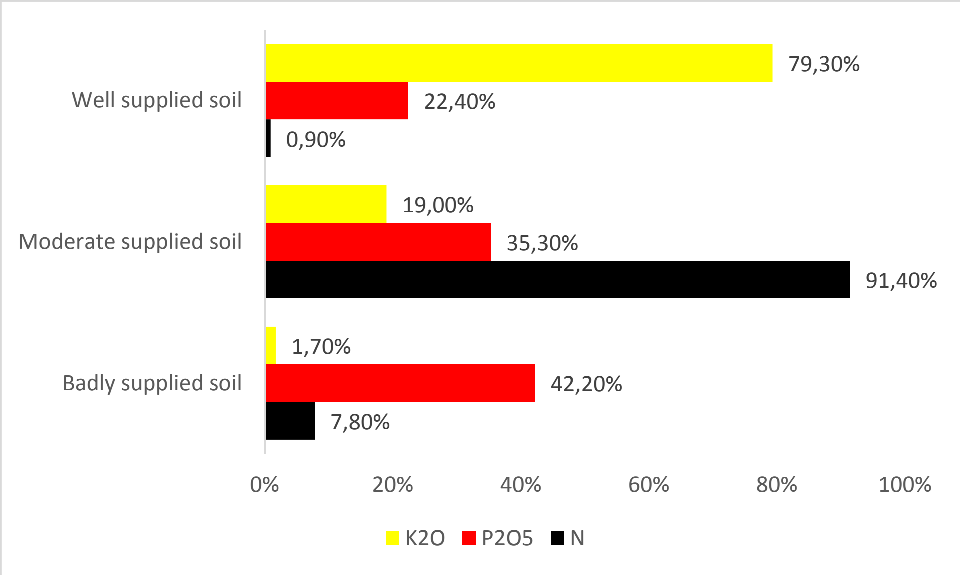
Table 3. Soil classification regarding the readily available potassium supply (classification by Jelić, 2012)

Types of soil	Content K_2O (mg $100g^{-1}$soil)	Percent (%) of samples K_2O
Badly supplied - poor	< 10	1,7
Moderate supplied soil	10 - 20	19,0
Well supplied soil – rich	> 20	79,3
Total		100.0

Table 4. Soil classification regarding the total amount of nitrogen supply (classification by Jelić, 2012)

Types of soil	Content N (N%)	Percent (%) of samples N
Badly supplied - poor	< 0,10	7,8
Moderate supplied soil	0,10 – 0,20	91,4
Well supplied soil – rich	> 0,20	0,9
Total		100.0

A total number of 116 samples were taken from agricultural soil of Doljevac municipality. Different number of samples was taken from different villages. The highest number of samples was taken in Pukovac, 52 samples, which is 44,8% of total amount of samples. The lowest number of samples was taken in Mekiš, 3 samples, which is 2,6% of total amount of samples. Samples were dried and analysed in labaratory and after that data was examined in IBM SPSS Statistics – Version 20 (trial version). Samples were divided acording soil supply level (Jelić, 2012) and data was imported into tables and graphic (Graph 1) for easier understanding.



Graph. 1. The percentage of the soil supply with K_2O, P_2O_5 and N

Based on sample analysis regarding phosphorus it was found that 42,2% of the analyzed samples of agricultural soil belonged to a group of badly supplied soil or ''poor soil'' in which the amount of available phosphorus was lower then 10 mg P_2O_5 $100g^{-1}$soil. Moderate supplied soil or soil with medium abundance (10-20 mg P_2O_5 $100g^{-1}$) had 35,3% of samples while 22,4% of the analyzed samples belonged to the class of well supplied soil (rich soil) in readily available phosphorus (>20 mg P_2O_5 $100g^{-1}$).

In the analysis of potassium results show that only 1,7% of samples can be treated as badly supplied soil namely soil with less than 10 mg K_2O $100g^{-1}$. Moderate suplied soil (10-20 mg K_2O $100g^{-1}$) owned 19% of total amount of samples while 79,3% of samples were for well supplied soil (>20 mg K_2O $100g^{-1}$). These results show us that soil in Doljevac municipality doesn't have problems regarding level of readily available potassium. On the other side, abundance of readily available phosphorus has majority of its samples marked as badly supplied.

Results based on total amount of nitrogen in soil point out that 7,8% of all samples represent badly supplied soil (<0,10% N). The largest amount of samples was classified as moderate supplied soil with 91,4% of total amount of samples. Only 0,9% of samples can be classified as well supplied or rich. Agricultural soil of Doljevac municipality has optimal amount of nitrogen so there is no need for excessive fertilization.

Conclusion

This paper presents the contents of plant available nitrogen (N), potassium (K_2O) and phosphorus (P_2O5) contents in the soil of Doljevac municipality. Based on our results it can be concluded that 79.30% of examined soil samples were well supplied with potassium, while only 1,70% of soil ware badly supplied with it. In case of nitrogen 91,40% was moderately supplied soil and only 0.90% was estimated to be well supplied soil. 42,20% of soil samples were estimated to be badly supplied with phosphorus and 20,40% were well supplied. Based on this, it can be concluded that soil of Doljevac municipality does not have problem with deficit of potassium and nitrogen but phosphorus level can be improved in order to have optimal level of all this macronutrients.

Abstract

Biogenic elements constitute a group of elements necessary for all living organisms. Among them, phosphorus and potassium take an extremely important place. This paper presents the results of readily available potassium (K_2O) and phosphorus (P_2O_5) contents in the soil of all five municipalities of the city of Niš (Serbia) in 2015. Samples were taken from the following municipalities of the town of Niš: Crveni Krst (181.5 km^2), Medijana (16 km^2) Pantelej (141 km^2) Palilula (117.37 km^2) and Niška Banja (141.1 km^2). The contents of readily available potassium and phosphorus were tested using the Egner-Riehm method, AL-method. The obtained data were processed in a IBM SPSS Statistics – version 20. The concentration of available forms of potassium and phosphorus was expressed in P_2O_5 or K_2O 100 g^{-1}. It was found that 63% of the potassium samples belonged to a class of soil abundant in potassium, while only 1.6% of the samples belong to a class of soil poor in potassium. The phosphorus content in the soil of Niš showed that 37.7% of the samples belong to a class of soil with medium abundance in phosphorus, 27.8% belonged to the soil abundant in phosphorus, and 34.5% belonged to the soil poor in phosphorus. The average pH in H_2O of the examined territory was 6.48.

Introduction

Of all the cations, potassium is adopted by plants in the largest quantity. Potassium is not included in the organic compound of the plants, but it does affect a number of vital processes of plants (Kastori et al., 2013). Young plant organs that are growing contain the largest quantities of potassium. Of the major and secondary nutrient elements, potassium is usually the most abundant in soils. However, the range of total potassium contents which occur in soils is enormous (Reitemeier, 1951). It can vary from 0.2-3.0% which for plowing part of soil deep 20cm means 6 to 90t ha^{-1}. Potassium is the most abundant in the primary minerals of the feldspar and lichen group. Sandy soils contain small amounts of total potassium since they have minerals that are highly resistant to decomposition and some of them do not even contain potassium. Of the total amount in the soil, only a small part is available for plant nutrition. Potassium fertilizing is therefore necessary (Jelić, 2012).

Phosphorus occurs in nature almost exclusively as phosphate, in all known minerals more specifically as orthophosphate with an ionic form of PO_4^{3-}. The distribution of the different species of orthophosphate is pH-dependent (Holtan et al., 1988). Phosphorus in the soil originates from the parent rocks, mostly from apatite and its content in the lithosphere is highly variable (0.02-0.15%) since it is a constituent of many different soluble minerals, and it is also bound in the organic matter of the soil. Most agricultural soils contain between 60% - 80% inorganic phosphorus and 20% to 40% organically bound phosphorus (Jelić, 2012).

In examining the contents of N, P and K in pear seedlings, in the bark and wood during winter Šebek et al., (2007) have found that the level of phosphorus in one-year old seedlings of indigenous varieties affects the resistance of pear seedlings to low temperatures. It has been

found that certain pear seedlings had a higher level of potassium in the bark and wood in relation to other seedlings examined, even more than wild pear seedlings, which leads to the conclusion that potassium has an important influence on the resistance to low temperatures.
Apart from the influence of phosphorus and potassium to plants, these elements are also necessary for animals, which receive these two elements through feed. Over 70% of the phosphorus contained in animal feeds of plant origin is in the form of phytic acid and its salts, phytates. Phytic acid is a storage form of phosphorus and energy in many plant species (cereals, legumes, seeds and nuts). However, phytic acid cannot be utilized by monogastric animals (horses, pigs, poultry...), since they create a very small amount of phytase enzymes, so it has to be added to their feed. There is research, according to which, phytic acid is "antinutrient," i.e. it prevents the body from absorbing minerals. This acid is linked to the minerals: zinc (Zn), iron (Fe), manganese (Mn) and calcium (Ca), in this way reducing the amount that is available to the body (Sakač et al., 2007). However, this absorption interference is only temporary, which means feeds rich in phytic acid and its salts should not be avoided. Studies have shown that phytic acid acts as an antioxidant, that it is anti-inflammatory and lowers cholesterol... (Gibson et al. 2010; Schlemmer et al. 2009).
Phytase is an enzyme that improves the digestibility of phosphorus from phytic acid (inositol-6-phosphate). The paper of Grčak T. D. (2015) examines the influence of premixes (vitamin and mineral supplements) that, in addition to other necessary nutrients for egg-laying hens, also contain phytase. It was found that the premix had a positive effect on the quality of table eggs. Testing the application of phytase in broiler chickens (a breed of chickens for fattening), with the aim to increase the efficiency and reduce the excretion of phosphorus in the environment (Živkov-Baloš et al., 2007) it was found that there was an increase in utilization of P and Ca (calcium) from feed, i.e. the amount of Ca and P in excretions was reduced. Due to a lack of phytase, phosphorus passes through the digestive system unchanged and is excreted through manure. In this way, it pollutes the environment with non-digestible organic matter in the manure.

Material and Methods

Analysis of the phosphorus and potassium contents in the soil covered the following municipalities of the town of Niš: Crveni Krst (181.5 km^2), Medijana (16 km^2) Pantelej (141 km^2) Palilula (117.37 km^2) and Niška Banja (141.1 km^2) (Figure 1). The total area, from which 284 phosphorus samples and 307 potassium test samples were collected, was 597 km^2 (0.7% of the territory of Serbia). The collection and analysis of samples was carried out in 2015.

Figure 1. Municipalities of the town of Niš

The concentration of available forms of phosphorus and potassium in the soil is expressed in mg P_2O_5 or K_2O $100g^{-1}$ of the soil. The measuring of available phosphorus and potassium in the soil was carried out using the Egner-Riehm method, AL-method (Grčak et al., 2018). Potassium is determined by flame photometer. Phosphorus is determined colorimetrically, by spectrophotometer.
The Egner-Riehm method, AL-method, is considered to be more suitable than other methods, because both readily available phosphorus and potassium are determined from the same extract. It is also suitable for the determination of readily available phosphorus in soils with a wide range of pH (Predić, 2011). The obtained data was processed in a IBM SPSS Statistics – version 20

Results and Discussion

In study, 284 samples were analysed regarding the amount of available phosphorus and 307 samples regarding the amount of available potassium in the soil. Chemical analyses were conducted in a laboratory of the Agricultural Advisory Professional Service in Niš and the results of the given analyses are shown in Table 1 (Jelić, 2012) and Figure 1.

Table 1. Soil classification regarding the readily available potassium and phosphorus supply (Jelić, 2012).

Types of soil	**Content P_2O_5 (mg $100g^{-1}$soil)**	**Content K_2O (mg $100g^{-1}$soil)**
Badly supplied - poor	< 10	< 10
Moderate supplied soil	10 - 20	10 - 20
Well supplied soil – rich	> 20	> 20

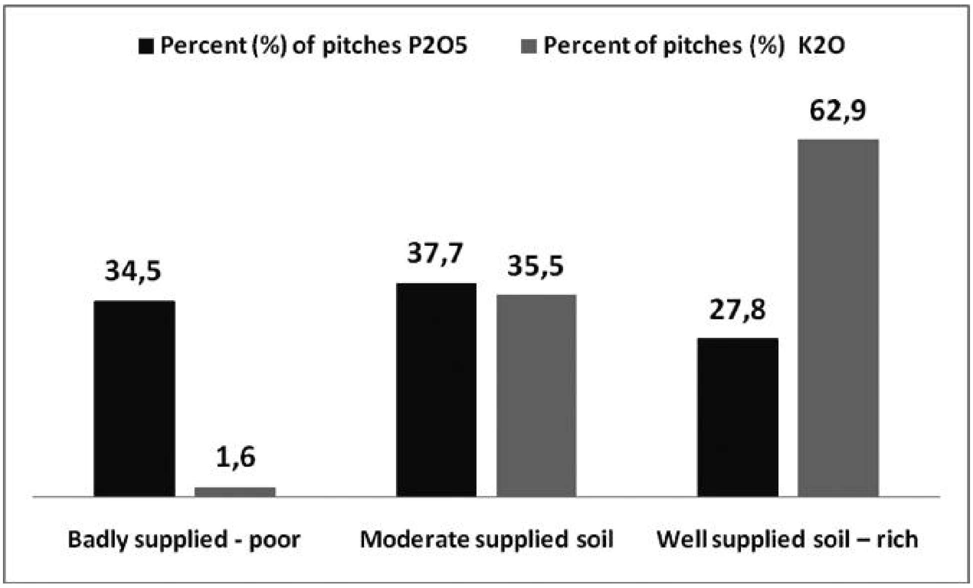

Figure 1. The percentage of the soil supply with P_2O_5 and K_2O

Based on 284 samples of the soil of the municipalities and the town of Niš that were processed for phosphorus, it was found that 34.5% of the analyzed samples belonged to a group of soil poor in available phosphorus (< 10 mg P_2O_5 $100g^{-1}$), while 37.7% of the analyzed samples of agricultural land belonged to the class of soil with medium abundance (10-20 mg P_2O_5 $100g^{-1}$) in available phosphorus.

Based on a large number of studies, our conclusion is that the content of phosphorus in the soil is around 0.02-0.15%. It is the most abundant in a non-organic form of different solubility, and this is why it is necessary to determine the abundance of readily available form of phosphorus P_2O_5 by analyzing the soil. After the end of the plant life cycle, it returns to the soil through organic matter. Acidic soils are poor, while neutral and alkaline soils are rich in readily available phosphorus. An excess of phosphorus in the soil causes the symptoms of Zn, Mn or Fe deficiency, since phosphorus binds these elements. Phosphorus deficiency causes reduced plant growth, where leaves are smaller and fall off prematurely. Phosphorus deficiency causes the synthesis of anthocyanins, where leaves turn purple at the margins and the lower side (on the back). Microorganisms adopt phosphorus to build their bodies, and after their death, phosphorus becomes available to plants. Phosphorus is accumulated in plant fruits. The amount of phosphorus that has left the soil should be returned through fertilizers. The acidic reaction of soil and an insufficient abundance of readily available phosphorus negatively affect the number of microorganisms in the soil. Microbial activity has a strong influence on soil fertility (Bjelić et al., 2015).

The total number of test samples for readily available potassium in the soil of the municipalities of Niš amounted to 307 samples. In terms of percentage, around 62.9% of the samples belonged to the class of soil abundant in readily available potassium (over 20 mg K_2O $100g^{-1}$), i.e. 193 samples of the total number of samples (307).

Around 35% of the samples (109 samples) belonged to the class of soil with moderate abundance (10-20 mg K_2O $100g^{-1}$), while we classified only around 1.6% of the tested samples (5 samples) as soils insufficiently abundant in potassium.

The soil samples taken were also analyzed for pH values. The average pH was 6.48. The minimum registered value of pH was 4.20 and the maximum was 7.17. Variability was calculated by means of the standard deviation was ± 0.39, indicating that there were no major differences between the pH values.

Based on many studies, it was found that the amount of potassium in the soil was around 2%, of which a small portion was readily available. Nitrogen (N) is the only element that plants adopt from the soil faster than potassium. These elements are followed by phosphorus, calcium, magnesium... Soils of a heavier texture, with more clay, have more potassium than sandy soils. Potassium affects photosynthesis, synthesis of proteins, transport, construction of carbohydrates, plant resistance to diseases and low temperatures, and the like. On the other hand, potassium deficiency can first be observed on leaves; the tops and margins of leaves turn yellow-green in color and the plant is more vulnerable to diseases.

An uneven application of fertilizers in non-agricultural soil results in a state of excessive content of readily available phosphorus and potassium (Tintor et al., 2015). A high content of phosphorus in soil affects the adoption of zinc (Zn) by plants, due to the antagonism of phosphorus and zinc (Bogdanović and Čabilovski, 2007). The same authors state that soil that has 40-60 mg K_2O $100g^{-1}$, where vegetables are grown, is considered to have sufficient content of potassium.

Chemical properties of soil are very important for the adoption of chemical elements by plants, and the soil reaction (pH) is particularly pointed out. The optimal pH of the environment for the adoption of macroelements is in the range of pH 6-7.5, while the acidic environment of pH 4.5-5.5 suits microelements, with the exception of molybdenum, to which neutral and alkaline environments suit. Different plant species have different requirements for soil pH (Bogdanović et al., 2004).

Humus is a very important factor of soil fertility. Humus soils contain large amounts of biogenic elements. Humic substances bind cations and anions in a form that is easily accessible to plants.

The analysis of soil from the municipality of Aleksinac found that over 55% of the soil belonged to a class of soil abundant in humic substances, having a content of humus from 3% to 5% (Grčak M.D, 2015).
A low phosphorus content in soil is usually solved by applying phosphatization, which is one of meliorative ways to introduce phosphorous fertilizers into the soil. The excess of phosphorus in soil can cause Zn, Fe, Ca, B and Mn deficiencies. It is recommended to omit phosphorus fertilization, and apply deep tillage, since phosphorus is generally immobile in soil, so it is accumulated in topsoil.

Conclusion

From results obtained by examining the contents of available phosphorus and potassium in the agricultural soil in the municipalities and the town of Niš, the following conclusions can be drawn:
When it comes to phosphorus, 37.7% of the analyzed samples were moderately supplied. There were 34.5% badly supplied samples. Finally, 27.8% of the analyzed samples belonged to the class well supplied soil.
As for the content of potassium in the soil, the largest number of samples, 62.9%, belonged to the group of well supplied soil with readily available potassium. 35.5% of the samples were moderately supplied and only 1.6% of the examined samples belonged to the class of soil poor in potassium.

Abstract

It is estimated that 30% of the world's useful agricultural area, equivalent to 300 kilos of food lost per inhabitant and corresponding to an economic cost of 750,000 million dollars, is wasted annually. On the other hand, in Europe there is an unacceptable direct relationship between economic development and the level of food waste where 89 million tons of food end up in the trash, in a scenario shared by different developed countries outside the European Union. In this context it is important to define and maximize strategies for reducing food waste, which is a global, social, civic, economic, technological, scientific and human commitment. Any strategy to be implemented will have to include different variables. In a reflected proposal, 5 intervention axes are to be considered: to carry out studies to know how much, how, where and why of food waste; disseminate and promote good practices and awareness raising actions; analyse and review normative aspects; encourage the design and development of new technologies; collaborate with the agents and organizations involved in this field. Considering these variables, in Portugal, in the past year of 2014, through a formal commitment "Combating Food Waste, a commitment of all", a common strategy was defined for all agents of the food chain who were actively involved in an organized, structured and coordinated way, committing to change attitude, working procedures and management systems.

Key words: *Portugal, food waste, strategy, good practices*

Introduction

It is estimated that 30% of the world's useful agricultural area, equivalent to 300 kilos of food lost per inhabitant and corresponding to an economic cost of 750,000 million dollars, is annually wasted. At the same time, the carbon footprint of food loss and waste (FLW) is estimated to be up to 3.49 gigatons of carbon dioxide equivalent (gtCO2e), representing up to 6–10% of total anthropogenic greenhouse gas (GHG) emissions (HLPE 2014) (Gromko and Abdurasulova, 2019). Food is produced for the purpose of being consumed, nevertheless, 33% of all produced food is wasted throughout the value chain, with some regions reaching 40% (FAO,2019). Those foods, that do not serve the purpose for which they are produced, constitute what is meant by "food waste", becoming a problem across the entire food chain, from production to consumption. In addition, an unacceptable and direct relationship between economic development and the level of food waste is observed. In Europe, projections show that between 30% and 50% of edible food will be wasted every year through the whole food chain until it reaches the consumer. This equates, in the 28 member states of the European Union (EU-28), to 173 kilograms of food waste per person. Considering the total amount of food produced in EU in 2011, around 865 kg/person, this represents a waste of 20 % of the total food produced and also an annual food waste around 89 million tonnes in the EU, distributed by households (42%), industry (39%), catering (14%) and distribution (5%). These figures allow us to predict that EU food waste by 2020 will be around 126 million tonnes, which will represent almost 20% increase since 2016 (Stenmarck *et al.*, 2016).

Within this framework, the reduction of food waste is both particularly relevant and also a moral obligation in a world where about one-sixth of the population is hungry and where 870 million people are in a state of malnutrition. In Portugal, considering the sum of food loss and waste that occur along the different stages of the supply chain, it was estimated that food waste represents 17% of the annual food production, approximately 1 million tonnes (Baptista *et al*., 2012). This scenario implies to adopt in civil society, public administration and government strategies, policies and behaviours that prevent and reduce the economic, social and environmental costs inherent to food waste. It is determinant the compromise of all stakeholders, including consumers' and the Government, in order to commit themselves in enhancing the efficiency of the food chain, with the short-term goal of a significant reduction of food waste. It should be present that re-using, redistributing and recycling the products is fundamental for food waste reduction, and that is positively influenced by food safety, food quality and other good practices in all stages in the food chain. This can never be neglected. The objective of the present paper is to deliver and to describe a set of policies and actions based on the commitment assumed in Portugal to reduce food waste by all partners involved in the food chain, consumers and civil society, public administration and government.

Materials and methods

In Portugal, considering the real lack of knowledge about the impact of food waste in the different sectors of the food chain and the non-existence of credible studies to support the implementation of reduction policies and strategies, it was essential the implementation of a set of targeted actions that alerted and committed the community for what was political consider a national purpose.

The different entities, organizations and associations, both public and private, that were directly related to this object were identified and grouped in:

1. Government (Ministry of Economy, Ministry of Agriculture and Ministry of Health), public administration (Directorates-General and Food and Economic Security Authority) and international organizations (FAO);
2. Confederation and associations of productive (agriculture), industrial (agri-food), trade (distribution) sectors, catering and consumers;
3. Teaching and research entities (universities and polytechnics, research institutes) and professional organizations';
4. Civil society (Food Bank Against Hunger and other NGOs).

On the basis of a common understanding, the document "*Food Waste - a commitment of all*!", was prepared. This document aimed to obtain at a precise characterization of the national situation and, at the same time, intended to institute a national strategy to combat food waste. Specific groups and thematic areas were established, in order to define actions, develop activities and disseminate policies and results to all the different focus targets.

Results and Discussion

In Portugal, in the past year of 2014, the formal commitment: "C*ombating Food Waste, a commitment of all*", was defined as the common strategy by all food chain agents. All stakeholders were actively involved in an organized, structured and coordinated way, assuming the importance and the will to change attitude and develop waste free procedures and management systems.

An inclusive approach was defined which required a compromise that united all partners in the adoption of a set of recommendations. This public commitment, which begins in production stage and ends in the final consumer, was based in the following common and crosscutting principles which are determinant "towards zero waste" objectives:

• Promotion of cooperation between all partners in a combination of efforts to fight food waste;
• Development of a waste reduction strategy and monitoring methodology definition;
• Awareness the society, in general, for food waste along the food chain;
• Development and disseminate best practices in the management of food losses;
• Promote the recovery of food products that are not in conditions to be consumed, as well as intermediate products and packaging material;
• Developing alternative solutions for potential food waste (re-use);
• Definition and acceptance of unconventional redistribution chains;
Any strategy to be implemented has to include different variables and domains. This planning foresees 5 intervention axes:
1. Primary production and transformation:
The food supply chain begins on primary production, one of the most wasteful stages. It is estimated that the initial and final stages of the chain area the ones where almost all losses occur. To limit waste as much as possible, the following measures are listed:

- Carrying out adequate and rigorous planning of food production;
- Minimizing losses, using natural resources efficiently and sustainably;
- Limiting food waste on farms by increasing efficiency in the harvesting process;
- Adapting the installed capacity of agro-industry for the estimated production;
- Managing, handling and storing properly the agricultural products for agro-industry;
- Innovating in packaging technology, creating new food preservation solutions;
- Optimizing production capacity to commercial storage and disposal capacity;
- Promoting better information to the consumer, on the contents of the labels, giving priority to the conditions of conservation, dates of minimum durability and consumption deadline;
- Working with stakeholders, in order to stablish different solutions for ingredients or intermediate products and foods that are not suitable for quality reasons but meet all legal requirements for food hygiene and food safety.

Within this axe, the articulation of the defined measures was implemented as in the structure presented in the figure 1related to the management of agricultural surpluses:

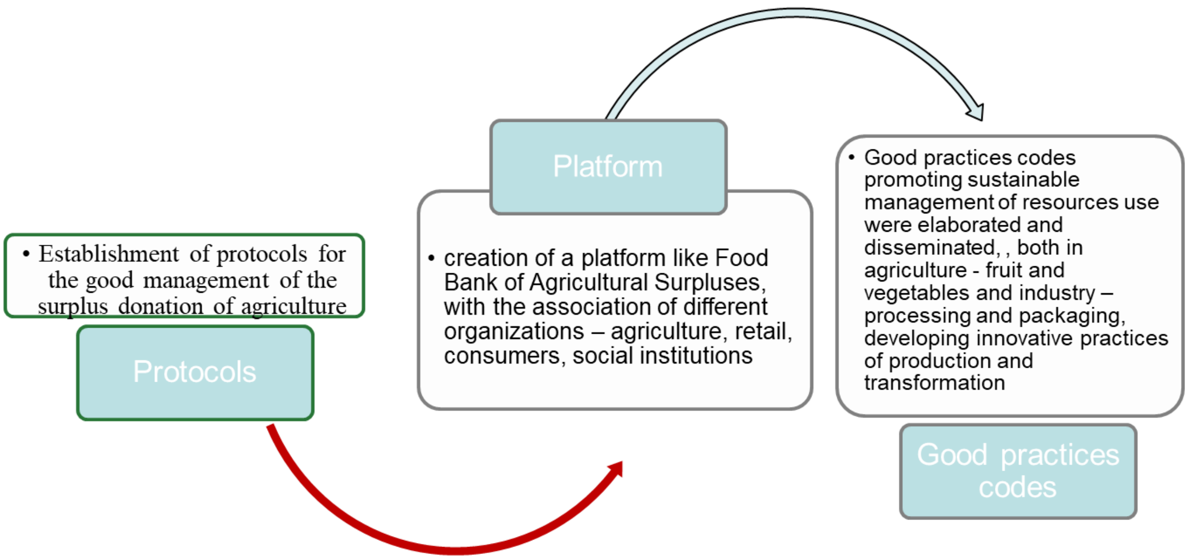

Figure 1 - Primary production and transformation measures

2. Logistic Distribution and Retail Market

Logistic distribution is an important link in the food chain, bringing goods closer to the population and transporting them from the origin and production zones to the places of commercialization and consumption. In the logistics and retail distribution sector, the following good practices were planned and implemented in order to reduce food waste:

- Valuing local production and domestic production;
- Defining strategies of consumption of local/national products, ensuring that Public Institutions (schools, universities, hospitals) prefer national production;
- Schedule logistics and transportation;
- Managing and storing the stocks properly: "first-in, first-out";
- Promoting the rotation of the products in the shelves, guaranteeing that products with nearer validity periods are placed ahead of the rest;
- Promoting the quick sale of products approaching the expiration date;
- Handling products properly in order to avoid packaging deterioration;
- Re-sizing of the packages in face of the needs of the households and consumption patterns;
- Promoting the sale in bulk in an appropriate manner.

The distribution sector already had an enormous concern to the problem of food waste and had already implemented a set of measures and actions towards reducing it. Good practice guides have been developed and disseminated to the distribution professionals and to the consumers, with training in specific activities and in which the concern to ensure food security is constant and a priority.

At the same time, new practices were introduced in product marketing, particularly in packaging, and food surpluses donation to charities was encouraged. Likewise, in the catering activities, actions of sensitization were promoted and started programs of collection of meals for reutilization, in an approach of support to the most deprived ones.

The measurements / results of this axis are summary present in Figure 2 below.

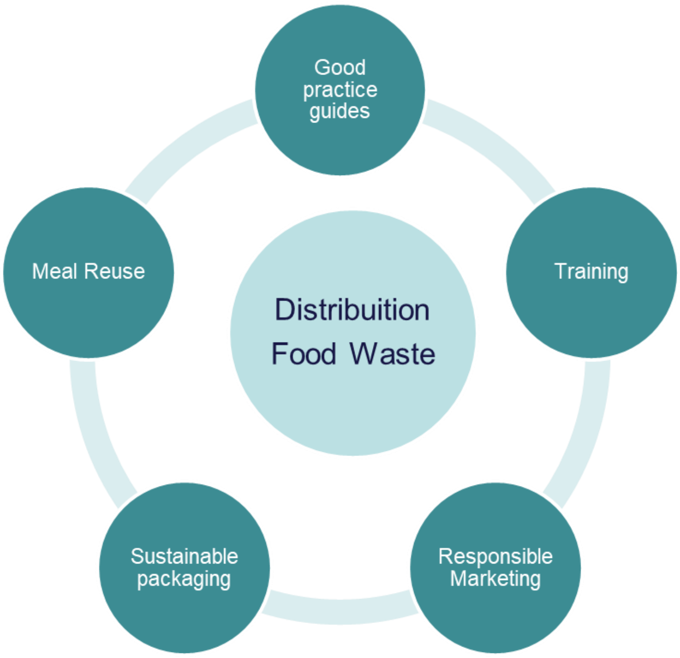

Figure 2 - Logistic Distribution and Retail Market measures

3.Education and Communication

The prevention of food waste is fundamental at the educational level as part of one communication strategy. Reducing food waste in the final stage (consumer) implies changing

behaviours, habits and even the routines of individuals, families and all society. Sensitization and media communication are important key factors for the success of this goal.
A set of recommendations are included to contribute to the reduction of food waste:
Introducing awareness in the school programs to prevent food waste;

- Application of the School Fruit Scheme in as many municipalities as possible;
- Dissemination of good domestic and purchasing practices;
- Raising awareness of the differential treatment of perishable and non-perishable products;
- Promotion of initiatives on food consumption indications and disseminating rules for good conservation practices;
- Motivation for more frequent buying in local markets;
- Encouraging the "shopping list" taking in account the size of the families;
- Promotion and encouraging the consumption of seasonal products;
- Developing culinary skills that prevent food waste and producing safe and healthy meals.

The receptivity of society and the academy to the problem of food waste was very high and very intense its mobilization. Numerous actions have been developed within the different strategic social segments that were translated in the following figure 3:

Figure 3 - Education and Communication measures

4. Awareness and Accountability

The general commitment against food waste implies a great social awareness, including the articulation and partnership with charity institutions. In this context, a group of recommendations were settled in order to boost the reduction of food waste:

- Awareness for the adoption of responsible consumer practices;
- Creation the notion of "*food footprint*" to enable families to calculate their level of loss;
- Food donation programs involving food donors, redistribution organizations and recipients;
- Promotion of agreements to redirect, for food donation institutions, the primary products: fruits and vegetables and other products that do not enter in the agro-industrial sector;
- Introducing the concept of "*healthy food*" into all procedures related to food donation or food support for vulnerable populations;
- Helping the donors to separate food products not eligible for sale, although they meet all legal hygiene and food safety rules and requirements;
- Making easy the exchange of good practices on the prevention, redirection and use of products and surpluses.

Within this axis, one of the most significant realizations was the launch of award "*PRA-TØ - Recognition of Food Waste Prevention Practices",* an initiative of the Government and Civil Society, under the high patronage of His Excellency, the President of the Republic of Portugal. The objective of this award was to distinguish the implementation of policies and models of good management in food waste reduction.

Figure 4 – 2015 Award Ceremony - Seal of Recognition *PRA-TØ*

The first edition distinguished entities that took responsibility for the impacts of their decisions and activities, created value for stakeholders and contributed to sustainable development, involved the Portuguese business community, and society as a whole, in the area of Food Waste and Social Responsibility and to highlighted the work already done in this field by different entities. This award was a success with 37 competitors in 5 categories.

5. Regulation, Implementation and Recognition

The mission of the Government is to regulate when necessary in the prevention of food waste, therefore, tools and studies that, directly or indirectly, promote food waste reduction can be created, as the National Platform of Knowledge on Food Waste. Some of the administrative proposes in order to reduce and prevent food waste were:

- Monitoring the reduction of food waste and improve the food chain sustainability;
- Creation of local markets and promoting local short commercialization circuits;
- Valorisation, at the level of public contracts, companies with social responsibility and good anti-waste practices implemented;
- Evaluate the possibility of acquiring food products from production and local markets by making public procurement rules more flexible, taking into account food security;
- Evaluate the possibility of implementing a fiscal and/or economic benefit aimed at food donation;
- Advertise or distinguish the distribution agents that have, by product range, levels of national products commercialization over 2/3;
- Create a competition to identify best practices in the "Prevention of Food Waste" throughout all phases of the process;
- Advertise good practices related food waste prevention with a "*seal*" that can be identified and valued by the consumers and stakeholders.

The evaluation and segmentation study of food waste in Portugal, with suggestion of proposals and lines of future action, was presented with its first conclusions. This information allowed decision makers and stakeholders to gain a more detailed knowledge of the reality, thus defining lines of action for their prevention, bringing the waste of reuse closer. Another result within this axis was the decree-law published on production local markets.

More recently, following the strategy initiated in 2014 and emphasizing that the fight against waste do not stop with the change of political cycles, the National Commission to Combat Food Waste was instituted (DR, 2016), which resumed the National Strategy to Combat Food Waste.

Last, Portugal was a pioneer in the development and elaboration of Codes of Good Practices that facilitate food donation. These guiding documents are currently undergoing review and adaptation, and these adjustments stemmed from the experience gained by donors and recipients (Food Bank, Re-food, among others), during the implementation of the policies defined in the National Strategy.

Conclusions

The strategy started in 2014 to trigger a more effective and articulated fight against food waste had the capacity to promote the discussion on the subject and served to place at the same table and with the same objective all stakeholders in the agri-food sector.

As an example, it is important to highlight that the aggregating strategy defined in 2014 by civil society, the public sector, the municipalities and NGOs currently has significant results. Observing the 2018 data of the Zero Waste Movement, the measures and attitudes implemented allowed the results presented in Figure 5, reveals:

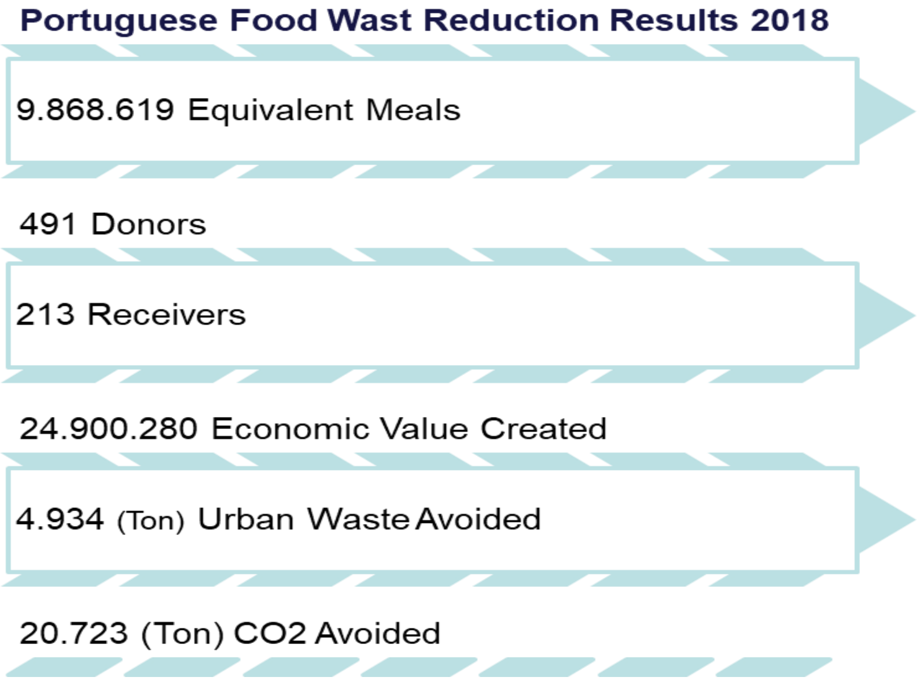

Figure 5 - Portuguese Food Wast Reduction Results 2018 – Zero Waste Movement indicators

Also, it is relevant to notice the Re-food evolution. This NGO, which aims to prevent food waste and distributing leftover meals from canteens, restaurants and caterings to needy people in 5 years achived to the results present in figure 6.

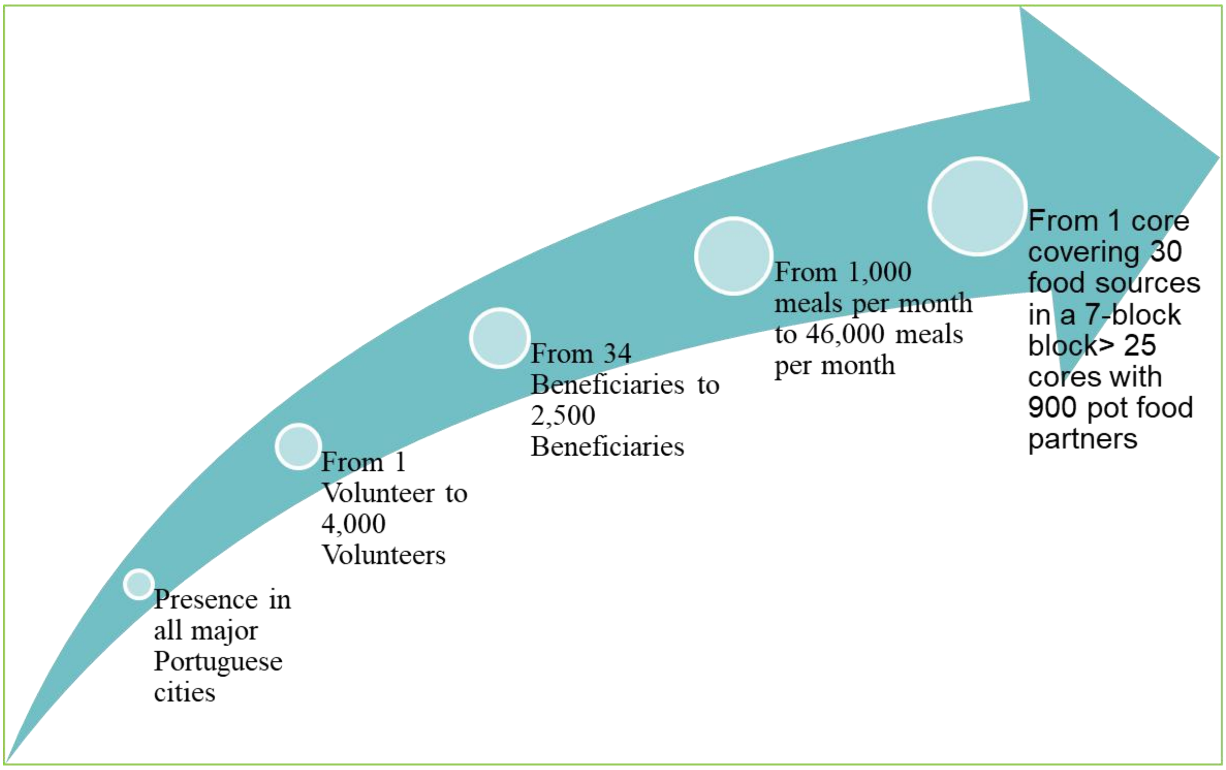

Figure 5 – Re-Food ONG 5 years results 2014-2019

Since then, all the strategy measures were aligned to the sustainable goals defined in the 2030 Agenda. Portugal and the Portuguese food sector undertake the 2030 Agenda, as a commitment to eradicate poverty and achieve sustainable development by 2030 worldwide, ensuring that no one is left behind.

The 17 Sustainable Development Goals (SDGs) and their 169 associated targets are global in nature, universally applicable and interlinked with the 2014 food waste reduction national agenda. All countries, developed and developing, have a shared responsibility to achieve the SDGs, integrating, in a balanced manner, the three dimensions of sustainable development - economic, social and environmental - and reflects for the first time an international consensus that peace, security, justice for all, and social inclusion are not only to be pursued on their own but that they reinforce each other (UN, 2015).

Portugal, as a project based on fundamental values and fairness, embraces the UN 2030 Agenda for Sustainable Development as a unique opportunity for a better future, also in food waste and food access matters. To preserve the future, the right policy choices have to be made today with a strong commitment between all the stakeholders.

Abstract

Existent trends in the use of renewable natural resources call into question the self-regulatory abilities of biocenoses to adapt to dramatic climatic and other changes. Activities on the development of rural economy through diversification and development of economic activities in rural areas, intensifying the process of urbanization, generate phenomena that directly threaten not only ambient values, but also nature as a whole. Opportunities and needs that were compatible a hundred years ago are now often in contrast, which is particularly reflected in the relationship between the needs of urban complexes for food, drinking water and air. By harmonizing the relationship between urban units, agrocomplex and forest biocenoses, it is possible to provide development that does not endanger the future generations of meeting needs, and meeting the needs of the present generations. Protecting and improving the state of forests, using existing potentials and their functions, such as raising new forests in order to achieve optimal forestry, spatial distribution and structure of the forest fund is a legal obligation. The law provides a basis for the sustainability of forest management and sustainable forest management. In this regard, from the point of view of area management, the imperative task is to harmonize ecosystems in the boundary areas (ecotons) that are located between different ecosystems. The equilibrium between the two ecosystems is unstable. Small changes in one ecosystem can significantly affect the survival of the second ecosystem, especially when it comes to forest ecosystems in relation to urban areas and agricultural complexes. The aim of this paper is to point out the possible negative consequences and possible solutions on the example of a tourist place based on the principles that the economic interest is equal to the ecological interest.

Keywords: *Renewable natural resources, Forests, Area management, Harmonization.*

Introduction

Existing trends in the use of renewable natural resources are under question because it is about autoregulating the ability of ecological biocenoses to adapt to climate and other changes. Numerous economic and economic activities in rural and urban areas have created phenomena that directly threaten not only ambient values, but also nature as a whole. In this way, there has been a discrepancy between opportunities and needs, which is particularly reflected in the relationship between people's need for food, drinking water and air, and the ability to provide it. Harmonization of relations between urban and rural units, agrocomplex and forest biocenoses can provide sustainable development that will not compromise future generations to undermine their living needs, and at the same time provide a realistic opportunity to meet these needs for the current generation of people. According to the Law on

Forests of the Republic of Serbia (2015) preservation, protection and improvement of the state of forest using all its potentials and functions, then raising new forests in order to achieve optimal forestry, spatial distribution and structure of the forest fund is a legal obligation of our country. This law has a foothold in two basic principles, which are permanent forest management and sustainable forest management. In this regard, from the point of view of area management, the imperative task is to harmonize ecosystem relations in the border areas (ecoton) located between different ecosystems. The equilibrium between the two ecosystems is unstable. Small changes in one ecosystem can significantly affect the survival of the second ecosystem, especially when it comes to forest ecosystems in relation to urban areas and agricultural complexes. The aim of this paper is to point out, in the case of the tourist place Vrnjačka Banja, the possible negative consequences of violation of relations in different ecosystems and possible solutions based on the principles that the economic interest is equal to the ecological interest.

Material and Methods

In this paper, data from the Republic Statistical Office of the Republic of Serbia for forests and agricultural lands from 2017 and 2018 were used, data from the GeoSrbija web portal - National Geospatial Data Infrastructure and the data of the program EU Copernicus Land Monitoring Service (2012), in which they are collected data from Earth observation satellites that are combined with observation data from sensor networks on the surface of the earth. To make the conclusions in this paper the logical method of generalization and generalization was used.

Results and Discussion

Municipality of Vrnjacka Banja is one of the most important tourist destinations in Serbia, and its significance is based on the rich mineral water and surrounding parks and forests, as the greatest treasure of this area. In this area there is a branched hydrographic network of watercourses belonging to the basin of the West Morava River, the Ibar River and Rasina. All watercourses on the territory of this municipality are characterized by large oscillations in the amount of water, which is a disadvantage from the aspect of water supply, but also flood risks. The touristic significance of this municipality rests on the existence of four types of mineral and thermo-mineral waters: Snežnik, Slatina, Topla voda and lake. Municipality Vrnjačka Banja covers an area of 23,900 ha, of which agricultural land occupies about 40%, then forests about 50% and populated areas about 10% of the total area. The importance of the forest ecosystem consisting of forests and forest park is of great importance not only in the landscape of this municipality, but also in the ecological and medical aspect, because the forests and parks have the primary goal of improving the psychophysical condition of the sick people who visit this tourist place (Strategy of Agriculture and Rural Development of the Municipality of Vrnjačka Banja 2014-2024).

The methodology of strategic planning is based on three basic points, the first being based on the assumption that the plan of the field and the sectoral plan and as such should have a binding role in the development of all strategic plans (Vider V. 1996). According to the second approach, the landscape should not be viewed as a specific aspect of sectoral plans, but as part of a whole, especially when it comes to planning and management of forest ecosystems. The third paragraph, which starts from the assumption that the inclusion of the concept of landscapes into the spatial planning system and practice is the establishment of regional diversification of precession units and different regional approaches to landscape planning, is objectively most realistic for the harmonization of urban units, agrocomplex and forest biocenoses (Maksin Mićić M. 2008).

Table and chart 1. Structure of the area of Vrnjacka Banja municipality

Structure	Hectares, ha
Vineyard	91
Infertile land	828
Orchard	1.574
Field and garden	3.292
Meadow and pasture	4.488
Forest and forest land	**12.090**
Town and village	**1.537**
TOTAL	**23.900**

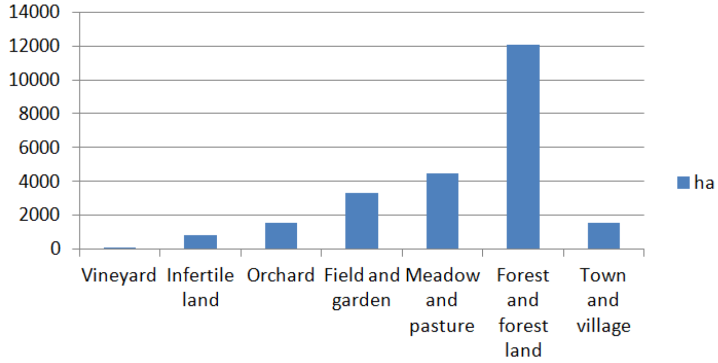

Figure 1. Scheduling of vegetation in the municipality and the urban settlement Vrnjačka Banja

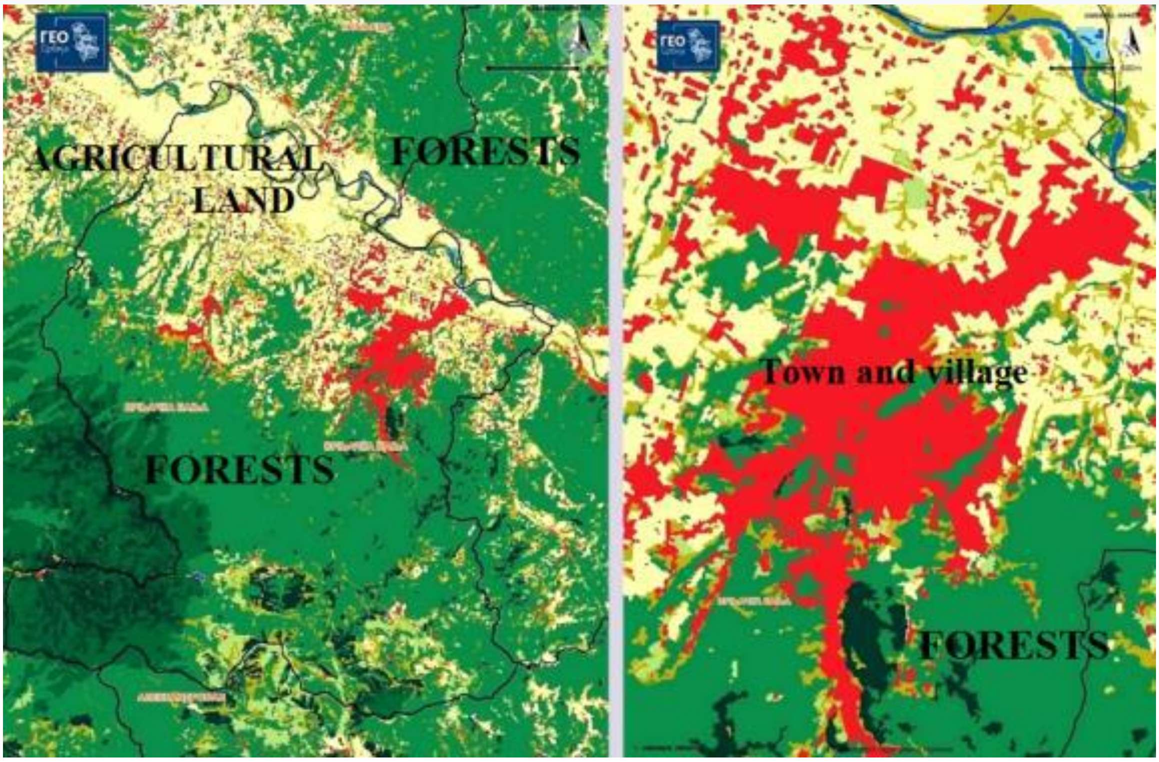

Starting from the methodology of the third strategic planning approach based on sustainable forest management in order to preserve and improve them, it is necessary to preserve the values of this area in order to maximize the use of ecological potentials as well as favorable geostructure. Figure 1 shows the forest areas, agricultural areas and urban settlement of this municipality. Border regions are important in terms of microclimatic processes of regulation, as well as protection against torrential flows, but due to the development of urban settlements and agricultural land, the marginal areas that have the status of forest park have been endangered. Reduction of forest vegetation can result in significant disturbance of ecological values that are treated as economic and tourist values in the current plans of this municipality (Jović et al., 1996, Šarčević, 2012).
According to the European Convention on Areas of 2000, a set of measures defining components of diversity of certain areas, regional and urban planning, which can have a direct

and indirect impact on some landscape, has been defined. If these measures are not properly implemented, the natural values of the Vrnjačka Banja area (forests, parks, water and mineral resources) will soon become a potential problem, since environmental interests are not in line with economic interests. This is particularly contributed by the current policy of renting natural values that become the source of profit, because they lose their original ecological values. The forest ecosystem of the Goc Mountains, as part of the tourist offer of Vrnjacka Banja due to the accelerated urbanization of the settlements, is very endangered. Such an approach is incompatible with the achieved uniformly sustainable development, and we can expect that the edge urban settlements will be increasingly developed, which is why the survival of marginal ecosystems (forests and agricultural land) will be jeopardized.
Future program tasks in the area management function can be articulated through the support of natural forms of bicenosis, avoiding the correct geometric shapes that disturb the dynamic shift of vegetation. Biological and landscape architectural measures need to protect the health and recreational value of the area, protecting the area from biological contamination by supporting diversification elements in the existing space. Only the use of forests does not exclude the principles of sustainable development, but these jobs must be consistent with maintaining functional durability and strengthening general useful forest functions. In this way, the excessive burden of space and its civilization deformation would be avoided, thus protecting the spatial plan from non-compliance with the natural environment. It is also necessary to intensify the development of rural tourism and domestic work, as an integral part of the economic development of this area. This implies the production of various textile and leather items, then items from ceramics and clay, to the collection of medicinal herbs and forest fruits, as well as the development of service activities related to rural tourism.
Harmonization of relations between urban units, agrocomplex and forest biocenoses as part of the management of the area is possible only through the process of optimal use of natural resources (agricultural land, water and forest), as well as their modernization and revitalization. In this respect, from the point of view of the area management, the imperative task is to harmonize ecosystems in the border areas (ecotons) located between different ecosystems, especially this refers to forest ecosystems, forests of parks, agricultural areas and human settlements. A marketing-commercial approach is essential, but within the functions of preserving resources and protecting the environment, by putting all program tasks in interconnection, with a concrete analysis of existing resources and optimizing all processes. Organizational and financial problems could be overcome by the scientific methodological, organizational and multidisciplinary approach, which would enable the harmonization of relations between ecosystems and settlements to gain the dimension of ecological thinking with the necessary financial results.

Conclusions

The harmonization of relations between urban units, agrocomplex and forest biocenoses as part of the management of the area is possible through the process of optimal use of natural resources, as well as the procedures for their renewal and modernization. Special emphasis should be placed on the ecosystem boundary areas, where there is always a risk of disturbing harmonic relations between the two border ecosystems. For the sustainable development of the municipality of Vrnjačka Banja, diversification of this area is necessary, where apart from health and spa tourism, activities in the field of Jaws tourism, sports tourism, as well as scientific and educational activities through the form of congress tourism will be included, which would contribute to the establishment of a complete tourist offer of this municipalities.

Abstract

Fish, as the top of the trophic pyramid of aquatic ecosystems, are one of the most sensitive bioindicators for the presence of heavy metals in the aquatic ecosystems that inhabit them. Concentrations of cadmium (Cd), lead (Pb), mercury (Hg) and zinc (Zn) were determined in the muscle tissue and liver of selected fish species from the Zapadna Morava River during 2013 and 2018, respectively. The aim of this paper was to obtain a more complete insight into the level of accumulation of heavy metals in the organism of fish, especially fish meat as an edible part that should satisfy the health safety for human consumption. Investigations of the concentration of the presence of heavy metals from *Carassius auratus*, *Abramis brama* and *Squalius cephalus* have revealed various bioaccumulation of heavy metals. Among the examined fish, the highest accumulation of heavy metals was found in *Abramis brama*, *Carassius auratus* and *Squalius cephalus*, respectively. In all fish for all four investigated heavy metals, higher concentrations were detected in the liver and less in fish muscle. Bioaccumulation of heavy metals had the following trend: Zn > Pb > Cd > Hg.The determined concentrations of the analyzed heavy metals in fish muscle were not within the permitted limits of the MAC national legislation of the Republic of Serbia. Meat of investigated fish species is not health-safe and hygienically correct for use in human nutrition (The Official Gazette Republic of Serbia No 22/2018 and No 90/2018). The content of tested heavy metals in fish meat indicates that in this aquatic ecosystem during the five year period there was no significant pollution with these heavy metals.

Keywords: *Heavy metals, Bioaccumulation, Freshwater fish, Zapadna Morava River.*

Introduction

Fish is a highly valued animal food in human nutrition. In addition to the nutritional value from the consumer's point of view, its hygienic or safety correctness is also significant. The majority of freshwater ecosystems are due to urbanization, industrialization and other forms of human activity, permanently exposed to the influence of various forms of hydrosalgia. For these reasons, many hydrobionts in them, and in particular the fish populations, suffer negative consequences, and hence the man as their consumer.

Fish come into contact with harmful pollutants through the skin, gill breathing (benthic organisms and plankton), and predator fish species bring metals into the body through other fish they feed. In this way, the metals directly reach the bloodstream in the liver, kidneys and muscle tissue, and accumulate in them more or less (Mansour *et al*., 2002; Erdoğrul *et al.*, 2006; Has-Schön *et al*. 2006; Yilmaz *et al*., 2007). Fish belong to the most sensitive organisms in the presence of increased concentrations of heavy metals, and the level of accumulation of certain metals in tissues and fish bodies depends on the age, size and trophic status of fish, as well as from the concentration of metal in water (Alibabić *et al*. 2007; Ural *et al*. 2012). The main goal of this research is to determine the level of accumulation of heavy metals (lead, cadmium, mercury and zinc) in the muscle tissue and liver of different species of fish that inhabit the river Moravia. In this way, a comparison of the results obtained in 2018 with the results from 2013 will be made, as well as an assessment of the health safety of their meat for human nutrition. At the same time, information on the concentrations of metal in the liver and muscles of the fish would indicate the degree of anthropogenic water pollution in ecosystem of the Zapadna Morava, as well as the assessment of the health safety of fish fodder for human consumption. According to available literature data, the fish populations in ecosystem of the Zapadna Morava River are largely affected by numerous pollutants, especially those of anthropogenic origin such as industrial, communal water and rural wastewater (Veljović *et al*. l992; Lazić *et al*. 2003; Marković *et al*. 2007).

Material and Methods

A field study of the sample collection in the western Morava River was conducted in June 2013 at the Stančići locality (coordinates: N $43^0$52'15,3" i E $20^0$26'17,1") and during July 2018 at the Parmenac locality (coordinates: N $43^0$53'44,5" i E $20^0$18'15,9"). Fish sampling was carried out using stackable mesh of 20 to 60 mm diameter fenders and a battery electro-picking device (AGK Kronawitter, IG200-2, battery power 12V, 20Ah). The species of fish are determined according to Simonović (Simonović, 2006), and for each fish sample, total body length and weight were measured. After fish dissection, samples of muscle tissue and liver were frozen for analysis. In the laboratory, composite samples for each fish species were prepared separately. The concentration of heavy metals in the muscular tissue and liver of the fish species of silver carp (*Carassius auratus gibelio*), as allochthonous species, bream (*Abramis brama*) and chub (*Squalius cephalus*) as autochthonous species in the ecosystem Zapadna Morava River. As for the selection of heavy metals whose content was analyzed in musculature and liver fish, we defined for cadmium and lead as very toxic metals, zinc due to the competitive relationship with cadmium and a highly toxic animal whose toxic effect on fish is present at very low concentrations in water from the 0,003 mg/l. The analysis were carried out according to the standard methodology for the analysis of heavy metals, using the necessary instrumental techniques. By the method of atomic absorption spectrometry (FAAS flame techniques), the content of cadmium, lead and zinc were determined, while the content of mercury in the tissues and organ was determined by the HGAAS atomic absorption spectrometry method, hydride technique.

Results and Discussion

The concentrations obtained for all four metals in the muscles and liver of the three species of fish from different trophic levels are shown in Table 1. During this study, 15 specimens of silver carp, 9 bream and 7 fish chub were analyzed. The highest concentrations of all four tested heavy metals were found in the liver and the lowest in fish muscle. Metal accumulation had an identical trend in all three types of fish: Zn > Pb > Cd > Hg, and the total content of all four metal fish had the following trend bream > chub > silver carp. In order to determine the health correctness of the meat of the examined fish, the comparison of the obtained values of heavy metals in samples of muscle tissue of fish with the maximum allowed concentrations (MAC) established by the European Union (Commission regulation (EC) No 1881/2006) and national legislation of the Republic of Serbia (The Official Gazette Republic of Serbia No 22/2018 and No 90/2018*)*. According to EU regulations (European Commission Regulation, 2006), the maximum allowable amount of Cd, Hg, Pb is 0.05, 0.50 and 0.30 $mg \cdot kg^{-1}$ per unit of fresh weight. According to the norms of national legislation (The Official Gazette Republic of Serbia No 22/2018 and No 90/2018) MAC za Cd, Hg, Pb is 0.05, 0.50 and 0.30 $mg \cdot kg^{-1}$, while according to the same legal regulation, the maximum content of Zn in fish products in cans is up to 100 mg·kg^{-1}.

Table 1. Average values (± SD) content of heavy metals in the samples of fresh fish (mg·kg^{-1})

2013 year, location Stančić					
Fish species	**Sample**	**Cd**	**Pb**	**Hg**	**Zn**
Silver carp n = 11	muscle tissue	0,004±0,04	0,324±0,15	0,135±0,21	17,392±0,05
	liver	0,084±0,20	0,372±0,03	0,152±0,05	18,190±0,26
Bream n = 8	muscle tissue	0,005±0,08	0,193±0,05	0,098±0,12	19,286±0,05
	liver	0,012±0,05	0,231±0,10	0,112±0,23	32,152±0,06
	∑	0,105±0,37	1,120±0,33	0,497±0,61	87,020±0,42
2018 year, location Parmenac					
Silver carp n = 5	muscle tissue	nd	0,150±0,10	0,110±0,28	19,560±0,06
	liver	0,025±0,31	0,186±0,08	0,150±0,05	21,250±0,14
Chub n = 7	muscle tissue	0,002±0,09	0,090±0,12	0,117±0,12	18,133±0,09
	liver	0,040±0,03	0,156±0,06	0,141±0,07	22,450±0,36
	∑	0,067±0,43	0,582±0,36	0,518±0,52	81,393±0,65

Based on the presented tabular results, it can be concluded that during 2013, the concentration of heavy metals in the musculature of the fish studied was significantly lower than their liver content. The lowest values of metal in the muscle tissue were established for cadmium and varied in the range of 0.004 mg·kg^{-1} in silver carp to 0.005 mg·kg^{-1} in bream. These are the permissible concentrations within the MDC regulations of the EU and national regulations of the Republic of Serbia. The reference concentrations prescribed by the national and EU legal provisions of the EU are determined in terms of the content of other analyzed metals in muscle tissue of the fish. The average lead value was from 0.193 mg·kg^{-1} in the muscle of the bream to 0.324 mg·kg^{-1} in silver carp (maximum of 0,3 mg·kg^{-1} is allowed Serbian Regulation). The zinc content was also in the legal framework for fish products in cans and varied from 17.392 mg·kg^{-1} in muscular weight of silver carp to 19.286 mg·kg^{-1} in muscle tissue.

Similar results, but with a somewhat reduced concentration of metal in fish muscle, were also found during the research in 2018. The concentration of Cd was up to 0.002 mg·kg^{-1} in chub, while Pb concentrations ranged from 0.090 mg·kg^{-1} in chub muscles to 0.150 mg·kg^{-1} in silver carp muscularity. The smallest Hg value was 0.110 mgkg^{-1} in silver carp, while slightly higher values of 0.117 mg·kg^{-1} were recorded in chub. The smallest Zn concentration of 18,133 mg·kg^{-1} was determined in the cluster musculature and the highest of 19,560 mg·kg^{-1} in silver carp. The metal concentrations in muscle analyzed fish did not exceed the permitted values prescribed by national and EU regulations.

By comparing the obtained average values of the content of the tested metals in the muscle tissue of the studied fish from 2018 with the data from 2013 year, it can be concluded that the accumulation of metals in fish from the Zapadna Morava River is significantly lower than the previous period. The total concentration of cadmium in musculature and liver in all types of fish in 2018 compared to 2013 was lower by 36%, lead by 48%, zinc by 6.4%, while the content of mercury was by 4.2% higher. The metal concentrations in the fish organism depend on their type, age, physiological state, type of tissue and feeding (Storelli *et al.* 2006; Szarek-Gwiazda *et al.* 2006). According to Oloy *et al.* (2005) due to the biodegradability and ability to accumulate along the food chain, heavy metals are considered to be one of the primary contaminants of the internal organs of fish and the entire aquatic ecosystem.

The obtained results of the concentration of heavy metals in the musculature and liver of the analyzed fish species clearly show that the aquatic ecosystem of the Zapadna Morava River is not encircled by pollutants from industrial waters, although this ecosystem is their basic recipient. The reason for this is the reduced level of industrialization and the cessation of work of a large number of factories. Determined concentrations of heavy metals in the liver all three types of fish varied within the limits of normal physiological concentrations for all three chemical elements and were below the level of human food tolerance (Biro *et al*., 1991). Lead (Pb), content in silver carp in 2013.year of 0,324 and 0,372 mgkg-1 is above the permitted values.This means that the Zapadna Morava River waterway on the studied profiles can be considered relatively unpolluted in terms of the loads of the tested heavy metals. The results of the research indicate the necessity of continuous sampling and analysis of this water course in order to prevent accidental situations and maintain the health correctness of the meat of fish that inhabit this ecosystem. In order to be able to make a final assessment of the hygienic quality of fish meat for human consumption and the ecological status of this ecosystem, it is necessary to carry out a complex analysis, which would include the determination of the content of heavy metals in water, sediment and commercially important fish species from the ihtiofauna composition. Other authors also point to the necessity of this kind of research (Đukić *et al*., 1998; Farkas *et al.*, 2002).

Conclusions

Taking into account that fish are usually located at the top of the food chain in the aquatic environment, they often accumulate large quantities of certain heavy metals, which is why they are considered one of the most sensitive aquatic organisms for the presence of toxic substances. Since fish meat is one of the basic components of human nutrition, excessive accumulation of heavy metals in fish muscle makes this food unsafe for human consumption. The content of heavy metals (Cd, Hg and Zn) in the muscle tissue of three types of fish silver carp, bream and chub from the Zapadna Morava River was within the boundaries of the maximum perm fish chub issible concentration MAC and in accordance with the prescribed national and EU legal acts on the content of metals and other poisonous substances that can be found in freshwater fish. Lead (Pb), content in silver carp in 2013.year of 0,324 and 0,372 mgkg-1 is above the permitted values. Based on the conducted surveys during 2013 and 2018, it can be concluded that ecosystem of the Zapadna Morava River shows a trend of improving the quality in terms of anthropogenic pollution, because the registered quantities of stored heavy metals in the musculature and liver of the investigated fish varied within normal limits for maximum permissible concentrations.

Abstract

The subject of research was diversity and distribution of the species of genus *Amaranthus* in Vojvodina. Genus *Amaranthus* is represented in Europe by 12 introduced and naturalized species, whereas *A. caudatus* is planted as ornamental and it sometimes occurs spontaneously. Other species are weeds or ruderal and common on territory of the northern and central Europe (Aellen and Akeroyd, 1993). In the Serbian flora this genus includes nine species of which all originated from America (Slavnić, 1972). Because of its foreign origin, the absence of predators and adaptive strategies, species of genus *Amaranthus* can easily expand their range in Vojvodina. Based on data from literature and herbarium collections ten species, two subspecies and one hybrid were recorded in Vojvodina. The nomenclature data collected from the literature and herbarium were systematized and harmonized with data provided by Flora Europaea (Aellen and Akeroyd, 1993). Data on general distribution and distribution in Serbia are given according to Flora of Serbia (Slavnic, 1972) and List of invasive species in Vojvodina (IASV, 2017). Data of distributuion in Europe are given by Flora Europaea (Aellen and Akeroyd, 1993) and List invasive species in Vojvodina (IASV, 2019). Floral elements are given to Gajic i Soó (Gajic, 1980; Soó, 1970). Analyzed data covered the period of 80 years, and obtained localities are grouped by regions: Backa, Banat and Srem. Ranges of taxa are shown in UTM maps (Universal Transverse Mercator) of Vojvodina, extent of 10x10 km (Walter and Straka, 1970).

Key words: ruderal flora, weeds, distribution, *Amaranthus*.

Introduction

Weeds and ruderal flora and vegetation of Serbia is very rich and diverse. This is a consequence not only of the impact of anthropogenic factors, but also of geographical location, climatic, geological, geomorphological, hydrological, historical and other circumstances. The area of Serbia is abundant in different categories of weed habitats and is an excellent model for the study of weed vegetation (Nestorović, 2005). Ruderal habitats are open, unstable and subject to rapid changes in floral composition and are found in the living and working environment of man. Anthropogenic impact has a decisive importance for the formation, maintenance, distribution and dynamics of ruderal flora and vegetation. Knowledge of ruderal vegetation is of particular importance for plant production, since many weed plants penetrate from ruderal habitat to arable land and act as strong competitors in crops (Stankovic-Kalezic et al., 2009). The genus *Amaranthu*s comprises about 70 species that are widespread in tropical, subtropical, moderately warm zones, as well as in temperate zones. Genus *Amaranthus* is divided into three subgenus: *Amaranthus* L., *Acinida* L., *Albresia* Kunth (Mosyakin and Robertson, 1996). The species of genus *Amaranthus* forms hybrids. Some species are cosmopolitan and these are mostly introduced naturalized weeds (Mosyakin and Robertson, 2004). The species of this genus were brought to Europe. According to the Flora of Europe, 12 species were naturalized. The species of genus *Amaranthus* in autonomus provinceVojvodina (Serbia), which were examined in this paper, are mostly ruderal and weed plants. The species of this genus are also used in the nutrition of humans and cattle, as medicinal plants, and some species are cultivated as ornamental plants. The aim of this paper is to present diversity of the species of genus Amaranthus in Vojvodina.

Material and methods

Data about distribution of genus *Amaranthus* in Vojvodina province were collected from literature and herbarium collections: Herbarium Department of Biology and Ecology at the Faculty of Natural Sciences of the University of Novi Sad (BUNS), Herbarium of Institute of Botany and Botanical Garden "Jevremovac" of the Faculty of Biology of the University of Belgrade (BEOU), Herbararium of the Natural History Museum in Belgrade (BEO), Herbal collections of the Serbian Nature Conservation Institute, Department of Novi Sad (HIPNS). The nomenclature follows Flora Europaea (Aellen and Akeroyd, 1993). Floral elements are given to Gajic i Soó (Gajic, 1980; Soó, 1970). Data on general distribution and distribution in Serbia are given according to Flora of Serbia (Slavnic, 1972) and according to the list of Invasive species in Vojvodina (IASV, 2019). Data on distribution on Europe are given by Flora Europaea (Aellen and Akeroyd, 1993) List of invasive species in Vojvodina (IASV, 2019). Analyzed data covered the period of 95 years, and obtained localities are grouped by regions: Backa, Banat and Srem. Ranges of taxa are shown in UTM maps (Universal Transverse Mercator) of Vojvodina, extent of 10x10 km (Walter and Straka, 1970). The data is grouped chronologically, and the timeframes are presented on maps: until 1925 the red circle, from 1925 to 1950 the blue circle, from 1950 to 1975 the green circle and from 1975 to 2017 the black circle.

Results and Discussion

Based on data from literature and herbarium collections ten species (*A. albus* L., *A.blitoides* S.Watson, *A. blitum* L., *A. caudatus* L., *A. crispus* (Lesp. & Thév) N. Terracc., *A.deflexus* L., *A. graecizans* L., *A. hybridus* L., *A. retroflexus* L., *A. viridis* L.), two subspecies (*A. hybridus* L. subsp. *cruentus* (L.) Thell., *A. hybridus* L. subsp. *hypochondriacus* (L.) (Thell.) and one hybrid (A. x budensis Prisztez) were recorded in Vojvodina. Of the total number of analyzed species of the genus, as very frequent can be distinguished taxa: *A. albus*, *A. blitoides*, *A. caudatus*, *A. crispus*, *A. deflexus*, *A. hybridus* and A. *retroflexus*. According to the List of invasive species in Vojvodina (IASV, 2019), this species have invasive character in Vojvodina.

Amaranthus albus L. 1759.

Floral element: adventive (Gajic, 1980); northamerican (Soó,1970)
General distribution: Originating in North America, today is adventive in warmer parts of Eurasia, Africa and South America (Slavnic, 1972)
Distribution in Europe: naturalized in almost all of Europe (Aellen and Akeroyd, 1993)
Distribution in Serbia: Vojvodina, eastern, southeast, and western Sumadija (Slavnic, 1972)
Distribution in Vojvodina (figure 1)

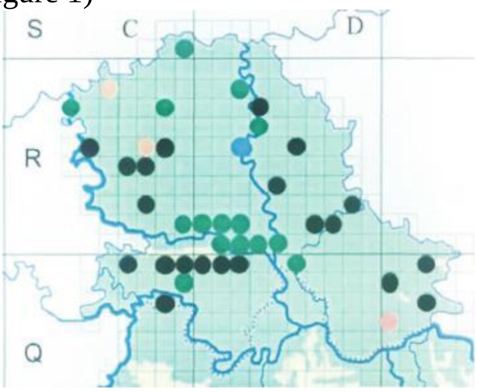

Figure. 1. Distribution of the *Amaranthus albus*, in Vojvodina

Amaranthus blitoides S. Watson 1877.

Floral element: adventive (Gajic, 1980); northamerican – midamerican (Soó,1970)

General distribution: introduced from North America, this species is acclimatized in all the hot areas of Europa and Central Asia (Slavnic, 1972)

Distribution in Europe: naturalized in Central and Southern Europe (Aellen and Akeroyd, 1993)

Distribution in Serbia: Vojvodina, northern, eastern, southern and western Serbia (Slavnic, 1972)

Distribution in Vojvodina (figure 2)

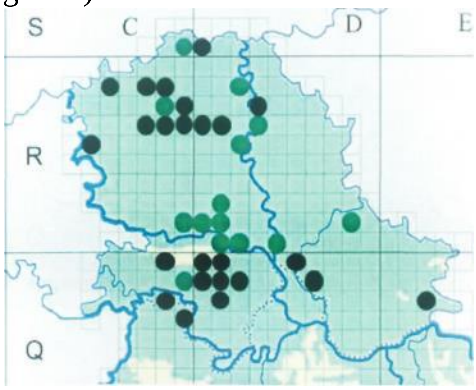

Figure. 2. Distribution of the *Amaranthus blitoides*, in Vojvodina

Amaranthus caudatus L. 1753.

Floral element: adventive (Gajic, 1980)

General distribution: northern, mid, southern America, in warm and moderate zone, eastern Africa and eastern Asia in warm and moderate zone, Australia and Oceania (Slavnic, 1972)

Distribution in Europe: eastern, southern and central Europe (Aellen and Akeroyd, 1993)

Distribution in Serbia: around Belgrade (Slavnic, 1972)

Distribution in Vojvodina (figure 3)

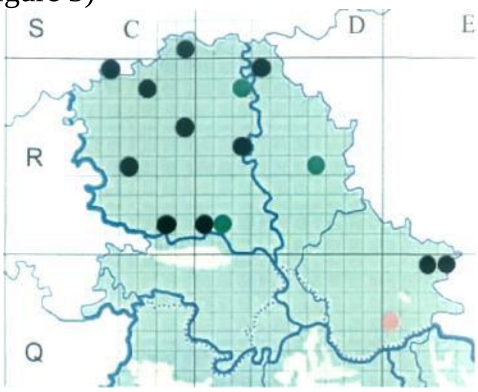

Figure. 3. Distribution of the *Amaranthus caudatus*, in Vojvodina

Amaranthus crispus (Lesp. Et Thév.) N. Teracc. 1890.

Floral element: adventive (Gajic, 1980), southamerican (Soó, 1970)

General distribution: Western Mediterranean and Pannonian basin in other parts of Europe is in expansion phase (Slavnic, 1972)

Distribution in Europe: naturalized in Central and Southern Europe, spread across the whole of Europe (Aellen and Akeroyd, 1993)

Distribution in Serbia: eastern and western Serbia (Slavnic, 1972)

Distribution in Vojvodina (figure 4)

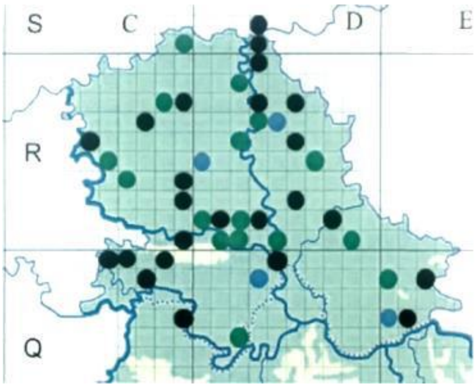

Figure. 4. Distribution of the *Amaranthus crispus,* in Vojvodina

Amaranthus deflexus L. 1771.

Floral element: adventive (Gajic, 1980), southamerican (Soó, 1970)

General distribution: South American plant naturalized in the warmer parts of Europe, North America and Africa (Slavnic, 1972)

Distribution in Europe: naturalized in southern Europe, widespread throughout Europe (Aellen and Akeroyd, 1993)

Distribution in Serbia: Vojvodina, south Serbia (Vranje) (Slavnic, 1972)

Distribution in Vojvodina (figure 5)

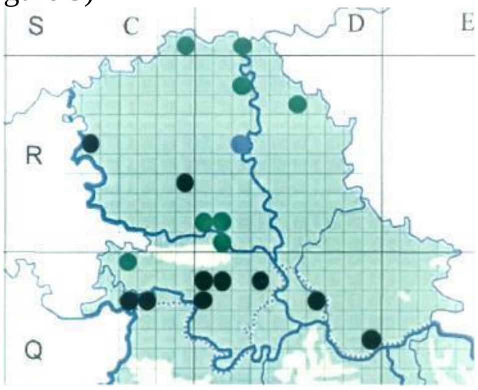

Figure. 5. Distribution of the *Amaranthus deflexus,* in Vojvodina

Amaranthus hybridus L. 1753.

Floral element: adventive (Gajic, 1980), originated from tropical parts of America (Soó, 1970)

General distribution: originating in South America, widespread in North America, North and South Africa and Central and Eastern Europe (Slavnic, 1972)

Distribution in Europe: almost all over Europe (Aellen and Akeroyd, 1993), eastern, southern, central and western Europe (Boza, 2011e)

Distribution in Serbia: Northern (Beograd), western (Sabac, Koviljaca), eastern (Ramski pesak) Serbia, Vojvodina (Slavnic, 1972)

Distribution in Vojvodina (figure 6)

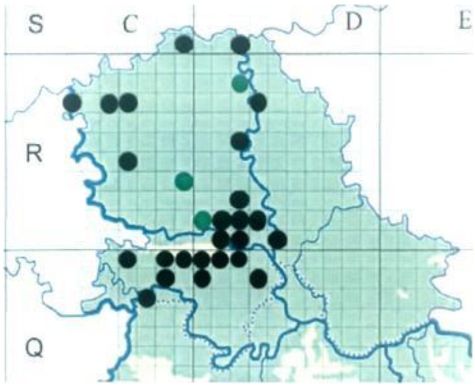

Figure. 6. Distribution of the *Amaranthus hybridus*, in Vojvodina

Amaranthus retroflexus L. 1753.

Floral element: adventive (Gajic, 1980), (northamerican) now cosmopolitan (Soó, 1970)
General distribution: almost cosmopolitan adventive plant, originating in northern america (Slavnic, 1972)
Distribution in Europe: almost all over Europe (Aellen and Akeroyd, 1993)
Distribution in Serbia: very widespread in Serbia (Slavnic, 1972)
Distribution in Vojvodina (figure 7)

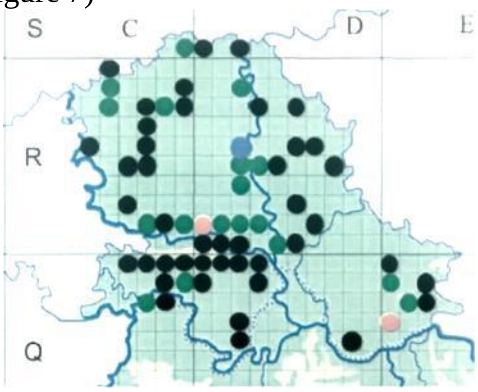

Figure. 7. Distribution of the *Amaranthus retroflexus*, in Vojvodina

All analyzed species are adventive weeds or ruderal plants largely originating from North America, Central America and South America. Genus *Amaranthus* is represented in Europe by 12 introduced and naturalized species, whereas *A. caudatus* is planted as ornamental and it sometimes occurs spontaneously. Other species are weeds or ruderal and common on territory of the northern and central Europe (Aellen and Akeroyd, 1993). In the Serbian flora this genus includes nine species of which all originated from America (Slavnić, 1972). In Vojvodina they inhabit nitrophilic, thermophilic, open anthropogenic dependent habitats. This kind of habitat corresponds to their invasive character in the area of Vojvodina. The species of genus *Amaranthus* today represent significant portion of the Pannonian part of Serbian flora. A significant number of species that were moved to Vojvodina, became naturalized and integrated as a part of the flora, points out enough about the potential of this genus. Because of its foreign origin, the absence of predators and adaptive strategies, species of genus *Amaranthus* can easily expand their range in Vojvodina which is covered with 76% of arable land (Bokic et al., 2012). Analized taxa are potentially marked as the most invasive (because in addition to habitation of the typical artificial, ruderal, arable and disturbed habitats, they also populate natural and salty habitats because of their vastness, high light intensity and small species number. These natural habitats are extreme concerning high salt content and negative water regime, which indicates high adaptability of taxa. The spreading of many alien species is closely related to human activities. Regarding this, these taxa are highlighted, *A. albus*, *A. blitoides* and *A. caudatus*, which appear on arable lands, orchards and ruderal places, where human and his activities predominantly affect the expansion (Bokic et al., 2012).

Although global chronological data is very valuable in the presentation of the total area, data from individual regions contribute to knowing the structure of the area and its more precise boundaries. Invaluable is the importance of such approaches to the analysis of the areals in those species that show the strategy of spreading the areal. The obtained information is of importance in the prediction of areals of alien plants, in particular in the characterization of the invasive character of certain taxa.

Conclusion

Based on data from literature and herbarium collections of ten species, two subspecies and one hybrid were recorded in Vojvodina. Seven taxa are potentially marked as the most invasive (because in addition to habitation of the typical artificial, ruderal, arable and disturbed habitats, they also populate natural and salty habitats because of their vastness, high light intensity and small species number. Ranges of that taxa are shown in UTM maps. The obtained information is of importance in the prediction of areals of alien plants, in particular in the characterization of the invasive character of certain taxa.

Abstract

This study investigated the effects of drip irrigation on citrus root distribution that were planted on ridge system. The study was conducted in a farm in Zagarlı village of Adana in Turkey. The trees were planted in 3 m intrarow and 7 m row. The orchard size was 364 daa and the trees were 6 years old. Root samples selected randomly from trees representing the orchard by the lateral side (L50, L100) and non-lateral side (Ln50, Ln100) of the tree from 4 different points and four different depths. According to the research findings Nova (*Citrus reticulate Blanco*), Okitsu (*Citrus unshiu Marc*), Valencia (*Citrus X sinensis*), the density of plant roots was found to be decreasing as the horizon deepens and away from the tree trunk. Furthermore, the root distribution on the lateral side was observed to be more uniformed and ampled than the non-lateral lines. It was observed that the root density on the lateral side was higher and uniformed more than on the non-lateral side.

Keywords: *Root distribution, orchard, planting on ridge.*

Introduction

Citrus cultivation is one of the major agricultural production activities which has an important place in fruit cultivation of Turkey. Citrus cultivation is developing at an increasing rate and contributing greatly to Turkish economy. Annual water requirement of citrus varies between 900-1200 mm depending on soil, climate and physiological condition of the citrus tree (Doorenboss and Kassam, 1979). Ridge planting systems were improved especially on citrus planting orchards in Turkey as locally in the Mediterranean part of the country. Inadequate Drainage, extreme winter rainfall and excessive surface irrigation causes fungal disease (Phytophthora citrophthora), damage the tree root and trunk while the ridge planting systems is successfully applied to avoid the negative effects. Citrus orchards are generally established as conventional planting in Turkey. Various researches about plant root distribution in these conventional orchards, which were established in the form of conventional planting and irrigated by drip irrigation. However, the effect of drip irrigation on the root distribution of the plant has not been studied well in the ridge cultivation systems. When there is enough water in the root area to meet plant water requirements, the development of root and stem system is at the highest level. Water, root volume and yield relationships in clayey soils are; a) Insufficient water and large root volume cause less yield b) Sufficient water and mid root volume cause high yield, c) excesive water and low root volume cause low yield (Hagan *et al*., 1967) In this context, the aim of this study is to investigate the effect of drip irrigation on the plant root distribution in citrus trees as planted on ridge cultivation systems.

Materials and Methods

The research was carried out in Turunçgil A.Ş., located in Zağarlı Village of Yüreğir District of Adana Province (Turkey) in summer 2005 as consturucted at 364 da 3x7 m intervals parcels. In citrus orchard, drip irrigation system were used on Nova, Okitsu and Valencia varieties with ridge cultivation system.

The ridges where citrus were planted created before planting during the establishment of the orchard. Ridges are trapezoidal and 80 cm high. The upper width of the ridge is 1.60 m, the base width is 6 m, the ridge edges are 2.3 m and the flat part between the two ridges is 1 m wide (Figure 1).

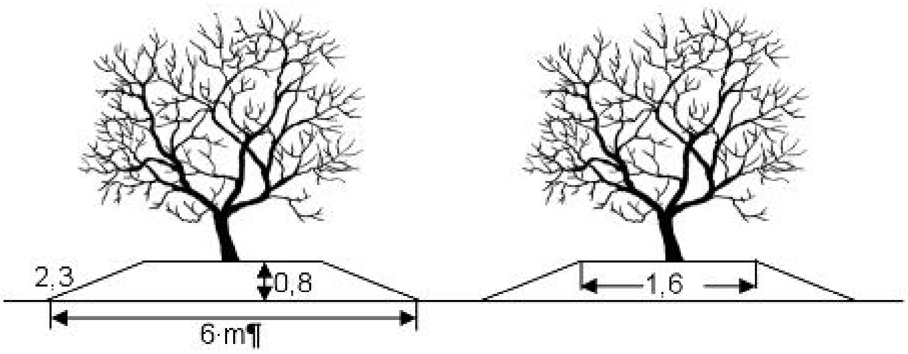

Figure 1. Cross section of ridges in the trial area

The research garden soils are AC horizon soils developed on alluvial deposits of aged river terraces called as Mursel series. In this series of soil pH values varies between 7.1-8.0. The average cation exchange capacity is 23 me/100 gr. The amount of lime varies between 15-30% and the clay content varies between 25% and 42% (Dinc *et al.*, 1990).

Table 1. Some physical and chemical properties of the soil of the trial area

Soil Depth (cm)	Texture (%)			Structure	Salinity dS/m	Lime (%)	pH	Field Capacity (%)	Wilting point (%)	Volumetric Weight. gr/cm^3
	Sand	Silt	Clay							
0-30	15.21	44.87	39.92	Clay-loam	0.50	15.80	7.6	33.58	16.25	1.23
30-60	24.41	42.33	33.26	Clay-loam	0.42	18.33	7.6	33.74	17.83	1.35
60-90	20.25	44.41	35.34	Clay-loam	0.39	18.33	7.6	33.61	18.62	1.41
90-120	43.53	29.64	26.83	Sandy-Clay-loam	0.28	22.12	7.7	33.41	17.54	1.33

Table 1 reflects that the soil in the trial area field capacity is 33.58-33.74%, wilting point 16.25-18.62%, volume weight 1.23-1.41 gr/cm^3, lime content was found to vary between 15.80-18.33 and pH value was 7.6. The parcels tested have a clayey loam structure and no problems were detected in terms of salinity.

Irrigation water is supplied from a 170 m deep well in the citrus orchard where the survey was conducted. Water samples were taken from the inlet and outlet of the irrigation system and some physical and chemical properties were analyzed in the laboratory according to USSL (1954), and the analysis results are given in Table 2. Irrigation water is classified as C2S1.

Table 2. Some physical and chemical properties of irrigation water

pH	Salinity dS/m	Cation me/l					Anion me/l					SAR
		Ca	Mg	Na	K	Tot.	CO_3	HCO_3	Cl	SO_4	Tot.	
6.8	0.476	0.98	2.09	1.96	0.06	5.09	-	2.50	1.63	0.94	5.09	1.59

Three trees were chosen by random sampling method. For each of the selected sample trees, samples were taken up to a depth of 50 cm (L50) and 100 cm (L100) at a distance of 120 cm from the tree trunk to the canopy area in the lateral direction (Figure 2). Similarly, a total of 16 samples from 50 cm (Ln50) and 100 cm (Ln100) distances from the non-lateral direction were taken after irrigation in July 2006 with the aid of a Viehmeyer Pristine soil sampling device (Yeşilsoy, 1976). The inner wall of the tube is lubricated to allow the Viehmeyer tube to advance more easily in the soil and to take out from the block-shaped soil. The tractor power was used to remove the Veihmeyer tube.

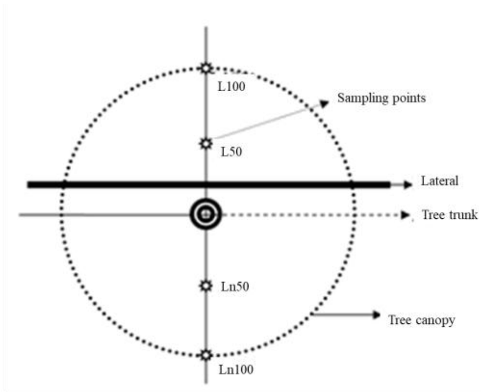

Figure 2. Schematic representation of root sampling points and root sampling with Viehmeyer intact soil sampling tool

Root samples were removed from the 120 cm profile in blocks with the help of Viehmeyer pristine soil sampling device and then cut into 30 cm layers. The samples taken in the field were labeled and packaged and brought to the laboratory.
The samples were taken into plastic containers and 0.1N NaOH solution was added and left to stand for 24 hours. A solution of 0.1 N NaOH (prepared by adding 1 liter of pure water over 4 grams of Na OH) lead to the heavy soil for dispersion. The samples were then taken into larger containers one by one, diluted with water, passed through 8.0, 6.3, 4.0 and 1.0 mm meshed filters to separate the roots.
Statistical analysis; SPSS in statistical analysis of collected data on trial subjects package program was used. LSD method for comparison of means was done.

Results and Discussion

Samples taken at 4 different depths at 50 cm and 100 cm distances from the both side (lateral side, non-lateral side) of the tree trunk for the distribution of the extracted roots determination as weight percent.
Root samples taken from a distance of 50 cm in the direction of drip irrigation lateral of the tree trunk were examined and the calculated root densities are given in Figure 3. When the root densities of all 3 cultivars are examined, Valencia and Okitsu varieties have a similar root distribution in the roots located 50 cm away from the stem, while it is seen that 30% of the roots are located in 90 cm in Nova cultivar.

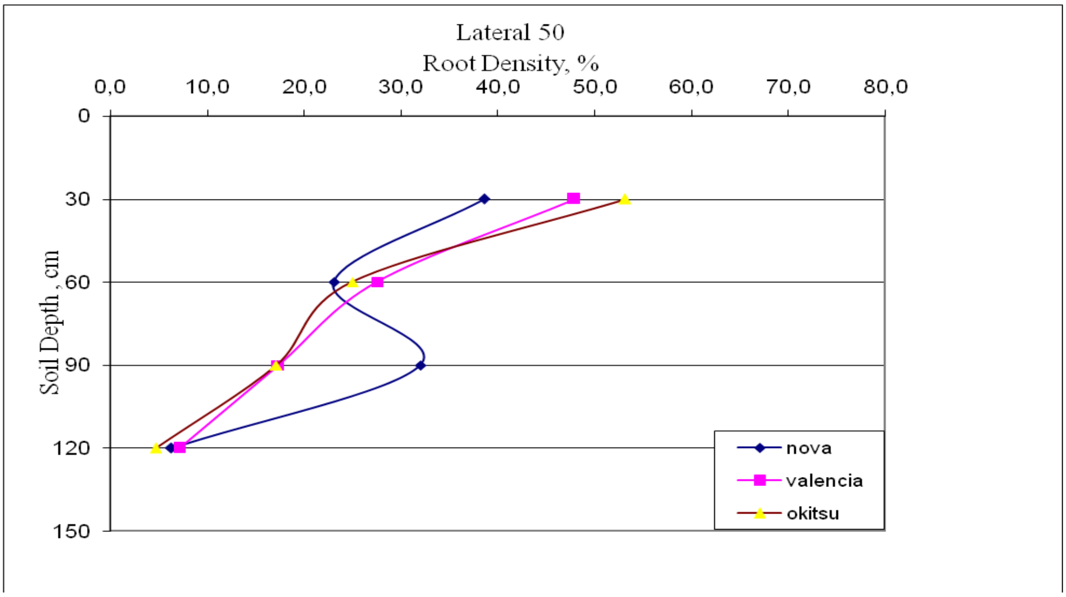

Figure 3. Root distribution according to depths at a distance of 50 cm in the direction of lateral side.

It is seen that the effect of water on the root distribution decreases as it moves away from the trunk and the lateral. When the Figure 4 is examined, it is seen that the roots are collected at the first 30 cm and the density of the roots decreases as the horizon deepens. It is seen that the root distribution of Nova cultivar is different from the other two varieties and the roots are not dense at surface but more uniformly distributed.

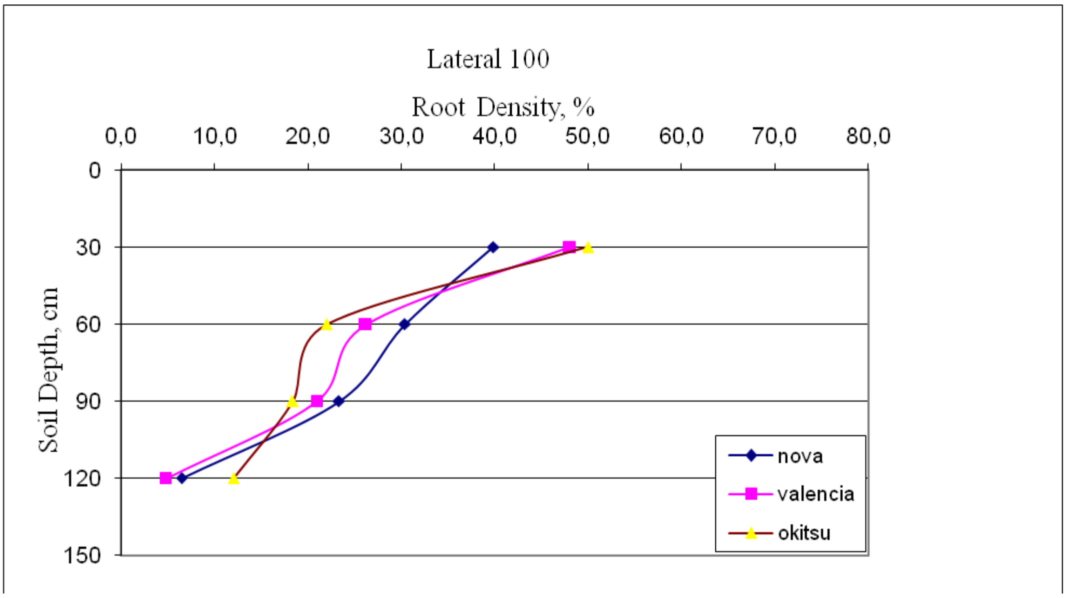

Figure 4. Root distribution according to depths at a distance of 100 cm in the direction that lateral side.

As the non lateral side away from the trunk, the roots showed a more homogeneous distribution. When the Figure 5 is examined, it can be seen that a large part of the roots were located near the surface for all three varieties.

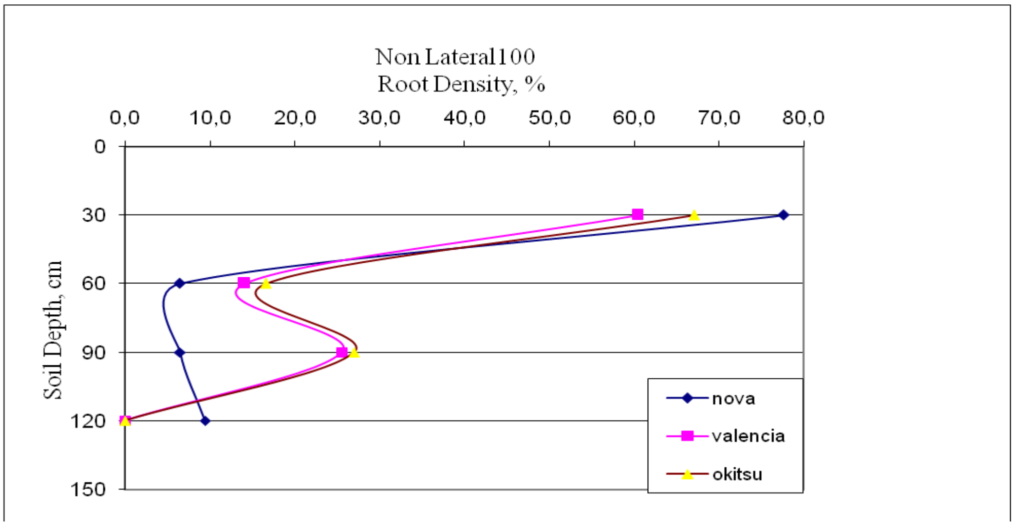

Figure 5. Root distribution relative to depths at a distance of 100 cm in the direction that the non-lateral side.

Juan (1977) stated that, citrus relative root density was decreased under the first 60 cm depth away from the tree trunk. Kanber *et al*. (1996) stated that the root density values obtained in the study decreased as the citrus root density moved away from the tree trunk and deeper in the soil horizon. Berkman (1996) was found that citrus, which is an outgrowth root structure, decreases as the roots move away from the tree trunk and deeper in the soil horizon, and differences in effective root depths occur depending on the water consumption of the grafted species in Karataş region of Adana. Kanber *et al*. (1996) reflect that the use of a single lateral drip irrigation systems and the wetting rate according to the percentage of the cover stated that the insufficient irrigation water is given. Root samples taken from a distance of 50 cm in the direction not exceeding the drip irrigation lateral of the tree trunk were examined and calculated root densities are given in Figure 6. When the root densities of all 3 cultivars in the experiment were examined, a similar root distribution was observed in the varieties of valencia and okitsu in the roots located 50 cm away from the tree trunk, while 70 % of the Nova cultivars were concentrated in the first 30 cm and had a root structure.

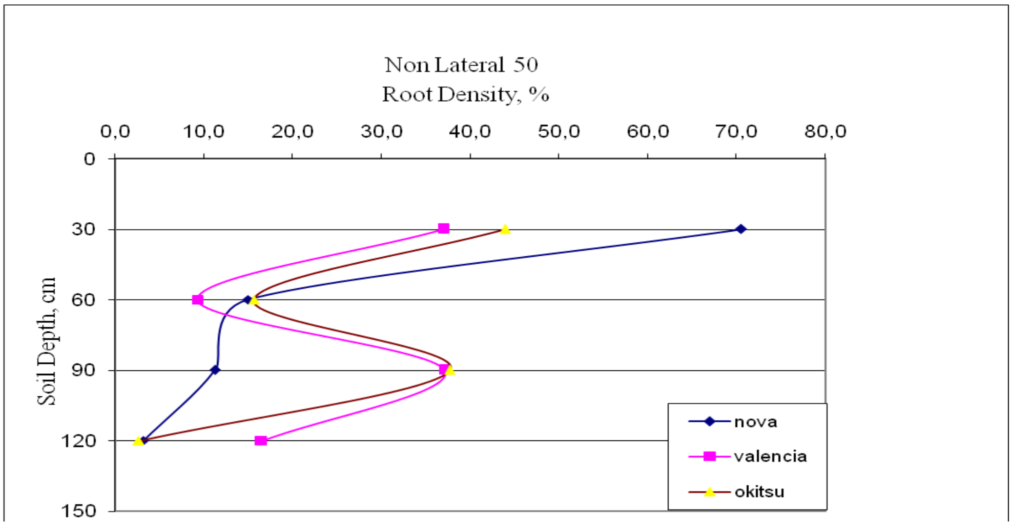

Figure 6 Root distribution relative to depths at a distance of 50 cm in the direction that the non-lateral side.

As the non lateral distance from the tree trunk, the roots showed a closer distribution to the soil surface. When examined in Figure 6, it can be seen that most of the roots of all three varieties are collected near the surface.
According to the results of the analysis of variance to determine the effects of lateral side and variety on plant root density (Table 3) separately, the direction of drip irrigation laterals side on the plant root densities and the varieties had significant effects at 1% significance level.
The results of this variance analysis reflects that the root development has significant differences between the lateral side and non-lateral sides. It also shows that the varieties gave different reactions to root development (Table 4).

Table 3. Root Density of Cultivars (gr/m^3)

		Cultivars			
	Reiteration	Nova	Valencia	Okitsu	**Average**

Total	17	9303804.769		

The aim of this study is to determine the root distribution in citrus orchard planted on the irrigated ridge by drip irrigation method. At the end of the studies, the following results were obtained. Root samples taken 50 cm away from the trunk were examined on the lateral side of the tree trunk. When the root densities of all 3 cultivars in the experiment were examined, a similar root distribution was observed in the varieties of valencia and okitsu in the roots located 50 cm away from the tree trunk , while it was observed that 30% of the roots were located at 90 cm. As a justification for this situation, it can be said that the plots where Nova varieties are used have more frequent irrigation application and this affects root development. When the root densities of all 3 varieties in the experiment in the non lateral side, a similar root distribution was observed in the Valencia and Okitsu varieties in the roots located 50 cm away from the tree trunk while 70% of the Nova cultivars were concentrated in the first 30 cm.
In the study, the root density was found to be higher in all three cultivars in the lateral side. Analysis of variance revealed that the root development showed significant differences between the lateral and non-lateral sides. This can be explained by the fact that the roots are oriented towards the side where they can easily find and use water. When the varieties were examined separately, it was seen that Valencia and Okitsu varieties on the same ridge showed

very similar root distribution. In the same parcel with the lemon variety meyer Nova has been found to have more root distribution. The reason for this is that the water demand of the citrus varieties varies and accordingly the irrigation in this parcel is done according to the lemon variety which has higher Evapotranspiration ET value. Because of this situation, the roots of the Nova variety found in the same parcel as lemon found the water they needed easily in the upper layers of the soil, and showed a more rooted distribution than the other varieties tested. And deep root development can be said to be less compared to Okitsu and Valencia.

Conclusions

It would be a more appropriate approach for irrigation programming and root development if the producers use the varieties with similar water consumption in the same parcels.

Considering that root development is more intense on the lateral side, the producers' use of systems or lateral designs that can supply water to both sides of the tree will provide a more uniform root distribution and the trees will be less affected by the physical damage caused by strong winds due to the developing stronger root structure.

Abstract

Rice crop has an important economic and social value in Portugal, being cultivated under continuous flooding irrigation. Despite the technological advances achieved in the last decades in Portugal, such as the common use of laser precise land leveling, the problems of water management are yet frequent. To cope with the global changes and the raising social pressure to reduce water consumption and the environmental negative impacts, there is an emergent consensus to improve water saving methods and technologies, for water use efficiency and the safeguard environmental quality. A research project into solving this problem is underway. It deals with the evaluation of water saving solutions, and the assessment of agro-economic sustainability. The case studies here reported refer to Lower Mondego Valley and *Lis* Valley Irrigation District, located on Center of Portugal. These perimeters have a Mediterranean Temperate climate, with critical issues such as water scarcity, soil salinization risks, and economic sustainability. The applied methodologies consider: I) Monitoring of the water irrigation use of on-farm systems, both the traditional practices and the newly water saving techniques; II) Evaluation the effect of water saving technologies on cropping system operation; III) Development of performance indicators, to allow the comparison with other regions. The evaluation of the sustainability of rice production will use several data sources with *stakeholders* support, including data collection in field parcels, irrigation district records of crop performance, farmers' questionnaires and interviews, social acceptability, and environmental issues. This communication will present the preliminary results of referred research project, particularly farmers' socioeconomic data.

Keywords: *Rice sustainability, Rice continuous flooding, Rice water saving, Lower Mondego Valley, Lis Valley.*

Introduction

Rice is the most cultivated and the most consumed cereal in the world. Rice crops, together with Wheat and Corn, occupy more than half of the world's agricultural land and, even though rice is neither a staple food nor an important crop in Europe, it has important socio-cultural significance and environmental importance in several European Mediterranean countries. The total area of rice cultivation in the 27 member countries of the European Union (EU) is about 472 thousand hectares, the average annual rice production is about 3.1 million tons and the annual average import of rice is 1,1 million tons. In 2015, the rice-growing cultivated area of Italy and Spain together comprised around 75 % of the total area, *i.e.* around 360 thousand hectares. (Kraehmer et al., 2017). Greece and Portugal account for around 12% of Europe's rice production (Pinto, 2015). The world's demand for milled rice can be expected to rise

from 439 million tons in 2010 to 496 million tons in 2020 (World Atlas, 2019). The annual *per capita* consumption of milled rice ranges from 3.5 to 5.5 kg in non-growing countries of northern Europe to 6-18 kg in southern Europe. Portugal has the highest European *per capita* consumption of rice, which is 17 kg *per* year. This figure, no more than one tenth of the Asian average, far exceeds consumption in other European countries, including Italy (Ricepedia, 2019). To improve rice cultivation and water management, with the aim of improving their competitiveness and environmental sustainability, some Mediterranean countries have joined together in a Prima Program research project, named MEDWATERICE. It deals with the quantification of water use efficiency and environmental, economical, and social sustainability of innovative water saving irrigation options, compared to the traditional flooding irrigation practice. Alternative irrigation techniques to be tested will be selected taking considering the specific characteristics of rice production, on the basis of available data and *stakeholders'* (SHPs) knowledge. A multi-scale – multi-disciplinary and multi-actor – approach is used in the project, which goes beyond the state-of-the-art in five dimensions.
The first ground-breaking objective is methodological: the introduction of participatory action research as innovation strategy in the Mediterranean rice sector. MEDWATERICE will use participatory action research to test non-conventional irrigation-efficient methods tailored to local conditions. Secondly, the project will develop a comprehensive multidisciplinary indicators-based tool to assess the overall sustainability of rice systems at the on-farm and district scales. Production with sustainable methods have the added advantage of being people and planet-friendly and of having greater chance of success and higher prices in the market. Thirdly, MEDWATERICE will build a novel framework for computing effective water efficiency and productivity by up-scaling farm efficiency data to irrigation district scale, in order to prevent fake or rebound effects of water saving measurements. Given that constraints on rice irrigation improvements are often connected to the difficulty to monitor and control irrigation inflows and outflows, the fourth action of the project will use state-of-the-art hydraulics and sensors to monitor and support water saving management practices.
Additionally, this will be a contribution to the implementation of the EU Water Framework Directive whose requirements for all water uses measurements is clearly unfulfilled in the rice sector. Finally, the set of water-saving techniques, proven in the field and ready to be adopted, which the project will produce, is unique in the Mediterranean basin; firstly because of the innovative nature of some of the techniques and secondly because of the methodology and approach to transnational research that will give them unprecedented strength and robustness. To the best of our knowledge, none of these five dimensions have been explored exclusively in Mediterranean rice agroecosystems in order to improve irrigation efficiency and overall sustainability. The development of water management practices as an alternative to continuous flooding is imperative to enhance water use efficiency and safeguard environmental quality in Mediterranean rice agroecosystems. (Masseroni *et al.,* 2017). The agroeconomics study considers the development of a set of indicators, which in turn will allow the comparison of water saving technologies, to assess the evaluation of rice production sustainability. Data collected through farmer's surveys and interviews is analysed and processed. This project meets the recent innovation system PROAKIS (Labarthe, et al, 2014) which stipulates that innovation is set up by stakeholders, including farmers, researchers, advisers, and companies operating in the agricultural and agri-food sector.

Materials and methods

Description of case studies: Lis: Valley Irrigation District and Lower Mondego Valley
The Lis Valley Irrigation District (LVID) is a state initiative, with a total area of about 2000 ha, it is an agricultural perimeter of the Centre of Portugal, located in the municipalities of Leiria and Marinha Grande, whose irrigation and drainage system dates from to 1957. The

main problems of water management in collective irrigation and drainage networks, as well as the field level, are due to the scarcity and poor water quality in the summer, flood risk and poor drainage, and incipient source of hydraulic and hydrological information to support the Lis Valley Water Users Association (ARBVL) planning and operating the network so that optimization of water productivity is achieved, and farmers' income is improved. Under the rural development program, modernization works are planned to transform water distribution networks (in sub-perimeter I, downstream), which will stimulate agricultural development. The dominant LVID soils are modern alluvial soils of high agricultural quality, some subject to poor drainage. The works present defence objectives of the fields through slope collectors, valley drainage and irrigation carried out with the application of several reservoirs from the Lis River and its tributaries (Fig. 1). The Perimeter is structured in seven hydraulic blocks designed according to the logic of the drainage network. The irrigation network comprises 17 dams and 15 pumping stations (PS), collecting water from the Lis, tributaries and drainage ditches, running by water through a gravity network with channel water conduction. The length of the primary irrigation network is 44,5 km; the secondary irrigation network consists of 180 km of small lined or earthen channels. In terms of water distribution, the most important problems are water shortage and poor water quality in the dry summer period, and the absence of automation mechanisms to control water levels in the network channels, leading to malfunctions and high labour load. The Baixo Mondego Irrigation Scheme (Lower Mondego Valley) has an area around 12,000 hectares and is located along the Mondego River valley, from Coimbra to Figueira da Foz. It is 5 km long and 4 km wide. Only 6,538 hectares of the potential irrigated lands are equipped: the secondary Ega and Arunca valleys and Pranto and Cernache streams, on the left bank, as well as river Foja and ribeira de Ançã, on the right bank, still lack infrastructures. The water source is a dam located in Coimbra, out of which a multi-purpose canal was built (for the irrigation of the right bank). The left bank is served by a water main installed along the left stripe irrigation fields. The irrigation scheme is divided into 18 irrigation blocks and, except for São Martinho and São João block, covering 696 hectares near Coimbra, irrigation infrastructures were designed and built for gravity irrigation. The predominant crops are maize and rice, with an area of more than 90%. In the areas of the secondary valleys, these are also the dominant crops, but with greater emphasis on rice. The total number of irrigation plots is around 16,600 and the number of farmers around 2,000. At this stage an inquiry was made, attempting to cover the different typologies of agricultural enterprise This approach allows obtained indicators that are "based on real farm conditions and represent the current agricultural management practices" and capture significant information on impacts on agricultural systems and simplify complex concepts such as sustainability (Dantsis *et al*. 2010)

The survey was conducted in person and at the site of the farms. The survey presented four sets of questions that allow (i) socio-economic characterization of the farmer; ii) characterization of production factors use; iii) optimization of production costs and lastly the characterization of production according to its environmental sustainability, especially in relation fertilizers and pesticides use. The questions were closed, single choice or multiple choice in as many as two possible choices. It attempted to evaluate the degree of satisfaction with the options taken in relation to certification mechanisms and commercialization channels. The concern with agrienvironmental issues was also evaluated. Some results are present in this paper.

Results and discussion

The survey was carried out in June 2019 in the *Mondego* Valley with a total of 34 surveys (20% of rice farmers in the Mondego Valley). These farmers hold 767 hectares (42% of the total rice area in the Mondego Valley). SPSS 25 software was used to analyse the data. The correlation between the coefficient of Pearson (r) and Spearman's coefficient (ró) was used to measure the strength of the association between the variables. According to the production area four farmer/producer classes may be considered. (Table 1)

Table 1 – Categorization of sample and farmers population in relation to production areas

Hectares	Farmers Survey		Rice Farmer		representative sample
	Number	%	Number	%	%
≤6,30	5	14.7	103	14.7	4.9
≥6.31 and ≤ 22,60	16	47.1	52	47.1	30,8
≥22,61 –and ≤ 38,80	5	23.5	8	23.5	62.5
≥38.81	5	14.7	11	14.7	45.5
Total	34	100	174	100	19.5

The study carried out with rice producers, has showed 82.4% of the interviewees are full-time farmers, 2.9% are part-time farmers and 14.7% are retirees from farming or other economic activities. Around 32.4% of the respondents are between 20 and 40 years old and 26,6% are over 60 years old; 62% had access up to the ninth year of schooling, while 26,5% have a higher education degree All farmers apply integrated production methods. When compared to national results, these values are better in terms of both farmers' age and at educational level. National average show 71.4% of the farmers hold basic education and only 5.8% possess higher education; in terms of age at national level, 54.6% are ≥65 years old (INE, 2017). There was a weak correlation which is significant at 5% or 1% of level of significance between the relevance of the agricultural activity and farmers educational level and age. For younger farmers, agriculture becomes more important as a main activity; they have a higher education level, but there is no correlation between the characteristics of the farmer and the size of the farm. Access to land is an important issue for generational turnover (Table 2).

About 77% of the surveyed area is occupied by Carolino rice (Oryza L, subspecies Japónica), Ariete cultivar. Although the European Commission recognized the name "Arroz Carolino do Baixo Mondego" as a Protected Geographical Indication (PGI) in 2015, none of the respondents stated having the PGI certification. All respondents applied for agricultural support (within the Rural Development Program), over the past ten years. There were three measures respondents did not apply to. Applicants degree of satisfaction concerning the results of the applications and their development is high and they feel satisfied or more than satisfied with the progress of the measures on their farms (Table 3)

Table 3 – Application for RDP measures over the past ten years and satisfaction degree

Partly Satisfied	9,1								3,0
Satisfied	66,7	28,6	38,2		32,3			12,5	42,4
More than Satisfied	21,2	71,4	44,1		48,4			75,0	42,4
Very Satisfied	3,0		17,6		19,4			12,5	12,1

All respondents want to continue farming in the next two years. Respondents could choose at most two main reasons for continuing agricultural activity. Economic viability and family income complement represented 24.3% of the responses, respectively, but 21.6% answered that agricultural activity would continue because of the lack of economic alternatives. Concerning rice cultivation, only one respondent (2.7%) answered he does not intend to keep producing rice because of the lack of economic viability of the crop. About 89,2% want to continue producing rice, and 45.5% said they keep growing this crop because alternative uses for their land are not available. About 24.2% consider that knowledge of the crop characteristics was an important factor to continue growing rice and 21.2% consider that rice economic viability justifies the option to go on growing rice. Considering marketing channels used by farmers, only one farmer sells 80% of his products to retail, under his own brand name, and the remaining 20% are sold to industry. About 59% of the farmers sell their yield directly to industry, and about 29% sell their production to the Montemor-o-Velho Cooperative. Only three producers use two marketing channels simultaneously. Thirty-two respondents (94%) answered the question concerning the commercialization channel which allowed the choice of two options, having provided 55 responses. About 22% of the respondents have chosen a marketing channel due to "production flow ease", and 20% have done it because they have no processing capability. About 16% have chosen the option "guarantee production output", and 15% have chosen "price stability". The options "best price" and "fastest payment" have been chosen by 13% and 11% of the respondents, respectively. Only two interviewees (4%) have chosen the channel because of the support given to production. These preliminary results of the survey demonstrate that rice cultivation is done by farmers with both knowledge in the area and skills to use community and national support measures. More data have been obtained to allow the development of socio-economic and quantifiable indicators of the environmental sustainability of agriculture (Reytar *et al.*, 2014). Studies are being conducted in different areas of the world to study alternatives to rice production systems with the aim of increasing productivity, net income and at the same time reduce environmental impacts (Sita and Ponnarasi, 2009**)**. The sixth task, fundamental to deal with knowledge transfer and innovation, is being carried out.

Conclusions

Among the numerous problems Mediterranean rice agroecosystems are currently facing, sustainability is of utmost importance and a great challenge. Due to drivers such as climate change, population growth, increasing concern of civil society towards environmental impacts of human activities, there is pressure on the rice production sector to reduce water consumption and minimise environmental impacts (OECD, 1993). At the same time, rice is a strategic production for food security, a nutritional alternative to wheat, and an important economic exchange-earning agricultural product. Therefore, there is great pressure to increase rice production within the Mediterranean basin, but these pressures have not changed much the state of rice production yet; continuous flooding is still predominant. So far, results have shown a dynamic sector in need of options to deal with new challenges, such as consumer perception of water use in agriculture and profitability increase generated by inputs efficiency boosting. The interest of this project is observable in the support farmers and Water Users Association have provided to the development of the work, which is a key indicator of the need for applied research to the business sector in which it operates.

Abstract

The quality of life on Earth in the future will largely depend on the amount of safe water. Any use of water from numerous sources for different purposes, leads to negative changes in its physical, chemical and biological characteristics, resulting in the formation of wastewater in many forms, as industrial, communal, agricultural or rain. This type of water should be collected, and purified using efficient and economical cost-effective technology, or otherwise pose a serious environmental problem. In order to stop this trend, a large number of countries are undertaking extensive measures and invests large resources in order to stop water pollution and return pure, unpolluted water to nature. In this paper, possible biological procedures for purification of the Ada Huja Lagoon Belgrade, using microorganisms from the genus *Bacillus*, are presented. The Laguna Ada Huja is the recipient of all the listed types of wastewater and as such represents a serious environmental problem. The experiment was performed in laboratory controlled conditions using two different doses of microorganisms. Measurements of essential parameters (pH value, Ammonium ion, Nitrites, Nitrates, Consumption of $KMnO_4$, Chemical consumption of oxygen, Biochemical consumption of oxygen (BPK), Total organic carbon (TOC)) were performed for 1, 15 and 60 days from wastewater treatment. It has been found that proposed technology, a mixture of heterotrophic, aerobic and optional anaerobic microorganisms produces extracellular enzymes for increased degradation of organic compounds in aforementioned environmental conditions. The use of these microorganisms leads to a decrease of the wastewater BOD/COD content, in addition, it reduces the amount of waste suspensions, reduces the filamentous bacterial reduction of the sludge population, and improves the characteristic of deposits, and therefore wastewater meets the regulated boundaries of the outflows and discharges into the watercourses.

Keywords: *wastewater treatment, lagoons, channels, environmental protection, microorganisms.*

Introduction

Municipal wastewater from industry is a major source of pollution in all environments. Municipal wastewater untreated by any technology (mechanical, chemical, biological), directly discharged into watercourses causes pollution of surface and groundwater as well as soil. The biological treatment of industrial and domestic wastew-ater is an important biotechnological application, constituting amultibillion-dollar global industry. When microbial populationsare enhanced in wastewater treatment systems, their benefi-cial activities result in the efficient removal of organic matter,toxic substances, nutrients and pathogens (Wang *et al.*, 2012). Despite the economic and environmental importance of these processes, understanding of the microbial communities existing in wastewater treatment plants and their potential for continued use is still limited, especially in developing countries. Bacteria are important contributors to the transformation of complex organic compounds in

wastewatertreatment systems and are essential for the optimal operation andpreservation of biological treatment systems (Moura *et al.*, 2009).
Special interest has been placed treat wastew-aters with high levels of organic pollutants in the form of fats, oilsand greases (FOG), since the removal of these substances repre-sents an important wastewater treatment challenge at a globallevel (Facchin *et al.*, 2013).
Several techniques involving microorganisms have been complemented in complementary treatment systems to processwastewater with high FOG content. These techniques have used enzyme extracts of pure cultures obtained by solid state fermentation of agro-industrial residues (Leal *et al.*, 2002) or active consortia grown in the wastewater to be treated (Fadile *et al.*, 2011).
Previously, Bacillus sp. has been described as a novel strain with a good performance of nitrogen removal. For example, Bacillus sp. LY was isolated from the membrane bioreactor system in which the efficiency of TN removal was up to 80%. After 24-day incubation, the removal efficiency of COD by Bacillus sp. LY was 71.7%. It also can denitrify nitrate while nitrifying (Lin *et al.*, 2007). The Bacillus sp. strain YX-6 is highly effective in removing nitrite. It could degrade the nitrite nitrogen (nitrite-N) from 10 mg/L to zero in 14 h and the nitrite-N degradation rate was approximately to 100% at the DO concentration of 5.2–5.8 mg/L (Song *et al.*, 2011.
Nitrogen has become a key factor leading to the eutrophication of receiving waters. Accordingly, in order to reduce its discharge, increasingly stringent environmental regulations are carried out, under which circumstance it is urgent to create a novel technological solution to improve nitrogen removal. As a fact, many solutions such as physical, chemical and biological methods have been applied widely, among which biological methods seem to be more promising for some advantages. It is well known that conventional nitrogen removal is composed of two steps: (1) nitrification by autotrophs under aerobic conditions and (2) denitrification by heterotrophs under anaerobic conditions. As such, this technology usually requires extra facilities and land, resulting in high costs of treatment. Thus, it is especially necessary to explore more cost-efficient and less land-occupied technology to remove nitrogen from wastewater. Simultaneous nitrification and denitrification (SND) might be an alternative, and a variety of microorganisms have an ability of SND like Acinetobacter calcoaceticus (Zhao *et al.*, 2010), Pseudomonas stutzeri (Zhang *et al.*, 2011), Halomonas campisalis (Guo et al., 2013).
This study aimed to determine whether bioaggregation with the strain Bacillus sp. and enzymes could successfully improve the removal of nitrogen, organic matter, under laboratory conditions. Attention was focused on the stability and efficacy of microorganisms in such an environment and on detecting the possible path of transformation of the present nitrogen compounds based on the measured data (pH, Ammonium ion, Nitrites, Nitrates, Consumption of KMnO4, Chemical oxygen consumption, Biochemical oxygen consumption (BOD 5), Total organic carbon (TOC). This study is of great importance to investigate the potential application of strains of microorganisms and enzymes and to establish an effective wastewater treatment system in lagoons and lakes.

Material and Methods

The Danube lagoon "ADA HUJA", Belgrade represents a water habitat of about 30 ha, which in the past few years has been the wastewater collector of the Mirjevski Potok. For many years, the lagoon was transformed into a fecal recipient. Samples of 50 l wastewater were taken from the most contaminated part of the lagoon (X 44o 49 "10.41" "Y 20o 31" 14.75 "" Z 69 m) for laboratory investigation. Homogenization (obtaining a representative sample) of the waste water samples "NULTI-Control sample" was performed under laboratory conditions. Experiments are performed in plastic buckets with a volume of 10 liters, with the following variants: 1. Control (untreated sample), 2. Variants 1 - treated wastewater sample with lower dose, optimal condition, 3. Variants 2 - treated wastewater sample with higher dose. Samples were left for two days under laboratory conditions to stabilize the optimum wastewater temperature for microorganisms (Bacillus sp) and enzymes: 22-25 ^{o}C. Wastewater quality was controled and monitored by measuring pH value, ammonium ion content, nitrite content, nitrate content, potassium permanganate consumption, chemical oxygen demand (HPK), biochemical oxygen consumption (BOD 5), total organic carbon (TOC). Controling was done at two time intervals of 15 and 60 days from biological treatment. Catalysts were added to maintain the optimal C: N: P ratio.

Results and Discussion

The chemical and biochemical changes of the untreated wastewater sample (Control) as well as the changes that occurred after the treatment of the wastewater with two different dose-variants are shown in Table 1.

According to results, it can be concluded that the Ada Huja is seriously endangered area and due to it cannot be used in the purpose as an Eco Zone for sports, recreation, rehabilitation and business.

The wastewater pH in the Control sample showed increased value and increases from 7.6 to 7.9 after 60 days. In the treated samples the pH value decreases from 7.7 to 7.6 in the first 15 days and from 7.1 to 7.2 after 60 days.

The average concentration of ammonia nitrogen in the control sample is 32.36 mg N / l which is significantly higher than legal values for V class water (1.5 mg N / l). After biological treatment of wastewater, there was an increase in the content of ammonia nitrogen due to both: bio-enzymatic activity and partially added catalysts, nitrogen-phosphate compounds for biological activation of microorganisms.

The concentration of mineral forms of nitrogen is low in the control sample of wastewater, so that it can be classify to the first class. In the first 15 days of biological treatment the NO_2 and NO_3 content decreases and after 60 days significantly increases.

The chemical oxygen consumption values of HPK-Kubel ($KMnO_4$ consumption) in the control sample are very high. The maximum measured value in the sample "Control 60" was 1286.5 mg / l, which belongs to the V class (Legislation 50/12), ie. corresponds to "very poor ecological quality" and that kind of waters cannot be used for any purpose. After biological treatment of wastewater, after 15 days, there was a significant decrease in chemical oxygen consumption by 6.3-7 times depending on the treatment procedure.

A high concentration of fresh organic matter in wastewater causes high HPC values. The average HPK value in the control sample of the Ada Huja lagoon is significantly higher than the HPK value defined by Class V wastewater (> 125 mg / l), indicating a significant degree of pollution of the lagoon. Concentrations of organic matter, expressed through the chemical oxygen cosumption, are very high for this type of surface water. Based on the classification (Legislation 50/12), water from the Ada Huja lagoon corresponds to a very poor ecological status and cannot be used for irrigation and industrial use as well as for its proposed purpose. After biological treatment of wastewater, there was a significant decrease in HPC values by 6.1 - 7.8 times depending on the treatment variant. HPK value decreases from 1760 mg / l to 226-289 mg / l after 15 days of treatment in Variants 1/15 and 2/15 and after 60 days of biological treatment there is significant decreasing of HPK value.

Tabela 1. Wastewater characteristic before treatment, and 15 i 30 days after treatment

Sample	pH value	Amonijum jon (NH_4)-N (mg/l)	NitritsNO_2^- -N (mg/l)	Nitrats NO_3^- -N (mg/l)	Cosumption $KMnO_4$ (mg/l)	Chemical oxigen cosumption $(K_2Cr_2O_7)$ O_2	Biochemical oxigen cosumption BPK_5 (mg/l)	Total organic carbonTOC (mg O_2 /l)
Control	7,7	32,36	0,024	0,23	1111,6	1760	1376,8	64,6
Variant1/15	7,6	40,2	0,011	0,23	158,1	226	11,2	28,8
Variant2/15	7,6	37,8	0,031	0,19	176,7	289	22,3	34,1
Control (60)	7,9	1,19	0,025	0,48	1286,5	1430	221,9	22,57
Variant 1/60	7,1	37,04	0,38	1,6	179,8	220	27,4	15,9
Variant2/60	7,2	37,34	0,27	1,68	148,8	239	42,8	21,25

The content of organic matter expressed through BOD-5 are very high (1376.8 mg O2 / l) for surface water in the control sample, indicating a high content of organic matter and pollution. The average value of BOD-5 in water from the Ada Huja lagoon is much higher than the value defined by the legislation for Class V. Water with an organic matter content of BOD-5 greater than 25 mg O_2 / L cannot be used for bathing and recreation and "cannot be used for any purpose" (Legislation 50/12). After biological treatment of wastewater, there was a significant decrease in BOD-5 depending of the treatment variant ie. from 1376.8 mg O_2 / l to 11.2-22.3 mg O2 / l after 15 days in Variants 1/15 and 2/15. Also, a decrease in BOD-5 was observed in the experimental variants (Variant 1/60, Variant 2/60) after 60 days.

The presence of biodegradable substances in wastewater is manifested by higher levels of COD relative to BOD. Biodegradable organic substances include: cellulose, coal dust, lignin, tannin and other synthetic organic compounds. HPC is always greater than or equal to BOD in lagoons, lakes and rivers. The HPK / BOD5 ratio is a characteristic of individual wastewater and their quality can be defined by this ratio.

The total TOC in the wastewater control sample is higher than defined value for the V surface water class (> 50 mg / l), ie. is 64.6 mg / l. After biological treatment of the wastewater from the Ada Huja lagoon, the organic carbon content was reduced to 28.8 mg / l in 1/15 variant and to 34.1 mg / l in 2/15 variant after 15 days. After 60 days in treatment variants 1/60 and 2/60, there was also a decrease in TOC content relative to control sample 60.

Additionally, organoleptic characterization (color, odor) was carried out. Based on this it was concluded that the effect of microorganisms usage was achieved, Figure 1.

Figure 1. Wastewater samples: ADA HUJA, 1-Variant 2/60, 2-Variant 1/60, 3-Control 60.

Conclusions

The applied technology represents application of unique bacterial *Bacillus* strains that increase the degradation of complex organic compounds into simpler compounds by the hydrolysis process. Used *Bacillus sp*. for verification of technology is formulated with four major enzymes that are important for the degradation of complex organic matter: Amylase, Protease, Cellulase, Lipase. Catalysts are defined as substances, food for microorganisms, which will accelerate or change the speed of reactions. Used *Bacillus sp*. is an advanced mixture of heterotrophic, aerobic and facultative anaerobic microorganisms known for production of extracellular enzymes for increased degradation of organic compounds. Purified bacterial strains and enzymes result in non-pathogenic, non-toxic and non-corrosive formulations.

Abstract

An aim of this article is to assess the process of biological waste management from households in Małopolska voivodship. Households are a source of waste biomass, which can be used, inter alia, as a raw material for energy and for agricultural purposes. The use of this biomass is part of the implementation of sustainable development goals, which tools are the bioeconomy and the circular economy. Households are a source of two types of waste biomass: food waste and sewage. Food waste is a particular problem, as 9 mln tons of food is being wasted in Poland and about third part is being wasted by the consumers. To examine Malopolska inhabitants regarding their attitude towards the food waste and waste segregation we run a survey. The results of this research revealed that Malopolska did not differ from the consumers of other developed countries. As many as 57% of respondents declared that they were throwing away bread; 54.5% vegetables and fruit. There were noted some differences of consumers behaviour, depending on the population groups of women and men as well as residents of villages and cities. Regarding the segregation of a waste, only 21.6% of respondents confirmed that they always segregated the waste. Among conscientiously segregating, there were more women than men and more inhabitants of rural areas then small towns. The second source of biomass generated by households is a sewage. The processing of the sewage and its purification by the Wastewater Treatment Plants is a source sewage bio-sludge. It is a problematic material, but can be potentially valuable due to the high phosphors content. However, in Małopolska, the infrastructure for using the biomass is developing, but not fast enough in a context of constantly growing amount of waste and not in a direction of achieving maximum value from the biomass.

Keywords: *food waste, bioeconomy, biowaste, Malopolska Voivodship*

Introduction

The purpose of the paper is to assess the process of management of biological waste from households in the Małopolska region. In 2016, the European Union generated 482 kg of waste per person, of which an average of 47% was in a subject of a circular economy, and 25% went to landfills. In Poland, these values were 307, 44% and 37%, respectively, which is a very poor result in comparison with countries such as Denmark, Sweden, Belgium, Germany or the Netherlands, where only 1% of waste is landfilled. The increase in the amount of waste is a result of the exploitation of raw materials, and it is in close relation with the growth of the world's population, the enrichment of societies and related changes in the consumption model (Kowalska *et al*., 2016), and has become a serious environmental threat enforcing a question about the efficiency of resource usage. Despite some initiatives related to the transformation concerning circular economy, in a global perspective, the dominant model is still linear economy, fed by a huge mass of raw materials to satisfy the ever-growing consumption (McDowall *et al.,* 2017). It is also worrying that 70% of the world's waste generated is not recovered or recycled in any way, by being directed to landfills (Tisserant *et al.*, 2017), what is not compatible with the policy promoted by the European Commission on circular economy and product life extension. This approach leads to a number of environmental problems and a significant burden on consumers' budgets. An important fraction of municipal waste is biodegradable waste. This fraction is a heterogeneous group, which includes kitchen waste, food remains, as well as waste from parks and gardens. Food waste offers a large reuse potential, especially in the paradigm of bioeconomy (Priefer *et al.,* 2016), has a significant share in this group. The second group of bio-waste is municipal sewage sludge (MSS).

Materials and Methods

The article uses primary data from surveys and data from biological waste management databases. The analysis apples to the area of the Małopolskie Voivodeship. A survey questionnaire (n=384) was used to investigate the behaviour and attitudes of the inhabitants of Małopolska in terms of food waste and waste segregation. The survey was carried out in 2018. The questionnaire consisted of 17 closed questions. The results of the questionnaires were analysed by gender and place of residence. The survey covered the frequency of food disposal by product category and the respondents' attitude to waste segregation. An analysis of documentation concerning the procedure of MMS handling and the organic fraction of municipal waste was also carried out.

Results and Discussion

The level of food waste in Poland is one of the highest in Europe. 42% of Poles admit to throwing away food, most often bread (49%), fruit (46%), cold meats (45%), vegetables (37%) (Food Banks, 2018). Among the respondents, the most wasted food products were bread (57%), and fruit and vegetables (54.5%). The least wasted articles were dairy products and eggs, which coincided with the conclusions of the national research. The analysis taking into account the gender of respondents shown that women more often threw away outdated and spoiled foods in all the categories considered. This can be linked to the still existing division of social roles of women and men in households, where women are primarily responsible for decisions related to the nutrition of household members.

Table 1. Food wastage (in %) by gender.

Details	Women		Men		In total	
	YES	NO	YES	NO	YES	NO
Meat and sausages	48,1	51,9	38,3	61,7	45,1	54,9
Dairy products and eggs	40,4	59,6	33,9	66,1	38,4	61,6
Bread	61,5	38,5	47,8	52,2	57,3	42,7
Fruits and/or vegetables	56,9	43,1	48,7	51,3	54,4	45,6
Other products	49,2	50,8	47,8	52,2	48,8	51,2

Source: Own development, on the basis of research conducted.

Similar conclusions are presented by Visschers *et al*., (2016). Other studies (Koivupuro *et al*., 2012**;** Silvennoinen *et al*., 2014) show a correlation between women's responsibility for food shopping and higher levels of food wastage. However, Secondi *et al*., (2015) presents a conclusion to the contrary, showing that at the level of EU farms, it is men who waste food more often.The origin of respondents had some importance in terms of the category of foods disposed of. Among Małopolska residents from rural areas, slightly less dairy products, eggs, bread, fruit and vegetables were wasted (Table 2). This may be related to different consumer preferences, satisfying nutrition needs with own produce, or feeding farm animals with waste food.

Table 2. Food waste (expressed in %) by origin of respondents.

Details	Large city		Medium city		Small city		Village	
	YES	NO	YES	NO	YES	NO	YES	NO
Meat and sausages	52,7	47,3	34,8	65,2	46,0	54,0	41,3	58,7
Dairy products and eggs	42,6	57,4	41,3	58,7	38,0	62,0	34,0	66,0
Bread	56,6	43,4	71,7	28,3	56,0	44,0	54,0	46,0
Fruits and/or vegetables	58,1	41,9	63,0	37,0	52,0	48,0	49,3	50,7
Other products	49,6	50,4	43,5	56,5	50,0	50,0	49,3	50,7

Source: Own development on the basis of research conducted.

The respondents were also asked about waste segregation (Table 3). As regards the segregation of municipal waste, only 21.6% of respondents confirmed that they always segregate waste (Table 4). Among those who conscientiously segregated waste, women outnumbered men quite considerably (77.7% vs. 60.9%). The largest number of respondents segregated waste in villages and medium-sized towns, while the smallest number of respondents segregated in small towns.

Table 3. Segregation and recycling of municipal waste in households (expressed in %).

Source: Own development on the basis of research conducted

Village residents were more likely to segregate waste than residents in cities with a population exceeding 100,000. This can be attributed to a functioning system of segregated municipal waste collection (especially paper, glass, plastics and metals), which has been solved quite well with respect to single-family housing, as opposed to multi-family housing estates in large cities. In Małopolska, in 2014, there were 115 PSCMW (Points of Selective Collection of Municipal Waste), in the region in 2017 – there were 122 points where selectively collected municipal waste is accepted (SP, 2017).

Table 4. Segregation and recycling of municipal waste in households (expressed in %) by the origin of respondents.

IN TOTAL	100,0	100,0	100,0	100,0

Source: Own development on the basis of research conducted

The research indicates that the model of behaviour of the Małopolska population in terms of food waste and waste segregation does not differ significantly from the behaviour of inhabitants of other regions of Poland. The results obtained are consistent with the conclusions of the KPGO (2016).

Until recently, most of the waste produced on farms was sent to landfills. Only in 2016, almost 1 million tons of municipal waste was collected from the Małopolskie Voivodeship. The direction of waste management generated by inhabitants from Małopolska region, which is developing dynamically, is the thermal recovery of energy (369 thousand tons). In addition to incineration plants, there are a number of installations for processing organic fraction waste in the region. According to data from SP (2017), the following operated in Małopolskie Voivodeship: 16 MBP installations (mechanical and biological process), where waste is processed mechanically; 17 composting plants, with an annual capacity estimated at 118.000 tonnes; 11 installations for the storage of waste generated in the MBP process, and residues from the sorting of municipal waste – 213.800 tonnes in total; and the rest was recycled (295.900 tonnes). Apart from municipal waste increase, the mass of municipal sewage sludge is constantly growing, and its proper management becomes a challenge not only in the Małopolskie Voivodeship. This is related to the dynamic growth of the population's access to the sewage network. In 2017, over 2.8 million inhabitants of the region used sewage systems (SP, 2017). Similarly, the length of the sewage network for the years of 2012-2017 increased by 39% (from just over 18.000 km to 20.500 km), while the population of Małopolska increased by only 3.2% at the same time. Consequently, only in 2017, 113435 dm^3 of municipal wastewater was discharged. As a result of their treatment, more than 51.000 tonnes of sewage sludge were generated. The largest sewage treatment plant operating in the Voivodship (Kraków Płaszów) operates a mono-combustion plant for sewage sludge with a nominal capacity of 23.000 tonnes of dry matter (d.m.) per year. To a certain extent, it guarantees the management of this fraction of organic waste generated from urban wastewater from Kraków. The remainder of sludge from the Voivodship was stored (2.1 thousand tons), used in agriculture, and to cultivate composting plants (11.5 thousand tons), and over 20 thousand tons was managed in a different, unrecorded manner.

Conclusions

The research confirmed that the residents of Małopolska are in line with the global trend of developed economies and the waste food level is high. At the same time, consumers are not ready to segregate waste, which means that some valuable raw materials, including biomass, are not fully segregated, and end up in mixed municipal waste. Significant amount of organic waste does not fulfil its potential in the circular economy model, going to landfills or incineration plants. Low environmental awareness is a barrier to the implementation of bio-management and circular economy solutions. Legislation which tries to force separate collection of organic fraction and its proper management is equally important. At the same time the existing landfill system fees does not motivate the commune and its subordinate entities responsible for municipal waste management to use other methods than landfilling. There are also infrastructural obstacles - in terms of municipal waste, there is still not enough infrastructure to manage it. From almost 1 million tonnes of waste in Małopolska Voivodeship, 213.000 were disposed of in landfills (over 20%). At the same time, over 369 000 tonnes were subjected to thermal transformation. Thus, about 50% of municipal waste is incinerated and stored.

Thanks to the development of water and sewage infrastructure in Małopolska, the amount of treated sewage and the municipal sewage sludge (MMS) volume is growing. Thermal transformation (mono-incineration or co-incineration) is becoming an increasingly important method of its management. The operation of sludge incineration plants, apart from numerous MBP installations or composting plants, allows for partial management of this type of waste generated by the inhabitants of cities and villages of the Małopolska. It should be added, that not all water and sewage companies, especially those with a small number of population equivalent, are able to finance the operation of the MMS management system on their own. Moreover, the data quoted above show that still, a disturbingly large volumes of sludge are landfilled.

Abstract

Soil nitrogen (N) is important macronutrient for plant growth and productivity. The aim of this paper was to examine the overload of the soil with easily available nitrogen on the territory of the Nis city (Serbia) in 2015 and 2016. Totally 6523 samples from 1219 farms were collected (4669 samples from 862 farms in 2015 and 1854 samples from 357 farms in 2016). The analysis showed that the soil of this area is medium provided with nitrogen. In 2015: 82% of samples belonged to the class of medium supplied and 13.8% were class of rich soil with nitrogen, while in 2016: 89.1% samples belonged to the class of medium supplied and 9.1% were class of rich soil with nitrogen. The percentage of nitrogen was determined from the percentage of humus, while the humus content was determined using the Tyurin method. Soil samples were taken from a depth of 0-30 cm in field crops and vegetables, and 0-60 cm in orchards and vineyards. According to the results of the research, the soil on the territory of the city of Nis is moderate-supplied by nitrogen. Certainly, it is highly recommendable to analyze the soil in order to be informed about the content of nitrogen which is necessary to all producers. Research data processing was performed by using a mathematical-statistical method in the computer program SPSS – Trial version (Statistical Package for the Social Sciences).

Keywords: *Nitrogen, Soil, Serbia.*

Introduction

Nitrogen (N), of all macronutrients, mostly affects the yield and quality of plant products. Despite the fact that nitrogen is mostly present in the air (N_2=78%), plants draw (assimilate) nitrogen from the soil. Nitrogen in the soil is found in the organic form (humus) in the amount of over 97% and in the inorganic (mineral) form (ammonia and nitrate), which is accessible to plants (2-3%). In nature, there is the nitrogen cycle, where Earth's atmosphere is the source, the transformation into soil nitrogen is performed by microorganisms in the process of nitrogen fixation. Nitrogen is introduced into the soil by fertilizing, as well.

Nitrogen originates from Earth's atmosphere (N_2), but is assimilated in the mineral form, therefore it belongs to mineral elements. In order to transform the molecular form of nitrogen (N_2) into ammonia (NH_3) and nitrate ($NO^-{}_3$), in which form plants assimilate it, energy is needed. In contrast, nitrogen is very easily returned to the molecular state, in which it is most stable, so it is easily lost from the soil. Nitrogen can be in the organic form and in the inorganic form. The organic form of nitrogen in the soil is humus and partially decomposed plant and animal remains. The mineral (inorganic) part of nitrogen in the soil is NH_4^+ (ammonium ion) and NO_3^- (nitrate ion), which is completely available for plant assimilation, only a small part (2-10%) of total nitrogen is in the soil. This quantity is generally insufficient for good nutrition of agricultural plant species (Jelić, 2012; Gudžić, 2015; Predić, 2011).

Soil microorganisms play a key role in the creation and maintenance of soil fertility. Microorganisms are indispensable members of all life functions; they are key to maintaining

the circulation of matter on Earth. In addition to azotofixators, which return nitrogen from the atmosphere to the soil, microorganisms mobilize phosphorus, potassium, iron and sulfur, making them available to plants (Ilić, 2016).
This study presents the results of the nitrogen content in the soil in the territory (567 km²) of the municipality of Niš (Republic of Serbia); coordinates of the municipality of Niš are 43°19′29″N and 21°54′11″E.

Materials and Methods

The research was carried out during 2015 and 2016. Humus (%) from the soil was determined by the Kotzmann method, and nitrogen (%) was calculated from the humus. The humus calculation method was: % N = % humus x 0.05. The mean pH of the soil in the research area was 6.48. The objective of this paper was to examine the content of nitrogen in the research area, which was the municipality of Niš, as well as to point out the importance of the optimal nitrogen content in the soil for plant production and the ecosystem. The mean annual temperature in the territory of the municipality of Niš in 2015 and 2016 was over 12°C, and the annual precipitation in both years was around 630 mm (Republic Hydrometeorological Service of Serbia, 2016, Republic Hydrometeorological Service of Serbia, 2017). By quantifying the impact of climate changes on plant production, making long-term plans in agricultural production is facilitated (Jančić, 2015). There are several methods for the determination of humus, and what all the methods have in common is the action of strong oxidants on organic matter, which leads to the oxidation of carbon (C) from humus (Grčak *et al*, 201).The research was carried out as a long-term stationary field experiment of the Institute of Field and Vegetable Crops in Srbobran, Serbia, in the period from 1996 to 1999, on the soil type carbonate chernozem. The paper examines the influence of increasing nitrogen doses (control group: 40 kg N ha^{-1}; 80 kg N ha^{-1} and 120 kg N ha^{-1}) on the yield of six inbred corn lines belonging to different FAO groups of ripening (L1-FAO 300, L2-FAO 400, L3-FAO 400, L4-FAO 600, L5-FAO 600, L6-FAO 600). Nitrogen fertilization showed a significant positive effect on the crop yield of corn lines. The crop yield depended on the line and year of research. On average, for all four years of research and all lines, the yield increase in the variant where 40 kg N ha^{-1} was applied amounted to 13.7% compared to the control group, in the variant where 80 kg N ha^{-1} was applied 18.7 %, and in the variant where 120 kg N ha^{-1} was applied 23.6%. The yield decrease in the non-fertilized variant also depended on the plant species, e.g. the yield decrease in barley was 49%, while there was only 10% of reduced yield in maize. Theoretically, the maximum yield of 4.91 t ha^{-1} is achieved at a quantity of 114 kg N ha^{-1} (Marinković et al., 2010). Assimilation of nitrogen also depends on the content of heavy metals in the soil (Župunski, 2017). In the turnover of nitrogen in plants, the release of nitrogenous compounds into the environment has an important role. One of the types of nitrogen release is volatilization of reduced and oxidized forms of nitrogen through the above-ground organs. Depending on plant species, genotypes and ecological conditions, through volatilization, plants can release, during vegetation, a significant part of the assimilated amount of nitrogen, and up to 80 kg of ammonia/ha. Plants, in addition to releasing ammonia into the atmosphere, simultaneously assimilate it from the atmosphere, and partly compensate for the loss caused by volatilization. The loss of nitrogen caused by volatization can be reduced by breeding. There are attempts to reduce the volatization of nitrogen compounds from above-ground plant organs by using physiologically active substances (Kastori, 2004).The effect of long-term harvesting of crop residues in combination with growing nitrogen (N) doses on the yield of two varieties of winter wheat in a four-year period has shown a significant increase in wheat yields. Long-term harvesting of crop residues has the same or similar results on the yield level and the improvement of soil properties, as well as the use of manure (Jaćimović et al., 2017).

Nitrogen is available to plants in the form of nitrate (NO_3) and the form of ammonia (NH_4). The nitrate form of nitrogen stimulates the accumulation of potassium (K), calcium (Ca) and magnesium (Mg) in plants. Nitrogen positively affects the resistance of plants to low and high temperatures and diseases. Not all plants have the same need for nitrogen; nitrogen deficiency or excess in the soil is not recommended. Nitrogen deficiency or a lack of nitrogen significantly reduces plant growth, thus branches are thinner. In winter grains, nitrogen deficiency is manifested through weaker tillering, plants have one stem and short spikes, and leaf growth is reduced. Nitrogen in plants is well mobile and moves from older organs to younger ones, so its deficiency is first spotted on the oldest leaves. Surplus/excess nitrogen negatively affects the productivity of plants; it is difficult to spot it on plants. Excess nitrogen leads to the excessive development of vegetative organs (roots, leaves and trunk), and such excessive development causes plant lodging. In winter grains (wheat, rye, barley, oats), it increases tillering, which results in uneven ripening. Nitrogen excess also affects the plant's roots, which become shorter and thicker, and become more susceptible to soil drought. Excess nitrogen prolongs vegetation and slows down the plant's ripening. The negative impact of excess nitrogen also has an ecological aspect, as it can lead to pollution of the environment by nitrates. Soil contamination by chemicalization from agriculture is increasing every year. The amount of nitrogen and phosphate fertilizers used to increase yields is growing. Therefore, attention should be paid to the possibility of pollution control (Zlatković D. and Zlatković J., 2017).

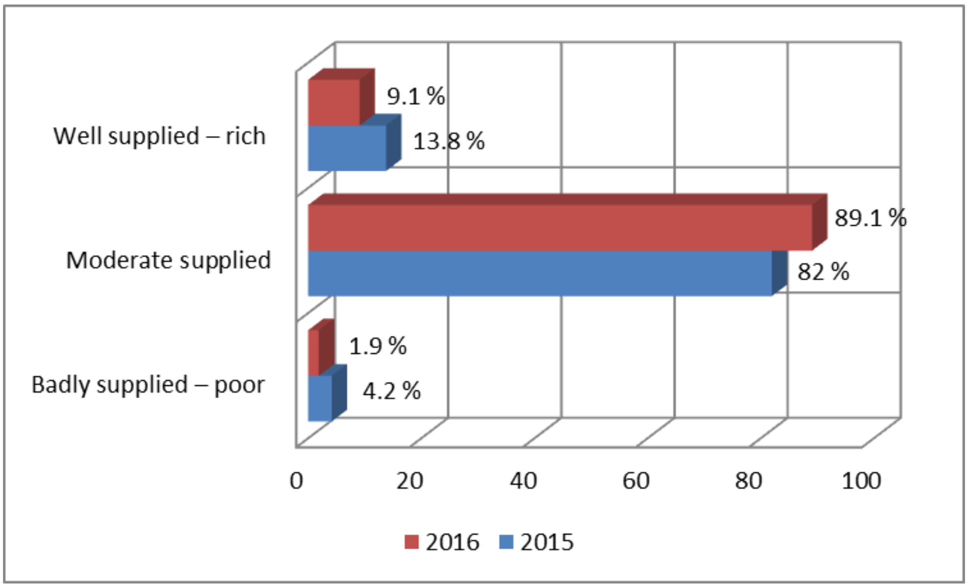
Results and discussion

The extraction of nitrogen from the soil also depends on plant species that is cultivated. Of the studied plant species, the highest amount of nitrogen has been found in triticale, and then in winter feed mixture, while the lowest amount of nitrogen has been found in vetch (Radanović, 2017). Due to growing ecological problems in developed countries, the so-called quotas for the use of mineral fertilizers (maximum quantities of mineral fertilizers per hectare are determined for each farm) have been introduced, especially in order to apply nitrogen in a controlled manner. The healthy and quality soil is a key component of healthy agricultural production. The main soil pollutants are: mineral fertilizers (especially nitrogen fertilizers), organic fertilizers, nitrates in plants, heavy metals, sewage sludge, municipal waste, plant protection products (herbicides, fungicides, insecticides, rodenticides), etc. (Aksentijević et al., 2017; Trikić, 2014). Plant species can be indicators of soil characteristics, based on the presence or absence of some herbs. If some "weeds" appear, for example nettle (*Urtica dioica*), it implies that the soil is rich in humus (Obratov-Petković et al., 2006).

Table 1: The sample share of particular classes based on the content of the available nitrogen (the categorization by Jelic, 2012) according to the analysis of 6523 pieces of land on the territory of Nis in 2015 and 2016

Classes	**Number of plots**		**Percentage (%)**	
	2015	**2016**	**2015**	**2016**
Badly supplied – poor (0-0,9 %)	194	35	4.2	1.9
Moderate supplied (0,1-0,19%)	3830	1651	82.0	89.1
Well supplied – rich (>0,2)	645	168	13.8	9.1
Total	**4669**	**1854**	**100.0**	**100.0**

On the basis of the processing of the data from 6523 pieces of land on the farms in the Nis municipality, it was concluded that 4.2% of the analyzed samples were the parts badly supplied by the available nitrogen (under 0,10%) in 2015 and 1.9% in next year. The part with moderate supply, with the nitrogen from 0.10 to 0.20% had the share of 82% in 2015 and 89.1 % in year of 2016 of the analyzed agriculture areas. The class of the soil well-supplied by the easily available nitrogen where the N was 0.20% or more had the share of just 13.8% and 9.1% (Table 1).



Graph 1. The sample share of particular classes according to the supply of the available nitrogen of the air-dry soil (%) in the Nis municipality by years (6523 samples)

Based on a classification (Graph 1), the samples with the nitrogen content ranging from 0.1 % to 0.19 % (moderate supplied) are far dominant, whereas the soils with the nitrogen content ranging from 0% to 0.9% and class where nitrogen content were more than 0.2% were less represented. In Serbia and in other parts of the world, experiments that have been carried out show that plowing harvest residues increases the yield and its quality, and it also increases the content of total nitrogen (N) and carbon (C) and organic matter - humus (Powlson *et al.*, 1987). Nitrate accumulation in nature, apart from causing ecological problems, directly endangers human and animal health (Kovačević et al., 2011).

Conclusion

Regular soil testing for the nitrogen content can provide an insight into the amount of nitrogen in the soil, so that the quantities of fertilizers applied are optimal and have no harmful effects on plants. It is very important to know the plant's need for nitrogen, so that nitrogen doses for certain plants are adequate and have no harmful consequences for both plants and the environment. In order to preserve soil fertility in terms of the yield and quality, it is necessary to re-enter the most important macroelements, such as nitrogen, phosphorus and potassium, into the soil every year. Often, intensive fertilization is carried out without previously conducted chemical soil testing, which can cause a contamination of the soil, plants and water; thereby, higher quantities of nitrogen and phosphorus fertilizers have shown the most unfavorable effects. Fertilizers that have not been utilized by crops reach the environment through the soil, and go to underground and surface waters, where they cause the greatest damage.

Based on the results of the analysis 6523 soil samples from the surface..., that is... *number of the households*, in the area of the municipality and city of Niš (Serbia), it can be concluded that the soil abundance in nitrogen is variable as a result of different types of soil, fertilization, and different exploitation of agricultural land. It is important that the soil analysis is carried out for every plot separately, at least once in five years, so that in this way, we obtain adequate recommendations for fertilization for the next four years, i.e. so that fertilizers are applied in accordance with their needs in order to avoid pollution and reduce excess costs.
According to the results of the research, the soil on the territory of the city of Nis is moderate-supplied by nitrogen. Certainly, it is highly recommendable to analyze the soil in order to be informed about the content of nitrogen which is necessary to all producers.

Abstract

The study of biological phases of soil reclamation by seeding the grassland has been conducted on the Deposol at internal disposal area for overburden from Raskovac open pit in Stanari coal mine (Republic of Srpska, Bosnia and Herzegovina). The aim of this study refers to implementation of biological phase of reclamation on yield biomass (green mass) in second swath and improvement of technogenic soil fertility, type Rekultisol. The survey task refers to measurement of impact of fertilization and liming on yield of biomass grassland and chemical properties of forming Rekultisol. The study was expended through three-year period (2011–2013). Three grass-leguminous mixtures and one grass mixture were studied; altogether four treatments of various doses of mineral fertilizer and lime. The research covered the selection of treatment with the most productive green mass and impact of chemical reaction of Rekultisol. Statistical analysis of measuring quantitative properties of vegetable mass was conducted by method of ANOVA, 3×4×4. The sandy-loam Deposol at the beginning of research had unfavorable physical and chemical properties. The applied treatments and interactions born impact on measuring quantitative properties of researched mixtures and chemical properties of Rekultisol. The TDS-1 mixture had the biggest green mass production (3.6 t ha^{-1}) in 2011. The TDS-3 mixture had the biggest green mass production in 2012 (6.9 t ha^{-1}) and 2013 (7,2 t ha^{-1}). The application of liming increased the pH of Rekultisol. The biological reclamation in researched agro-ecological conditions was successfully conducted by seeding grasslands, raising selected species in grass-leguminous mixtures and application of optimal agromeliorative measures.

Key words: *open pit, soil reclamation, grass-leguminous mixture, Stanari*.

Introduction

Main objective of the reclamation of degraded areas, caused by open pit mine exploitation of the ore reserves, is to establish the management functions on these newly created technogenic soils (technosols). The main task of all these man-built terrestrial ecosystems is to stabilize and revive production and ecological functions of a technogenic soil, ie Deposol (the surface layer of the disposal area for overburden).

The fertility of the Deposol and most other types of technogenic soils (e.g. mine soils) is usually low. The concentration of the Deposol with the basic biogenic elements (N, P and K) is within or below the minimum concentrations (Dvurechensiy and Seredina, 2015; Pivić et al., 2011; Sheoran et al., 2010; Coppin and Bradshaw, 1982; Antonović et al., 1978). In addition to the deficit of nutrients, technogenic soils have low content of pedobi'os and organic matter, and poorly developed adsorptive complex (Rasulić et al., 2005). Shukla et al. (2004) states the following disorders in technogenic soil: loss of aggregate and soil structure, decrease in soil C concentration, increase in volume, and decrease in porosity.

The results of the past physical and chemical analyzes of Deposol at disposal area for overburden at the Stanari mine found that they have favorable physical - mechanical but unfavorable chemical properties (Malić et al., 2017a; Malić, 2015; Malić i Marković, 2012).

The same authors state that, based on the content of organic matter, the researched Deposol belongs to the class of low and medium content, while there is no pure humus and nitrogen. According to the content of P_2O_5 and K_2O in the Deposol, they are classified as very poorly secured by these elements. The Deposol is characterized by a non-carbonate substrate, a strong unsaturation with base cations, a medium and highly acidic chemical reaction. The fact that the content of organic matter is very low and acidic chemical reaction make are the biggest problems in Stanari Deposols.
A significant part of the agricultural reclamation refers to the establishment of artificial grassland. Studies on the methods of grassland establishment in the reclamation process and potential yields have started in 2008 at the Deposols of Raškovac open pit external disposal area in Stanari (Malić and Lakić, 2011).
Pioneer species in agricultural reclamation include species from the families of Poaceae and Fabaceae. Seeding grasslands establishment through seeding grass-leguminous mixtures and pure cultures of certain grass species is significantly present at mine in Bosnia and Herzegovina, Serbia and abroad. Since the earliest reclamation works in the USA, a vast expanse of recultivated areas has been under seeding meadows and pastures (Thorne, 2010, Skousen and Zipper, 2010, Lyle, 1987, Vogel and Berg, 1968). Normally, most commonly sown species during reclamation process are grasses (family Poaceae) because they are producing a large amount of biomass and quickly adapt to specific and harsh environmental conditions. For biological reclamation most commonly used grass species are from the following genus: *Poa*, *Festuca*, *Lolium*, *Panicum*, *Agrostis*, *Phleum*, *Dactylis* (Malić and Lakić, 2011, Smith et al., 2002). Participation of leguminous in mixtures depends on the type and characteristics of Deposols used for reclamation. In addition to the potential yields of forage and hay, multiple significance of all types of grasslands is reflected in the changes of basic physical, chemical and biological properties of Deposol by increasing its fertility. The aim of this survey refers to implementation of biological phase of reclamation and improvement of technogenic soil fertility.

Material and method

The coal basin Stanari is located between 44°40' and 44°50' N and 17°45' and 18°00' E, in the northern part of the Republic of Srpska / Bosnia and Herzegovina. Research on biological reclamation of a direct type was carried out at the experimental field (GPS Coordinates: y = 6.486.822.33; x = 4.957.645.63; altitude 220 m a.s.l) within internal disposal area for overburden of the excavation from the open pit Raškovac in the lignite coal basin Stanari: ''EFT - Mine and Thermal Power Plant Stanari''. The survey was conducted in a three-year period (2011–2013). Part of the disposal area for overburden where the experimental field is located was formed during 2010.
The three-factorial experiment was set by the random block method in four repetitions. The experiment plots area is 10 m^2 (5×2 m). The distance between the plots is 50 and 80 cm, and between the blocks is 1 m. Plots are without inclination.
The first factor of research refers to the year (factor A), with three treatments. The second factor refers to various grass and leguminous species in mixtures (factor B), with four treatments. The third factor is agromeliorative measures (fertilization, liming and mulch, factor C), with four treatments (Table 1).
Statistical analysis of the measured results has been conducted with the green mass yield by the ANOVA method, 3×4×4. Establishment of the seeding grassland was carried out during the spring sowing period in 2011. Seeding rate amounted to 45 kg/ha. When the crops reached their maximum growth, mowing – lawn mulcher was performed. The measurements of green mass yield were carried out on: 31 August 2011, 20 July 2012 and 05 August 2013).

Table 1. Treatments three-factorial experiment

<table>
<tr><th>Factors</th><th colspan="4">Treatments</th></tr>

</table>

The third factor (C) represents dosages of mineral fertilizer (pure nutrients) applied during sowing period (doses: $N_{90}P_{90}K_{90}$, $N_{60}P_{90}K_{90}$ and $N_{60}P_{60}K_{60}$) and spring supplementation with nitrogen fertilizer (doses: N_{54+54} and N_{40+40}). The mineral fertilizer NPK 15:15:15 was used before sowing, and KAN (27% N) during supplementation phase. Limestone was added during the primary tillage of the Deposol (treatment c_2). After the sowing, wheat straw in the form of mulch was used on treatment c_4.

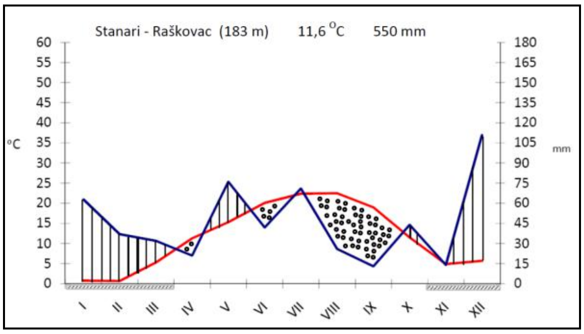
The determination of the studied types of technogenic soil was carried out according to Resulović and Čustović (2007), and the WRB classification (2014). According to the soil classification in Bosnia and Herzegovina, the newly discovered soils mine belong to the class of technogenic soils (types Deposol and Rekultisol). Deposol represents the type of surface layer of disposal area for overburden prior to biological phase of the reclamation. Rekultisol is a layer of soil where reclamation measures have been carried out and the initial processes of humification and mineralization begin. The researched Deposol and formed geogenic Rekultisol are of a silicate subtype. According to the WRB classification (World Reference Base for Soil Resources, 2014), these soils are determined as technosols (Epiarenic and silicit material).

For the purposes of laboratory pedological research, the average samples of the Deposol were taken before the study at the beginning of 2011, and the samples of Rekultisol in the final phase of vegetation in 2013. The samples were taken from a depth of 0-20 cm. The analysis of the Deposol included the examination of the following parameters (Table 2): content of organic matter (dry burning method at 550 ^{o}C), humus (Tjurin method), soil reaction (pH) in H_2O and 1M KCl (electrometrically combined electrode in pH-metre), total N (semimycro Kjeldahl method), plant available P and K (AL-method). At the end of the research in 2013, the pH value was analysed one more time. The classification of Deposol and Rekultisol based on the chemical reaction was carried out according to Živković (1991) for pH in H_2O, and according to Šefer-Šahtašabel for pH in KCl.

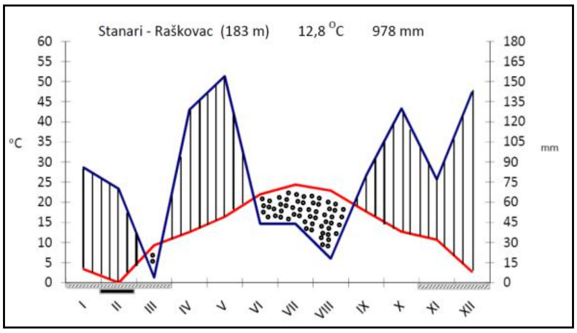
Table 2. Results of the analysis of chemical properties of Deposol

No. of sample	pH		Organic matter	Humus	Total N	AL - P_2O_5	AL - K_2O
	H_2O	KCl	%			mg/100g soil	
1	6.2	4.9	2.1	0.0	0.0	0.0	1.3
2	5.8	4.5	1.2	0.0	0.0	0.5	2.2
3	5.2	4.0	1.6	0.0	0.0	0.6	2.7

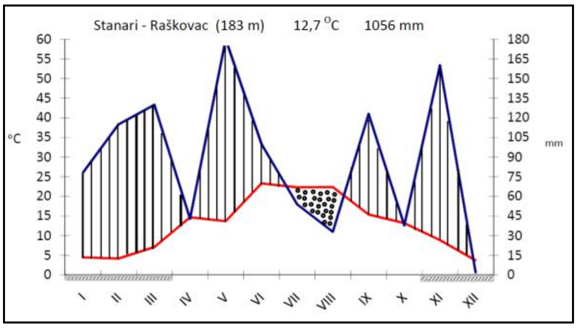
The basic climate indicators (precipitation and air temperature) in the studied three-year period are shown in the following graphs (climate diagram to Walter and Lieth).



Graph 1. Climate diagram in 2011



Graph 2. Climate diagram in 2011



Graph 3. Climate diagram in 2013

Results and discussion

Three-year research and application of the intensive agrotechnical measurements in the implementation of the biological phase of reclamation (by the dominance of the anthropogenic factor) resulted in formation of the Rekultisol as the thin surface layer of the technogenic soil. The researched Rekultisol is formed in the process of the direct reclamation while the lawn forming.

The crops were mulched so the dry mass stayed on the Deposol surface in the process of reclamation. Table 5 shows the average values of the green mass in the second swath, the results of the variance analysis, and the Lsd test. The identified interaction effect is given in Graph 4.

Table 5. Average yield (t ha^{-1}) of green mass in the second swath

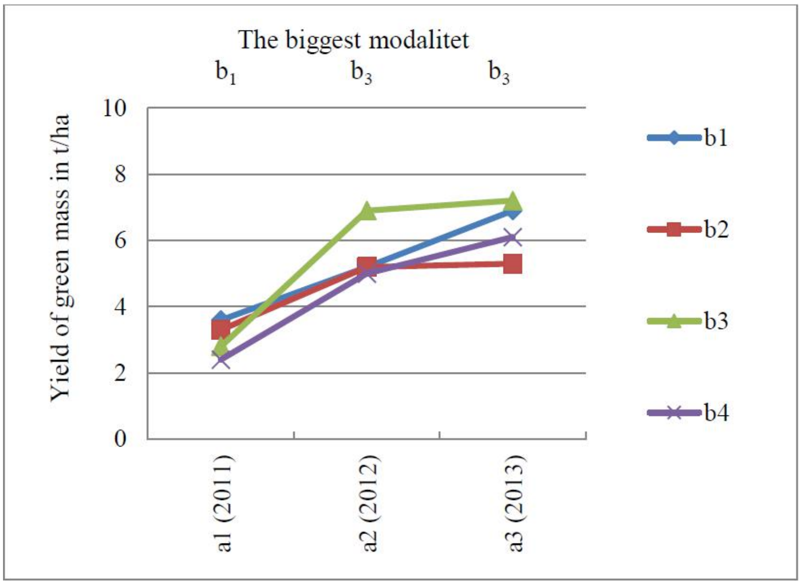
With the researched mixtures, yields during the research were variable in some of the treatments. The results in Table 5 indicate the increase of the average yield of the green matter during the research. The average value of the green mass yield in the first year was 3.0 t ha^{-1}, in the second 5.6 t ha^{-1} and in the third 6.4 t ha^{-1} of green mass. The analysis of the variance shows the statistically significant influence of the basic factors of the year (A) and different mixtures (factor B), while the interaction of factor A and B (year × agromeliorative measurements) is significant. The factor of a year with three treatments had a statisticly significant impact on the green mass yield in 2012 and 2013 from other 2011.

The analysis of the interaction effect of the years × mixtures (A × B) on the average values of green mass yield in the second swath shows the variations between the individual mixtures in the second and third year compared to the first year of the study. Differences in the yield of the green mass between the modalities of the factor B are not significant in 2011. Change in these tendencies was recorded in 2012, when the mean value of treatment b_3 showed a statistical significant influence comparing it to other treatments (b_1, b_2 and b_4). The differences between these three treatments are random. In the third year of the study there are very significant differences only between the treatment b_3 (the highest mean value) and treatment b_2 (yield with the lowest mean value).



Graph 4. Interactive effects of research year (factor A) and mixtures (factor B) on the yield of green mass in t ha^{-1}

According to Malić et al. (2017b) mixture TDS-3 (treatment b_3) had the biggest green mass production in three-year study in the first swath (4.8 t ha^{-1} in 2911, 16.7 t ha^{-1} in 2012 and 25.8 t ha^{-1} in 2013. The same authors reports the maximum average yield of green matter in the second two years of the survey (17.3 t ha^{-1} in 2012 and 32.1 t ha^{-1} in 2013) was measured in the combination of the b_3c_3 treatment. The minimum variation of the yield is evident for the TS-2 mixture on all treatments of factor C, which is the result of seedling of grass species only. The measured values of green mass yield match the results of previous research with the type of *Festuca arundinacea* Schreb on the Deposol of the outlying landfill of Raškovac, where Malić and Lakić (2011) state the average yield of 7.9 t ha^{-1} of green mass in the first swath and 5.0 t ha^{-1} in the second swath at the dose of fertilizer $N_{35+80}P_{100}K_{150}$.
Lower values of the green mass of grass-leguminous mixtures are also reported by Grandt and Lang (1958), who achieved an average yield of *Medicago sativa* L., with more grass species of 8.4 t ha^{-1}, in three years of direct reclamation of Deposols in Illinois. The same authors report the yield of the green mass of the mixture *Lotus corniculatus* L. and grass of 8.1 t ha^{-1}, with a mixture of other legumes and grasses, the yield of 5.4 t ha^{-1} was measured. Moreover, with the mixture of *Lespedeza bicolor* Turcz. and grass, the yield of 4.6 t ha^{-1} was measured. Measured production of green mass of the mixture *Trifolium repens* L. and grass is 7.1 t ha^{-1} and *Trifolium pratense* L. and grass 5.1 t ha^{-1}. The measured yields of green mass in direct reclamation are significantly lower than the potential of these species in the production of green fodder (Malić et al. 2017; Malić, 2015). The main reason for this is the difference in the fertility of natural soils and Deposols.
The extent and intensity of the applied agro-technical measures are interrelated with the time of the reclamation, which together affects the properties of the re-cultivated land. Beginning of the pedogenesis of the Deposol at the investigated site overlaps with the completion of the discharge of the discovery on this part of the internal landfill site Raškovac, which was carried out in late 2010. The results of the analysis of the chemical reaction of the Rekultisol at the end of the study are shown in Table 6.

Table 6. Analyses of pH of Rekultisol in late 2013

No. of sample	Treatments	pH	
		H_2O	KCl
1	b_1c_1 (TDS-1, $N_{90+54+54}P_{90}K_{90}$)	5.3	4.2
2	b_1c_2 (TDS-1, $N_{60+54+54}P_{60}K_{60}$ + 8 t ha^{-1} $CaCO_3$)	7.5	6.5
3	b_1c_3 (TDS-1, $N_{60+40+40}P_{60}K_{60}$)	6.3	5.0
4	b_1c_4 (TDS-1, $N_{90+40+40}P_{90}K_{90}$ + mulch)	5.9	4.8
5	b_2c_1 (TS-2, $N_{90+54+54}P_{90}K_{90}$)	5.6	4.3
6	b_2c_2 (TS-2, $N_{60+54+54}P_{60}K_{60}$ + 8 t ha^{-1} $CaCO_3$)	7.5	6.5
7	b_2c_3 (TS-2, $N_{60+40+40}P_{60}K_{60}$)	6.0	4.6
8	b_2c_4 (TS-2, $N_{90+40+40}P_{90}K_{90}$ + mulch)	5.7	4.8
9	b_3c_1 (TDS-3, $N_{90+54+54}P_{90}K_{90}$)	6.2	6.9
10	b_3c_2 (TDS-3, $N_{60+54+54}P_{60}K_{60}$ + 8 t ha^{-1} $CaCO_3$)	7.5	6.6
11	b_3c_3 (TDS-3, $N_{60+40+40}P_{60}K_{60}$)	5.8	4.9
12	b_3c_4 (TDS-3, $N_{90+40+40}P_{90}K_{90}$ + mulch)	6.2	5.1
13	b_4c_1 (TDS-4, $N_{90+54+54}P_{90}K_{90}$)	5.9	4.8
14	b_4c_2 (TDS-4, $N_{60+54+54}P_{60}K_{60}$ + 8 t ha^{-1} $CaCO_3$)	7.2	6.2
15	b_4c_3 (TDS-4, $N_{60+40+40}P_{60}K_{60}$)	6.1	5.0
16	b_4c_4 (TDS-4, $N_{90+40+40}P_{90}K_{90}$ + mulch)	5.9	4.9

Based on the value of the results of the analyzed Rekultisol chemical properties of all the average samples given in Table 6, an improvement in the pH value was observed, comparing to the values of the results in the testing of the Deposol before the start of the biological reclamation (Table 2).
The values of the active reaction (pH in H_2O) of all the samples in Table 6 enter the interval from strongly acid to weak alkaline chemical reaction of the soil. The value of the pH of the sample 1 represents the soil of a highly acidic reaction. According to the sample values no. 4, 5, 7, 8, 11, 13 and 16 in these combination treatments, the Rekultisol is determined in the category of moderate or moderate acid reaction. Examined samples include all treatments with grass-leguminous mixtures (TDS-1, TDS-3 and TDS-4). As far as factor C is concerned in these samples, samples with treatments c_1, c_3 and c_4 are present. Rekultisol with the values of the pH within samples 3, 9, 12 and 15 is classified as low acidity. In this case, there was no significant change in pH compared to the applied treatments in the study. Neutral and weak alkaline reaction was determined in samples 2, 6, 10 and 14, or on plots under treatment c_2 where calcification was performed at a dose of 8 t ha^{-1} of $CaCO_3$.
The values of the substitution reaction of Rekultisol (pH in KCl) in Table 6 assign samples 1, 4, 5, 7, 8, 11, 13 and 16 to the category of very acidic reaction. Samples 3, 12 and 15 are the categories of moderately acidic reaction. The values of pH in the sample 2, 6, 9, 10 and 14 categorize the Rekultisol into the soil of a slightly acidic reaction. Comparing the results of this division and the division of the pH into H_2O, the samples 2, 6, 10 and 14, in which the acidity is the lowest (ie, the highest pH), are the same treatment of factor C. In these

treatments, calcification is applied, and the pH value in the KCl moved from 6.2 to 6.6, and belong to the category of poorly acidic reactions.
According to Malić and Marković (2012), the partial increase of the pH value of the Deposol in the reclamation process at the Raškovac mine was also achieved in previous researches of agricultural reclamation, where calcification was applied. An increase of pH in KCl from 4.12 to 6.46 with the previous application of 15 t ha^{-1} of hydrated limestone is indicated by Kovačević et al. (2011), which corresponds the results on treatments where calcification is applied. The same authors note the decrease of pH in KCl in the case of meliorative fertilization with phosphorus and potassium, without the use of calcification. In a study of the pedological changes on the marl substrate during the thirty-two-year period, Mujačić (2013) states that the pH in H_2O had an insignificant decrease of value, which is 7.7. The possibility of successful calcification in the reclamation process of Deposol using limestone materials is cited by Sheoran et al. (2010).

Conclusion

The establishment of a seeded grassland with the sowing of grass-leguminous and grass mixtures, with the application of agromeliorative measures, concludes the following:

- The chemical properties of the researched Deposol are characterized by the non-carbonate and non-humus substrate, the strong unsaturation of the base cations, the medium and highly acidic chemical reaction, the low content of organic matter and basic biogenic elements.
- The ecological conditions during the research and applied agro-technical measures have had an impact on the growth and development of grass and legumes, as well as on the changes in the surface layer of the researched technogenic soil.
- The highest average yield of green mass in the second swath was measured with the TDS-1 mixture (3.6 t ha^{-1}) in 2011 and TDS-3 mixture in 2012 and 2013 year (6.9 t ha^{-1} and 7.2 t ha^{-1}).
- Under the influence of intensive implemented measures of biological reclamation on the Deposol, the condition of the reclamation soil was conditioned as well as the type of Rekultisol, which on the basis of the analysis indicates the increase in the pH value.

AGRICULTURE AND LAND USE: CONTEXT ANALYSIS AND FUTURE PERSPECTIVES FROM THE MEDITERRANEAN TO THE APULIA REGION

Simona GIORDANO*

CIHEAM, Mediterranean Agronomic Institute of Bari and University of Bari Aldo Moro (Bari, Italy)
* Corresponding author: simo_giordano@yahoo.it

Abstract

Land use patterns have, over the centuries, reflected the continuous interaction between human activities and natural environment, and have resulted in significant environmental impacts and its consequences, both positive and negative on the well-being of human groups. The scarcity of resources, land and water, represents a great social challenge, especially in a context of climate change and food insecurity. These challenges are particularly significant for the Mediterranean, a region characterized by dynamic population and high density, with strong constraints on land and water resources. The Mediterranean has a long history of land use and represents one of the richest areas in terms of biodiversity; because of its cultural and environmental characteristics and its long history, the Mediterranean basin hosts a variety of land use systems of varying intensity and levels, ranging from intensive systems to traditional "mosaic" ones. These traditional mosaic systems are associated with high biodiversity values and landscapes particularly vulnerable to global changes, which see their survival threatened not only in terms of food supply, but also with respect to a number of ecosystem services linked to the multifunctional dimension of agriculture. In this context, starting from the report on land use in Italy, the contribution aims to provide a broad and precise picture of its current patterns at different levels, up to the Apulian regional scale. Agriculture itself, to which the delicate issue of land use is necessarily linked, today represents a fundamental strategic sector for the Mediterranean countries, whose centrality in Euro-Mediterranean regional cooperation requires an in depth reflection and analysis.

Keywords: *Land use, Mediterranean, Multifunctional agriculture, Ecosystem services, Biodiversity.*

Introduction

Nowadays, as to the term "land use", it is difficult to refer to an unambiguous definition; Pileri (2009) defines it, generally speaking, as the anthropogenic process that involves the gradual transformation of natural or agricultural surfaces through the construction of buildings and infrastructures; it is assumed that the restoration of the pre-existing environmental state is very difficult, if not impossible, due to the nature of the earth matrix. This definition encompasses a negative perspective as long as the issue of the subtraction of natural or agricultural surfaces is perceived as a serious problem, considering the finiteness of the earth's surface; as a consequence, it could be more correct to define or talk about land or soil transformations, rather than mere consumption. Land use, as a matter of fact, is a practice inherent in the anthropogenic activity, since all the human communities have abandoned nomadic life, built, transformed and consumed land according to their needs through time. On the one hand, the most extremist exponents of ecology argue, for example, that even the transformation of forests for agricultural purposes represents a phenomenon to be limited; this is particularly true with reference to tropical countries, due to the presence of rainforests, while it can be considered a "non-European" problem, inasmuch as almost all European forests have disappeared.

On the other hand, the issue at stake has gained attention within the scientific community as a result of what can be observed in the last 20-30 years: the really important aspect is that the consumption and transformation of land does not constitute a problem in itself, but becomes so when it is consumed without a specific and real need. It is vital and appropriate to specify that, as well as a quantitative question, the consumption of land is also a matter of distribution: it is often possible to observe, outside the built-up areas, construction works that erode agricultural or natural territory, which is fundamental for guaranteeing food production and to regulate the climate and the water cycle. It is vital to analyse the reasons why land use and consumption has to be considered as an issue and a problem. Following the profound changes that the processes of industrialization have brought to the geomorphology of the earth in the last century, a strong interest in ecology issues has been affirmed both in the scientific community and in civil society, supported, since the 1970s, by environmental movements. This is true with particular reference to, on the one hand, the more or less stable presence of environmentalist political parties in the parliaments of most developed nations (e.g. in Italy: Verdi and SEL, Sinistra-Ecologia-Libertà) and, on the other hand, the fact that it is possible to observe an increasing interest from political parties and political coalitions in organizing their own programs with numerous references to the environmental component. The European Union strongly supports States and Regions for the promotion and development of programs and policies aimed at enhancing the safeguard of the environment, in general, as well as in the specific field of land use. Starting from the definition of land use and consumption, the present contribution aims at carrying on a sound analysis of legislation concerning the mentioned subject and, as a context analysis, of the case of the Alta Murgia National Park in Apulia region. Conclusions will be drawn regarding the importance of investigating the link between land use and sustainable agriculture.

Materials and Methods

Analysis of land use causes

It is fundamental to carry on an in depth analysis of the underlying causes of the phenomenon of land use. Firstly, industrialization[6] and its expansion in many countries has been perhaps the greatest change in the history of mankind. It is a process that is based on the intensive exploitation of the main resources made available by nature (i.e. air, water, earth and fire, energy). After centuries of technological development and economic growth, most countries have begun to become aware of the negative effects of this development model, while other countries, those of the so-called "South of the World", have in turn taken the industrial model as a guide to well-being, with results, however, at least questionable in many respects. As a consequence, it is fundamental to consider how the beginning of the new millennium presents itself as a challenge to face: reconciling the growing demands of democracy and well-being of all peoples with the needs of survival of the earth. Sociologists and economists repeatedly try to find an academic and theoretical answer to this question (Pallante, 2011), whose solution needs to take into account a simple but vital concept, i.e. the awareness that land use and consumption is a real and serious issue, whose origin lies in the fact that natural resources are not infinite, and that land and soil are part of these same resources. Nevertheless, as above mentioned, it is important to emphasize that nowadays, with regard to the "North of the World", it would be more correct to speak of "waste" of land; this circumstance derives from the expansion of cities on order to meet specific needs of society, the satisfaction of main needs, such as housing and services. This is certainly true up to a certain limit, beyond which land use becomes a speculative phenomenon, unjustified by the mentioned needs. Starting from a basic ecological point of view, it is vital to cease land waste, as this represents a unique and irreproducible resource, and has vital and strong relationships with the quality of air, water, and energy consumption. As an example, in addition to occupying the soil and

[6]The term industrialization refers to the process of transforming a community (society) from a type of rural economy to a type of life with an industrial economy.

limited ground, a built-up area interferes with the infiltration of rainwater into the subsoil, partially or totally blocking the recharge of the aquifers; the population that inhabits it consumes energy resources, contributing to the use of fossil fuels, such as methane for the operation of boilers, coal or oil or nuclear energy used for the production of electricity that serves the functioning of the technological components of homes and public lighting equipment[7]. Moreover, the need linked to mobility of the inhabitants is satisfied with the use of means of transport (whether public or private) that obviously use other fossil fuels (petroleum derivatives or methane) that release emissions into the atmosphere. The air of urbanized areas is, for these reasons, partly polluted, causing damage to the health of the inhabitants and, in general, to the ecosystem; in addition, rainwater carries pollutants into the soil and underground, creating further environmental damage. The construction of free soils not only involves the concreting of a specific piece of land, but also includes the consumption of other soils, i.e. those used for the extraction of materials to produce cement, or quarries, which represent further land consumption. The issue of hydrogeological instability needs also to be taken into consideration, as building works are often carried on in areas that, although they appear to comply with norms, prove to be extremely dangerous, causing severe damages and accidents with victims. As clearly stated in the European Commission Document entitled "Framework for the protection of soil" highlighted the importance of land as a vital and non-renewable resource (European Commission, 2006. N.232), land embeds multiple functions, being a strategic resource for a country and its citizens, as well as a common good. Free soil is an irreplaceable potential for food production, and an ecological and environmental multifunctional resource, as it preserves carbon, regulates the hydrological cycles, governs humidity, provides shelter to many animal species, and represents a habitat for other species, supports vegetation and its functions (primarily oxygen production and the subtraction of CO_2) and so on. Free soil is a fundamental condition for the quality of the landscape, as it guarantees the indispensable presence of open spaces, crucial for urban well-being and the health of citizens. As a consequence, the future development of cities, indicated by illustrious scholars and urban planners (Arcidiacono et al., 2014), in the context of the National Urban Planning Institute (official website of INU), needs to take into account the reuse of already compromised land.

Results and Discussion

Legislation and focus on Apulia region

As above mentioned, with regard to the legislation on land consumption, there is a lack of organic unity. The mentioned European Commission Document entitled "Framework for the protection of soil" highlighted the importance of land as a vital and non-renewable resource (European Commission, 2006. N.232). This concept was reiterated by the Commission itself in 2011 with the "Roadmap to a Resource Efficient Europe" (European Commission, 2011. N.571), linked to the 2020 Strategy, with the goal of a zero increase in net employment of land to reach in Europe by 2050. This Objective was reaffirmed with the approval of the Seventh Environmental Action Program, called "Living well, within the limits of our planet" (European Parliament and Council, 2013. N.1386).

In Italy a series of government initiatives, dating back to 2012, embed several expectations related to the need to safeguard natural and agricultural soils as well as relaunch the building

---

[7]Although research on photovoltaic and solar thermal technologies are attempting to gradually replace the use of these fuels for civilian use, they still contribute in a minority to the total production of electricity; nuclear energy, on the other hand, beyond the possible and well-known incidents that can occur in power stations (Cernobyl, 1986; Fukushima, 2011), provides for the disposal of radioactive waste in special landfills placed hundreds of meters underground, which in turn, they could have (and have) negative repercussions on the entire ecosystem since the radioactivity of uranium or plutonium is extinguished in tens of thousands of years.

activity towards the regeneration of urban fabric, aimed at improving the quality of life of citizens, to improve the environment and urban and suburban landscape and to recover eco-systemic functions. It is possible to observe, nevertheless, a lack of an organic law for the protection of the environment, the territory and the landscape, with a specific focus on sustainable development and on increasing the resilience of urban areas in the face of old and new challenges, due to both the fragility of Italian territory, and to the need to adapt to ongoing climate change. Many regions have specific land use regulations, while others set targets in the area of land governance laws, although there are significant derogations or exceptions related to envisaged types of interventions and land transformations that, as long as they are not included in the calculation (and, therefore, in the limitation), in reality represents a further cause of land consumption. (ISPRA, SNPA, 2018; ANCE, 2016). As far as the Italian territory is concerned, land consumption continues to grow at a rate of 15 hectares per day, thus strengthening the progressive artificialization of the same territory that continues to cover natural and agricultural areas with asphalt and cement, buildings, roads and other infrastructures, commercial, productive and service settlements, and through the expansion of urban areas. Given the geomorphological structure of the Italian territory, it is vital to analyse the coastal strip where the phenomenon shows itself in all its dramatic force. In fact, at a national level, almost a quarter of the range within 300 meters from the seaside is consumed; Liguria and Marche, with almost 50% of land consumed, represent the most serious data, while Abruzzo, Campania, Emilia Romagna and Lazio show values between 30 and 40%. Between 300 and 1,000 meters from the seaside, Abruzzo, Emilia-Romagna, Campania, Liguria and Marche show values equal to or greater than 30% of consumption. In the range between 1 and 10 kilometers, it is possible to observe the greatest percentage increase (ISPRA, 2017) and Campania stands out with 16.4% of land consumed. It is fundamental to note how, although the increase is less evident in the bands adjacent to the seaside, i.e. in the range below 300 meters, data show an increase in land consumed equal to 0.10% (ISPRA, 2017; ISPRA, 2018).
Another important focus, as regard the Italian territory, concerns protected areas, such as national and regional parks, natural areas and reserves. According to the ISPRA report (2017) almost 84 hectares (+ 0.11%) with the most dramatic situation in the Monti Sibillini National Park (over 24 hectares) and in the Gran Sasso and Monti della Laga National Park (over 24 hectares as well). The highest percentages of land used can be observed in the national parks of Vesuvius, the Archipelago of La Maddalena, and Circeo (ISPRA, SNPA, 2017). At a national scale, protected areas are still less consumed than the remaining areas, with a percentage of soil consumption within protected areas equal to 2,4%. In total, almost 6% of the bound territory, compared to 7.6% registered throughout the national territory, is consumed. The regions with the highest percentage of bound territory consumed are Campania (11%), Veneto (9%), Apulia (9%), Emilia Romagna (8.5%) and Lombardy (8%). Land use, in these mentioned cases, is due to construction sites and areas devoted to infrastructures, buildings or other permanent coverings over the next few years, as well as yards on agricultural or natural soil, linear infrastructures and new extractive areas.

Apulia Region

In particular, in Apulia region, the regulation on land use stems from the Regional Law 13/2008 which states that the territorial government tools must contain the necessary indications to promote the sustainability objectives of territorial and urban transformations, including the reduction of the consumption of new territory, avoiding the occupation of soils of high agricultural and/or naturalistic value, favoring the rehabilitation and recovery of degraded areas. Regional Law 15/2017 (which modified Regional Law 26/2014) defines land use as the reduction of agricultural areas due to interventions that determine its waterproofing, urbanization, construction and overbuilding, of areas used de facto for agricultural purposes, regardless of their urban destination and those areas, free from buildings and infrastructures, susceptible to be used for agricultural purposes. Finally, Regional Law 12/2018 (which amended Regional Law 24/2015) aims at favoring a planning of the territory in compliance with the criteria of sustainability and reduction in land use. More in detail, protected areas in Apulia extend for a total of approximately 245,154 hectares, of which 75.8% is represented by national parks (Gargano National Park and Alta Murgia National Park) and 8.3% by regional natural parks and reserves. It is vital to consider the ICSANP indicator (Intensity of Soil Consumption in Protected Natural Areas. http://www.paesaggiopuglia.it/aree-protette-in-puglia-footer.html) that represents the increase/decrease in land use over time within protected natural areas in Apulia, calculated as a percentage resulting from the relationship between change in land consumed in a given time period (in the specific case 2016-2017) and land consumed at the initial time (T0 = 2016) (Arpa Puglia, Environmental indicators of Puglia, 2018). This shows the percentage of land consumption within protected natural areas which, although limited to relatively low values (around 3%), showing on average an increased propensity to naturalness of these territories, proves values different from zero and therefore not in line with the objectives of maximum protection of these areas (ISPRA, 2017; ISPRA 2018).

Conclusions

The Alta Murgia National Park

In the context of Apulia region and its natural territory, the Alta Murgia National Park, founded in 1998 and officially proclaimed a National Park in 2004, covers a total area of almost 68,000 hectares and is entirely included in the Natura 2000 Site SIC / ZPS IT9120007 "Murgia Alta" of about 125,000 hectares. The municipalities that are part of the same Park are: Altamura, Andria, Bitonto, Cassano delle Murge, Corato, Gravina in Puglia, Grumo

Appula, Minervino Murge, Poggiorsini, Ruvo di Puglia, Santeramo in Colle, Spinazzola and Toritto (Table 1). The territory represents a typical Mediterranean karst landscape, with the presence of medium deep or shallow karstic valleys (Fracchiolla et al., 2017; Ricchetti et al., 1988). Overall, the Park territory is composed of agricultural areas (33,399 hectares), forests and semi-natural areas (33,421 hectares), artificial-man-made surfaces (1,211 hectares) and water bodies (8 hectares) (official website of Alta Murgia National Park. Figure 1).

Table 1: Municipalities in the Alta Murgia area

Alta Murgia	Surface in the area	Surface in the area/Total surface (%)
Total surface	1.992,73	---
Province:	---	---
Bari	1.489	39%
Barletta Andria Trani	381,85	25%
Taranto	121,89	5%
Comuni:	---	---
Acquaviva delle Fonti	42,21	32%
Altamura	427,70	100%
Andria	136,52	34%
Bitonto	19,86	11%
Cassano delle Murge	53,26	60%
Castellaneta	58,42	24%
Corato	65,58	39%
Gioia del Colle	176,94	86%
Gravina di Puglia	380,82	100%
Grumo Appula	6,86	9%
Laterza	63,47	40%
Minervino Murge	121,15	47%
Poggiorsini	43,01	100%
Ruvo di Puglia	109,78	49%
Santeramo in Colle	143,18	100%
Spinazzola	124,18	68%
Toritto	19,81	27%

Source: our elaboration from Puglia Region

In the last decades of the twentieth century, thanks to the use of modern technology and machinery, and favored by a questionable European Community subsidy policy (Giordano, 2017), the removal of stone was carried out with a high intensity. Large parts of the territory have been affected by changes in land use, resulting in the destruction of karst systems (and karst ecosystems therein) through the removal of stones, even large ones, in order to create fields where to plant crops such as wheat or vineyards. A definite loss of the natural karst landscape (Caldara and Ciaranfi, 1988; Parise 2011) has therefore been recorded in vast areas of the Murge. Furthermore, the removal of the original soil has had the direct consequence of an increase in erosion processes during adverse atmospheric phenomena, even in those sites characterized by low or very low gradient. The long history of occupation of this territory has led to the loss of most of the ancient remains of the original karst landscape; this is particularly true with reference to the last decades, when an often uncontrolled urban expansion characterized large areas of Apulia region in general, and Murge as well, and many traces of historical heritage were irretrievably destroyed (Perrino, 2013). In other cases, land forms such as lakes, or small depressions and karst caves, have become sites of frequent discharge of solid and liquid waste, with serious consequences for the natural environment, the karst ecosystem and quality of groundwater. Pollution and degradation events are continuously observed and recorded, with more or less serious consequences on soil quality and consumption. According to the Regional Territorial Landscape Plan and with regard to the Alta Murgia, it is fundamental to note how land and landscape are under threat because of the different types of anthropic occupation (e.g. homes, plants, service areas) that contribute to fragmenting the natural morphological continuity of the landscape, and to increasing hydrogeological risk. Further research in this field should be carried out aimed at analysing the vital connection between sustainable agriculture and land safeguard.

Abstract

Gold extraction via small scale mining in the Amazon rainforest of Peru has become one of the greatest threats to deforestation and land degradation in the Amazon, especially in the Madre de Dios region which is one of the last biggest remnants of continuous tropical rainforest in the world. Restoration of these degraded ecosystems have become a priority in the last decade but without concrete actions, however, few research has been conducted in response to these restoration activities nor natural regeneration. The significance of this research was to study a chronosequence of natural regeneration in two active gold-mining sites in Madre de Dios-Peru (Paolita-PA; Santa Rita-ST) and how the nearby remnant forest contribute to natural regeneration. Sites were chosen depending on its management and the proximity to nearby remnant forest. Floristic composition of natural regeneration following abandonment of mining activities was studied by establishing a total of 12 plots (20x50m each), 6 with an abandonment period of 2 to 16 years and 6 were considered as reference forest. A total of 753 individuals from 44 families and 144 species were identified. To analyze biodiversity and similarity composition, Shannon and Jaccard indexes were used, respectively. The results showed that the abundance of species (Shannon) was higher in Paolita than in the Santa Rita mining site. From Jaccard's similarity index each mining site was analyzed in clusters finding that in Paolita, nearby remnant forest might not have a great influence over natural regeneration when compared with Santa Rita site which showed similarity between remnant forest, but instead the time of abandonment, availability of nutrients and forest fragmentation might be the cause of the recovery of degraded forest.

Keywords: *Chronosequence, Natural regeneration, Gold mining, Amazon rainforest, Peru.*

Introduction

The tropical rainforest is considered as one of the most biodiverse sites in the world (Connell, 1978) and the efforts of preserving these valuable ecosystems are highly important for the sake of humanity (Venter, et al., 2016). In the attempt of preserving the biodiversity, Peruvian amazon rainforest hosts various protected areas designate not only to preserve nature itself but also human populations. According to an official list of protected areas in Peru published by SERNANP (2019), only in the Region of Madre de Dios 3 National Parks, 1 National Reserve, and 2 Communal Reserves are part of the National Administration , and 25 Private Conservation Areas aim to preserve this great biodiverse ecosystem (Vuohelainen, et al. 2012). But despite these efforts, the region has face severe deforestation caused by agriculture, logging, cattle raising and gold mining (Román - Dañobeyta , et al., 2015) . A recent study (Caballero Espejo, et al., 2018) showed that from the years of 2010 to 2015, mining took the lead as cause of deforestation in the region and in a laps of 7 years (2010 – 2017) 64584ha were lost to gold mining. Given the current situation of deforestation and consecutively loss of biodiversity due mining, this study aimed to 1) conduct a chronosequence of secondary successional forest in active gold mining sites in the Region of Madre de Dios to analyze the response of forest after abandonment taking a close look into the floristic composition and structure, and 2) to analyze how remnant forest influence natural regeneration of nearby degraded lands. Thus, to accomplish our objectives, satellite images and aerial photographs were used for the site selection. To address biodiversity, Shannon's diversity Index was used (Kennard, 2016) and to analyze similarity between successional stages, Jaccard's similarity index was used.

Materials and methods

Study area and site selection

The region of Madre de Dios is one of the 24 first-level administrative subdivisions of Peru. This region, part of the tropical rainforest, is located in the southeast side of the country neighboring Bolivia and Brazil, with an area of 85,182.63 km² and, divided into 3 provinces (Tambopata, Manu and Tahuamanu), is the third biggest region in Peru (Instituto Nacional de Estadistica e Informatica [INEI], 2017) According Holdridge (1966), 14 life zones are found and, notwithstanding the richness in biodiversity that this region holds (Gentry, 1988), it has been suffering the constant pressure of human activities such as cattle raising, agriculture, logging and mining (Venter, et al., 2016). Gold mining has increased rapidly in the region (Asner, et al. 2013, et al**)** and has become the main source of income for local and outer residents. This activity is mostly realized in a small scale, but it has led to a severe loss of forest cover, 6145ha/year (Román - Dañobeyta , et al., 2015).
To conduct this study the sites and plots were chosen based on two criteria: 1) managed by the same individual or organization and 2) early successional plots must had a considerable distance to remnant forest. Thus, following the first criteria, 2 sites were chosen (Figure1). The first was Paolita Mining Site, following the Madre de Dios River 30 minutes away from the town Laberinto which is located 45 minutes away from the capital of the region (Puerto Maldonado), and Santa Rita mining site, located in the buffer zone of the Tambopata National Reserve, adjacent to the Interoceanic Highway. Satellite images and aerial photos where used to stablish the plots.
The study area lies within two Landsat scenes (path-rows 02-69 and 3-69). A collection of all Landsat Thematic Mapper (TM)/Enhanced Thematic Mapper Plus (ETM+)/Operational Land Imager (OLI) images with less than 40% cloud cover from archives of the United States

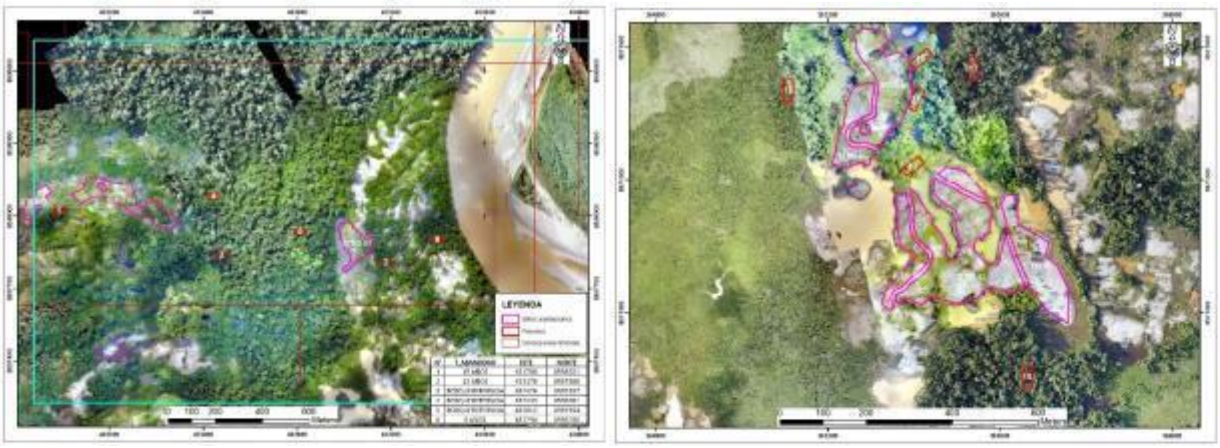

Figure 4: Aerial photos of Paolita mining site (left) and Santa Rita mining site (right).

Geological Survey (USGS) were used. This resulted in a collection of 68 Landsat images spanning 34 years from 1985 to 2017. With this results 6 plots, each one measuring 20mx50m

(0.1ha), were randomly stablished at each site, giving a total of 12 plots (6 plots with an early stage of succession and 6 plots that served as reference forest) with an age after abandonment that goes from 2 to 18 years.

Data analysis

Each plot was given a name depending on the mining site. For Paolita mining site plots were named after the letter P and numbered from 1 to 6 been early stages of succession plots P1, P2 and P6, and old growth forest P3, P4 and P5. In Santa Rita mining site plots were named after ST and number from 13 to 18, where early successional plots were ST13, ST 14 and ST15, and old growth forest ST16, ST17 and ST18. For each plot, the total number of individuals was recorded as well as recognized to the maximum level classification (specie). Nomenclature were valeted and cross-checked using the Taxonomic Name Resolution Service v4.0 (Boyle, et al., 2013) and the website www.tropicos.org for double rectification. Diameter at breast height (DBH) of all seedlings equal or greater than 1cm was measured. For multi-stemmed individuals, each steam with a DBH ≥ 1cm was considered as one individual. Basal area of all species were computed. Diversity and similarity were measured with quantitative and qualitative indices (Kalacska, et al., 2004; Mora, et al., 2014). Thus, Shannon diversity index (H') and its respective evenness (E) was estimated (Kalacska, et al., 2004) and, for similarity analysis Jaccard's similarity clustering was computed (Kennard, 2016).

Results and discussion

Species composition

A total of 753 individuals were described in both sites, representing 144 species scattered in 44 families. The total number of individuals and species on each mining site were significantly different. At Paolita 436 individuals and 164 species were identified whereas at Santa Rita 317 individuals and 120 were found. The results showed a variation of species and individuals along the successional stage gradient as well as the dominance of some species. Number of individuals per plot and species composition was variable. It was expected (Wilkinson, 1999) that the number of seedlings of all species will decrease and become even as the stage of regeneration increases due its light demanding or shade tolerance. As other studies found (Peterson & Heemsker, 2001 and Liebsch , et al., 2008, et al.), it was confirmed that seedlings in old stages of regeneration were small in number compared with early stages. Early successional stages had a higher quantity of pioneer species and, although some pioneer species were found in remnant forest (P4&ST16) suggesting that at some point old growth forest were perturbated, results showed that there are some families exclusive to early and old stages (URTICACEAE and SAPOTASEA respectively) while others are present in all stages (MORACEAE). See Table 1. Stem density also changes along the years after abandonment together with dominance. For example, in Santa Rita mining site, plots with 8 years after abandonment(ST13&ST14), *Hieronyma alchorneoides* (Allemão) and *Guatteria megalophylla* (Diels) were the most representative species in early stages with a Relative Abundance (RA) equal to 20.83% and 25% respectively but, in the old grow forest the RA for both species changed significantly. Only one individual of *Guatteria megalophylla* (Diels) was found in both reference forest, and no natural regeneration of *Hieronyma alchorneoides* (Allemão) was found in old stages. In Paolita mining site, *Ochroma pyramidale* (Cav. ex Lam.) Urb. and *Cecropia pachystachya* Trécul were two of the most abundant species in plot P2 (2 years after abandonment) with a RA equal to 41.79% and 17.91% respectively but, as the forest matures in age (P6 = 6 years) the RA of both species changed dramatically (1.8% and 3.64% respectively) and these two were not found in old growth forest. Presence or absence of some species generally suggest that the area has been perturbed at some point of its successional growth. Pioneer species, such as *Hieronyma alchorneoides, Ochroma pyramidale* and *Cecropia pachystachya* are early successional species or pioneer species with rapid growth, low nutrient requirement but highly light requirement (Kennard, 2016). Also, basal area (Relative Dominance) will change across successional stages as seen in the results. Early stages in Santa Rita's plot ST13&ST15 had a Relative Dominance (RD) of 33.26% and 23.25% for *Cecropia pachystachya* Trécul and *Ocotea obovata* (Ruiz & Pav.) Mez respectively while plots in Paolita showed a RD of 49.99% and 19.81% for *Muntingia calabura* L. and *Zanthoxylum rhoifolium* Lam. respectively.

Table 6: Structure composition of families found in Paolita mining site (P) and Santa Rita mining site (ST). Plots are arranged from early successional stages (upper row) to old growth stages (downer row). Only families with a composition major or equal to 6% are represented in this table

	Family	**Composition (%)**	**N◦ of species**		**Family**	**Composition (%)**	**N◦ of species**

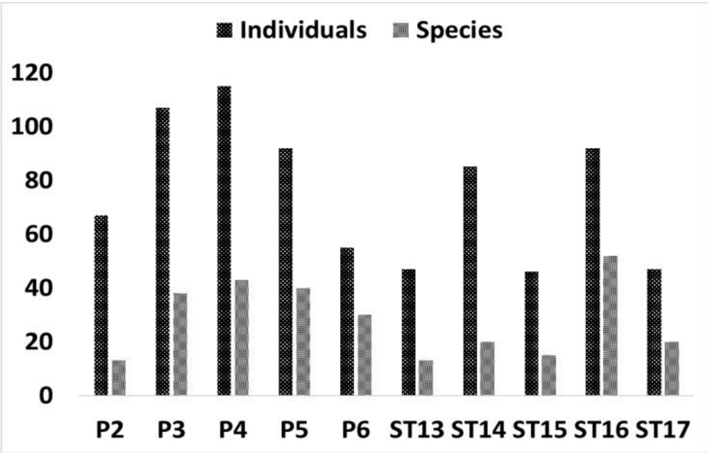
Diversity and similarity measurements

Wilkinson (1999)proposed that immediately after the disturbance of an ecosystems, low levels of diversity is expected and as the successional stage increases, diversity will increase proportionally (Intermediate Disturbance Hypothesis). Not only our results agree with this hypothesis but also the results from several studies (Kalacska, et al., 2004; Mora, et al., 2014; Peterson,et al., 2001).



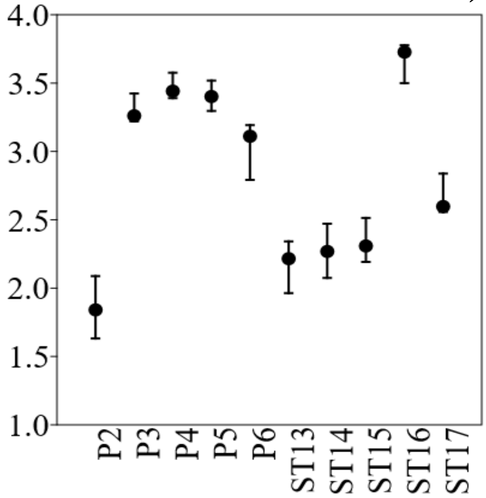


Figure 5: Paolita and Santa Rita's individuals and species composition (left). Shannon's diversity values of all plots (right)

As seen in Figure 2 and Table 2, Low levels of biodiversity, species and individuals were found in early stages and showed progressive increase over time. A significant difference in diversity was found not only within plots but also between mining sites (Paolita had higher diversity than Santa Rita mining site). In Paolita, the most resent disturbed plot (P2) showed the lowest level of diversity among all study plots, consecutively plot P6 (6 years successional stage) showed a remarkable diversity, almost similar of the remnant forest.

Table 7: Detailed summary of data from Paolita and Santa Rita's plots indicate that as the successional stage of regeneration increases, levels of biodiversity increases in a proportional way.

Plots	SHANNON (H')	Evenness (J')	Individuals	Species	Years after abandonment
P2	1.84	0.72	67	13	**2**
P6	3.11	0.91	55	30	**5**
P3	3.26	0.90	107	38	**RF**
P4	3.44	0.92	115	43	**RF**
P5	3.40	0.92	92	40	**RF**
ST13	2.22	0.86	47	13	**8**
ST14	2.27	0.76	85	20	**8**
ST15	2.31	0.85	46	15	**15**
ST16	3.73	0.94	92	52	**RF**
ST17	2.60	0.87	47	20	**RF**

Remnant forest showed in Paolita mining site showed an oscillation of diversity values as well as in its structural composition and, compared with Santa Rita mining site, early stages

also presented low but increasing levels of diversity. When the data was computed, plot ST16 and ST17 (both old growth forest) presented a significant difference in diversity (ST16 = 3.73 and ST17 = 2.60). This significantly difference between these two old growth forest's diversity and number of individuals made us suggest that 1) although plots in Santa Rita are older than the stablished in Paolita and despite the fact that Santa Rita is located in the Tambopata National Reserve's buffer zone, the pressure over the land its proved to be higher (Asner et al. 2013)since its proximity to the Interoceanic Highway (Caballero Espejo, et al., 2018), 2) soil condition varies between sites and plots. Moran, et al. (2000) inicates that soil fertility greatly influences seccondary succession and that nutrients are stock in the vegetation rather than the soil itself. Thus, with a simple visual identification of soil properties, we found that soil in Santa Rita where secondary forest was present was sandy (Podzol)
indicating that leaching of nutrients was hiegher. Therefore, having sandy soils and low nutrients avobe-ground gives as results less individuals and diversity with a slow recovery.

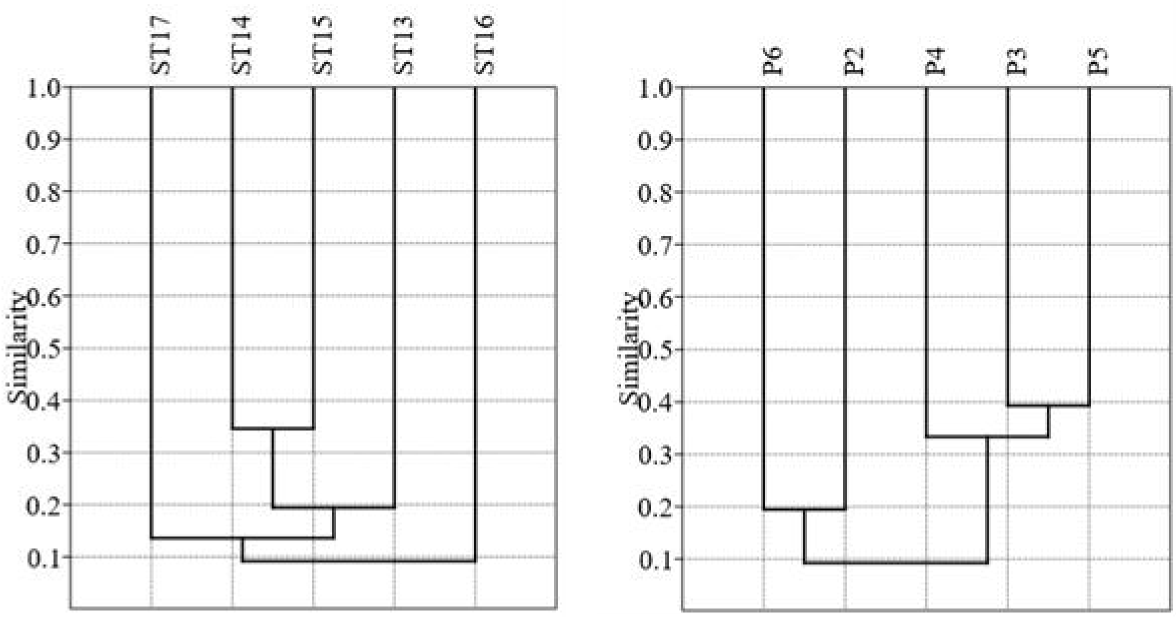

Figure 6: Jaccard's similarity clustering computed for both mining sites suggested that nearby remnant forest in Santa Rita has effect over natural regeneration over secondary succession.

Paolita, in the other hand, presented a different type of soil, where alluvial rocks were predominant, its proximity to the Madre de Dios river makes the soil much richer in nutrients which increases favorable conditions for the forest recovery (Jordan, 1985) even when disturbed. Plot P6 is an example of how fast the area could recover giving a great expectancy over P2 (2 years after abandonment) to follow the same trent (Liebsch, et al. 2008). Finally, 3) although both sites presented extreme pioneers, we proposed that nearby remnant forest accelerates recovery of disturbed areas and that the isolation of remnant forest and how far are located from the early stages could suggest lower or higher levels of diversity affecting recovery after disturbance. Thus, to address this hypothesis we conducted a Jaccard's similarity clustering (Figure 3) . This index was used to find floristic similarity between successional forest and old grown forest (Kalacska, et al., 2004). In the clustering graphic the similarity distance goes from 0 (0% of similarity) and 1 (100% similarity). Thus, clustering analysis showed that the closest similarity between early successional stage (P6) and old grown forest (P4) was 18%, both plots 713m away from each other, and the less similarity was found between P2 (early successional stage) &P3 (old growth forest), these two plots were 100% dissimilar and both plots 616m away from each other. For Santa Rita the closes similarity was found between plot ST17&ST15 (old growth forest and early stage respectively) with a similarity equal to 18%, both plots 124m away from each other, and the lest similarity was found between plots ST13&ST16 with a similarity equal to 2%, both plots 544m away from each other. From these results we could corelate diversity and similarity between plots at each site. Even though in both sites, the closest similarities between early stages and old growth forest is the same (18%) and considering the distance between plots, suggest that there is no significant influence of remnant forest over species composition and recovery in Paolita since these plots (P6&P4) are considerably far from each. This observation has relation with the study presented by (Tabarelli, Mantovani, & Peres, 1999) on how fragmentation affects diversity. Another factor for boosting the recovery observed in Paolita might be caused by the Madre de Dios river itself which could serve as a natural corridor for seed dispersal (Tewksbury, et al., 2002) and, following the same statement, in Santa Rita mining site, similarity between plots ST17&ST15 suggest that remnant forest has influenced over the recovery of early stages of regeneration due its proximity from each other but, considering that ST17 has a low diversity level and the forest fragmentation is considerably higher, it also caused a low-diversity regeneration present in early stages, even when plots in this area are older than those stablished in Paolita.

Conclusion

The impact produced by gold mining over forest lost has been studied previously by Caballero Espejo, et al., (2018) and several reforestation trials have been conducted in the last decade (Román - Dañobeyta , et al., 2015). Between 1987 and 2017 nearly 100,000ha of forest were lost and, as seen during the process of making this paper, it is more likely that this number has already been surpassed. Ecological restoration is far to be accomplished due the severity of the degradation not only above-ground but soil itself. Results proved that forest regeneration could be achieve in at least 6 years after abandonment as seen in Paolita (Table2) but we must consider that there are several factors that might and might not boost natural regeneration although nature has a high resilience over disturbances; severe deforestation, forest fragmentation and soil condition directly affects natural regeneration. We might concluded that nearby remnant forest might not have a direct influence over regeneration as results from Paolita showed (Figure 3), but instead several factors influence the recovery of degraded tropical forest. For a deeply understanding of the recovery of degraded forest, the addition of some other factors (seed bank, proximity of remnant forest to the degraded area, etc.) is required. This study focused on the passive ecological restoration of the tropical rainforest ecosystem. There are some studies that proposed different approaches of restoration or reforestation (Attiwill, 1994; Romell, et al., 2008, Pereira, et al., 2008; et al.) but given the scale of deforestation seen in Madre de Dios, a holistic approach that include stakeholders and other actors as part of the restoration of this valuable ecosystem is needed.

Acknowledgment

This study was made possible through the funding of the United States Agency for International Development (USAID) under the terms of USAID/WFU Cooperative Agreement No. AID-527-A-16-00001 to establish the Centro de Innovación Científica Amazónica (CINCIA). Additional funding was provided by the World Wildlife Fund (Agreement OT11) and the Wake Forest Center for Energy, Environment, and Sustainability.

Abstract

Lignite used in thermoelectric factories contains a number of trace elements which are dispersed in the environment during coal combustion. In this scientific research a comparative investigation has been carried out concerning the bioaccumulation of seven heavy metals (Cr, Mn, Fe, Ni, Cu, Cd and Pb) in trees, mosses and lichens from the northwest part of Greece, where the facilities of West Macedonia Lignite Center (WMLC) are located. In that direction, 71 soil samples and 92 samples of plant organisms were collected and utilized. In essence, the heavy metals concentrations were determined in all samples and then the calculation of the soil to plant Transfer Factors was conducted. The results revealed a discernible loading in some tree species, which however, did not exceed the legally established limits. On the contrary, mosses and lichens displayed much higher transfer factors, confirming their ability to bio accumulate air pollutants. Another conclusion is that chromium, manganese, iron, nickel, cadmium and lead compared to unpolluted areas are systematically increasing in tree leaves in the vicinity of WMLC. This fact cannot be attributed to soil uptake, given that soil parameters in the study area immobilize most of the heavy metals. The most reliable explanation for their origin is the flying ash of CPPs, which is rich in more of the metals in question.

Keywords: *Fly ash of lignite, Heavy metals, Bioaccumulation, Lichens and Mosses.*

Introduction

Low quality lignite is the main fuel for electricity production since 1950 years in Greece (Ganatsios *et al*., 2001). West Macedonia Lignite Center (WMLC), located in Northwest Greece has four lignite power plants, which release significant amounts of fly ash. The particulate matter of ash, which contains heavy metals (Adamidou *et al*., 2007), is the main pollutant of the WMLC basin (Triantafyllou *et al*., 2006). This paper investigates the uptake and accumulation of pollutants in plants, which may follow two different paths, i.e. through the root system or through the leaves or other aerial parts. From this point of view it is interesting to investigate simultaneously two different kinds of plants. The first one includes mosses and lichens, which have neither real roots nor vascular system. They are well known to scientists as ideal pollution bio-indicators, especially for airborne particles containing metals and radionuclides, because they appear high values of accumulation rates (Sawidis *et al*., 1993), (Sawidis *et al*., 1995). The second category contains two types of trees, evergreen and deciduous, which are not the best indicators, however they are the major plant types found around the WMLC stations.

The ability of plant organisms to absorb and accumulate pollutants is better described by numerical parameters such as Transfer Factor (TF), defined as the ratio of the concentration of a given element in the investigated terrestrial organism to that found in the soil (Papastefanou *et al*., 1999).

In this paper the concentrations of seven heavy metals were determined in samples of mosses, lichens and trees, collected from the WMLC basin and an investigation was performed towards the relationship of the metal concentrations in the plants with the respective ones in the soil. Furthermore, the TF values were calculated using data for the soil concentrations based on previous work (Tsikritzis *et al*., 2002).

Material and Methods

The samples were collected from 13 sampling points, i.e. 11 for trees and 2 for mosses and lichens (Fig. 1) following the North-Northwest to South-Southwest direction of the wind, which is the dominant one at the WMLC basin (Triantafyllou *et al*., 2006). Sample point No 11 was chosen as a reference.

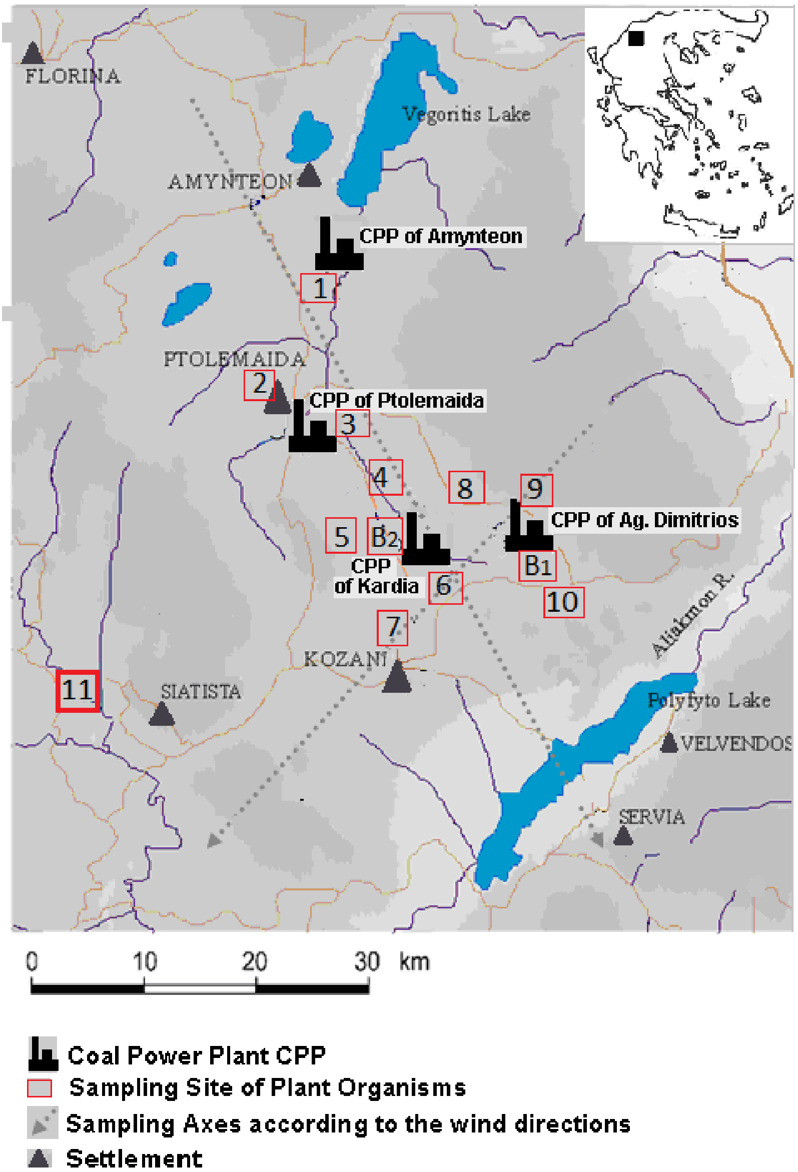

Figure 1. The general map of WMLC with the sampling points. (B1) and (B2): the sampling points of both mosses and lichens. (1) – (11): the sampling points of tree leaves.

The following species of plant organisms were investigated:

a) Six moss species: *Grimmia laevigata, Rhocomitrium canescens, Tortula ruralis, Eucalypta strteptocarpa, Homolotecium aureum, Tortella tortuosa.*
b) Five lichen species: *Cladonia rangiformis*, *Parmelia sulcata*, *Pertusia sp.*, *Cladonia convoluta*, *Xanthoria parietina* and

c) Leaves of four tree species: *Pinus nigra, Pyracantha coccinea, Prunus amygdalus* and *Populus nigra.*

After being collected all samples were washed, air dried, grind and sieved with a 2 mm mesh. Instrumentation: The metals Cr, Mn, Fe, Ni, Cu, Cd and Pb were determined using a graphite furnace Perkin-Elmer AAnalyst 800 complete with AA Winlab software. For this purpose 0.5 g of dry samples were digested with 4 ml of HNO_3 (Merck pro analysis) 65%, and 1 ml of HCl (Merck pro analysis) 37 % for 20 min in a Paar Physica microwave oven.

Results and Discussion

The concentrations of the investigated 7 heavy metals in plants are shown in Table 1 for each plant category. Table 2 contains the TF average values for each metal excluding Fe, that had not been measured in soil and therefore its TF value was not calculated.

Table 1. Average values (± SD) of the heavy metals determined in lichens, mosses and tree leaves (in mg/kg).

Type of plant	Cr	Mn	Fe	Ni	Cu	Cd	Pb
Lichens (23 samples)	53.3 ± 9.2	75.8 ± 45.0	5935 ± 2693	42.2 ± 1.7	12.4 ± 2.0	0.48 ± 0.15	19.53 ± 6.08
Mosses (25 samples)	68.93 ± 43.7	313.2 ± 93.6	11982 ± 9335	46.2 ± 23.7	23.7 ± 8.4	0.95 ± 0.81	28.44 ± 10.20
Tree leaves (44 samples)	2.07 ± 1.44	73.3 ± 46.5	382.1 ± 173.9	4.87 ± 4.47	7.31 ± 2.61	0.18 ± 0.35	1.45 ± 0.70
Toxicity range*	5 to 30	400 to 1000		10 to 100	20 to 100	5 to 30	30 to 300

*Kabata-Pendias A. and Pendias H. (1992)

Table 2. Average values of the TF of the metals determined in lichens, mosses and tree leaves

Type of plant	TF of Cr	TF of Mn	TF of Ni	TF of Cu	TF of Cd	TF of Pb
Lichens	0.172	0.151	0.127	0.324	1.824	1.207
Mosses	0.291	0.406	0.152	0.584	3.015	1.712
Tree leaves	0.010	0.140	0.032	0.233	0.737	0.134

The following conclusions could be extracted with regard to the dispersion and bio-accumulation of the determined metals in the plant organisms through the air and the soil:

In mosses and lichens the metal values are classified according to the following descending order Fe > Mn > Cr > Ni > Pb > Cu > Cd. These results are similar to those reported earlier (Sawidis *et al*., 1993), (Sawidis *et al*., 1995), (Sawidis *et al*., 2001), for the same region. However, the metals Fe, Mn, Cr, Ni and Cu revealed higher concentrations than those found in other polluted regions (Rodrigo A. *et al.*, 1999), (Genoni P. *et al*., 2000), (Bargagli R. *et al*., 2002).

The TF values are less than one (<1) for all investigated metals, except Cd and Pb, which show TF values more than one (>1) for both mosses and lichens.

Mosses display systematically higher transfer factors (TF) than lichens and therefore a higher bioaccumulation level. *Grimmia loevigata* is the best Cr and Fe indicator of all mosses, whereas the species *Cladonia convoluta* is the best Cr indicator of all lichens.

Concerning the tree leaves, the concentrations of the investigated metals are classified according to the following descending order Fe > Mn > Cu > Ni > Cr > Pb > Cd. In comparison with the respective classification of metals in mosses and lichens the Cr has been seen to recede from the third to the fifth place in tree leaves, which is mainly due to the almost zero uptake of Cr^{3+} through the tree roots, as explained in detail at the end of this chapter.

The bioaccumulation capacity in tree leaves is much smaller than in mosses and lichens and the TF values of trees is always <1. This profound "superiority" of mosses and lichens is attributed to the fact that they have a long cycle of life during which they continuously accumulate heavy metals from the environment and thus are more suitable subjects for long term pollution investigation. On the contrary, trees, evergreen or deciduous, are more suitable for monitoring of short term pollution processes.

It should also be mentioned that for the same category of plants, the concentrations of the metals in question are slightly influenced by the type of each species.

The final and perhaps most important conclusion is that the concentrations of most metals (Cr, Mn, Fe, Ni, Cd and Pb) in the leaves of all tree species are systematically higher than those of the reference (unpolluted) station. This cannot be attributed to their exclusive uptake through the soil, because: 1) The concentrations of these metals in the soil are very low. 2) The characteristics of the most soils in the study area, such as the alkaline pH values and the high concentrations of calcium, drastically reduce the mobility of most metals and result in low Transfer Factors to the plants.

Therefore, taking into consideration that the possibility of metal uptake from the soil is quite low, the relatively high concentrations of metals in the leaves of most tree species must be attributed to the uptake through the atmosphere and mainly through the deposition of the suspended particles of the lignite fly ash, which is rich in most of the investigated metals. More specifically, the main source of metals Cu, Cd, Ni, Pb and Cr is the fly ash particles, whereas the presence of Fe and Mn is basically attributed to their uptake from the soil. Figure 2 shows a Multidimensional Scaling (MDS) diagram, where Fe – Mn determined in tree leaves form and belong to a separate cluster (I) from the other metals (II). This division of metals into "soil group" (I) and "fly ash group" (II) does not apply to mosses and lichens, which is quite reasonable, since the nutrients and other ingredients of these organisms are almost exclusively uptaken from the atmosphere.

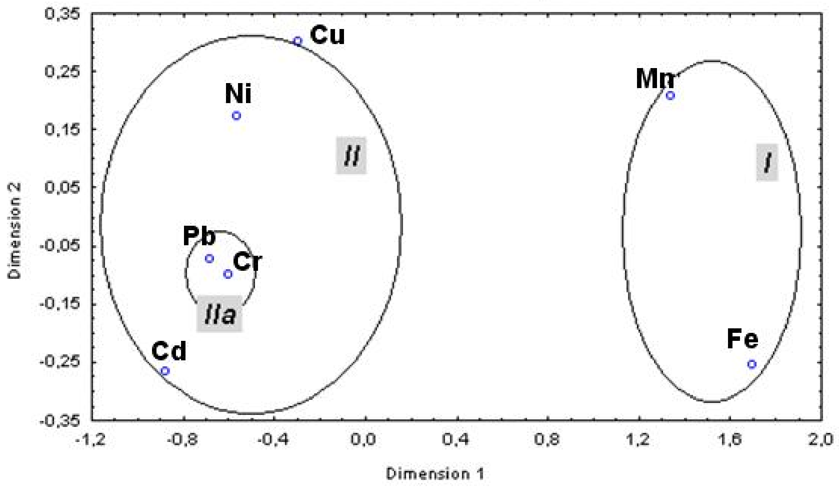

Figure 2. Results of MDS analysis applied on the concentrations of the heavy metals determined in the tree leaves

Furthermore, the spatial distribution of the sampling points shows that the trees around the coal power plants (especially the Ptolemais one) are more polluted, without great differences though.
Finally, special consideration should be given to Chromium. Cr values for all species are systematically higher than those of the reference (unpolluted) station. Particularly in *Populus Nigra* they approach the bibliography toxicity or excess limits, that is 5-30 ppm (Kabata-Pendias A. and Pendias H., 1992)
One would expect that the high concentrations of Cr in the soil of some areas of WMLC basin (central–eastern and southwestern) (Tsikritzis *et al*., 2002) should be accompanied by similar increase in the concentrations of Cr in tree leaves collected in the above mentioned areas (No 7,8,9,10). But in reality this is not the case, or more correctly it is less common than expected, because in these soils Cr appears mostly as Cr^{3+} ions which are insoluble at high pH values as those ones of the study areas, pH 7- 8,5 (IGME, 2001).
Since the likelihood of the leaf Cr being uptaken from the soil has been almost eliminated, the relatively high concentrations of Cr in the tree leaves should be attributed to the air pollutants, i.e to the deposition of the flying ash of CPPs, which is rich in Cr.

Conclusions

The comparative investigation of three different categories of plants with respect to the distribution and bioaccumulation of seven heavy metals (Cr, Mn, Fe, Ni, Cu, Cd and Pb) has shown that the highest capacity to absorb and accumulate these elements belongs to mosses and lichens and less to tree leaves.
In comparison with unpolluted areas, the concentrations of Cr, Mn, Fe, Ni, Cd and Pb are systematically increased in vascular plant leaves in the vicinity of all CPPs. This fact cannot be attributed to soil uptake, given that soil parameters in the study area such as high pH and calcium values, immobilize most of the heavy metals. The most reliable explanation for their origin is the flying ash of CPPs, which is rich in more of the metals in question.

BROWNFIELDS AS ENVIRONMENTAL QUALITY INDICATOR: CASE OF LATVIA

Velta PARSOVA*, Vivita PUKITE

Department of Land Management and Geodesy, Latvia University of Life Science and Technologies, Latvia
*Corresponding author: velta@parsova.lv

Abstract

The background of investigation is the growing importance of the global economy, which shows that one of the basic natural resources - intensity of land use - is increasing. Often it is the cause of land degradation processes. Expressions of brownfields are diverse, and their elimination and gradual prevention is the first prerequisite for the sustainable use of land resources and development of each territory. Earlier studies in Latvia show that degraded land does not have one significant feature which would allow to determinate it as a "typical" brownfield. Sustainable land management is a key factor in the rational use of land resources, including the reduction of land degradation and putting in order of degraded territories. Improvement, maximal and efficient engagement of brownfields in economic activity is one of the key challenges for sustainable resource use that makes significant contribution to regional development. Determination of brownfields is essential part of territorial and land use planning which is strongly related to the implementation of sustainable development programmes and planning of further actions in all municipalities. The reuse of brownfields has significant impact on sustainable development as meets all objectives: improving the economy, improving social cohesion and the environment. The objective of investigation is on the basis of special literature to develop scientifically based proposals for possible solutions in regeneration of brownfields and its benefits for development and sustainable use of resources, transformation of brownfields into recreational areas, as well as further use of brownfields in cities and rural areas.

Keywords: *Degraded territory, brownfield, land resources, regeneration, sustainable development*

Introduction

It is very important to ensure conservation and sustainable use of the land because the land is limited, non-renewable resource. In circumstances of growing of global economy, intensity of land use is increasing as well. Because of different economic activities, including industrial activities, and influence of natural conditions, land and soil degradation process has occurred leading to the formation of brownfields. Reduction of land degradation and arrangement of brownfields is one of the factors in rational use of land resources (Akhtar-Schuster M. et al., 2016).

One of the aims of sustainable environment resolutions adopted by the United Nations General Assembly in 2015 was "to restore degraded land and to aim to achieve having a world neutral to land degradation" (UN General Assembly, 2015). This is the first worldwide document where universal and comprehensive measures regarding land degradation are provided. In recent years have been accepted a lot of high-level decisions in regard to land and soil degradation and its prevention. These documents set goals for sustainable development that includes an economic, social and environmental dimension. One of objectives of environmental dimension is regeneration of brownfields.

The process of formation of brownfields in Latvia has been similar to other Eastern European countries and partly to Western Europe. Most amount of brownfields appeared after collapse of the Soviet system, their development was influenced by transition to market economy and changes in industry. Brownfields mostly are industrial sites, their infrastructure, abandoned military bases and sites where construction started many years ago but still is not completed. Total area of brownfields in Latvia is considerably small compared to some Eastern European countries. Ministry of Environmental Protection and Regional Development has discovered that about 6 thousand ha of municipal and private land is degraded (Gerhards, 2018).

At the end of 2014, Land Management law in Latvia was adopted. The law defines the term of land degradation and obliges local authorities to display degraded territories on territorial planning documents, while land owners are obliged to carry out prevention measures of land degradation. Land degradation is defined as reduction or disappearance of the economic or ecological value of land and associated to land resources, as a result of natural processes or human activity, or inaction. In general, degraded area is explained as an area with damaged surface of the earth, or abandoned build-up, mining, economic or military activity territory.

The general objective of brownfields revitalization is to promote the sustainable development of urban and rural area: maximal elimination of brownfields thus contributing to environmental regeneration. This includes solving of environmental problems and increasing the economic efficiency of territory use, improving visual and structural functional quality of environment, as well as humanization elements of the social environment. Specific circumstances in each region determine which aspects should be more observed in the context of real situation.

Latvian scientists have shared results of their scientific investigations and experience in evaluation of brownfields (Parsova *et al*., 2017; Platonova *et al*., 2017; Klavins *et al*., 2008). Systematic approach to land degradation issues has been demonstrated in investigations of Western European scientists (Ferber, 2006), etc. Significant contribution to this problem has been made by Central and Eastern European scientists (Kunc *et al*., 2014; Frantal *et al*., 2015; Simion, 2016; Juozapaviciute, 2016)

Material and Methods

The **purpose** of this article is to evaluate Latvian and foreign experience in brownfield regeneration on the basis of scientific literature and other information, as well as analyse its benefits. To achieve this goal **tasks** were performed as follows:

- to gather and analyse the sources of foreign and Latvian scientific literature on brownfields and their regeneration;
- to develop possible solutions in regeneration of brownfields;
- to analyse benefits of brownfield regeneration for development and sustainable use of the land.

To achieve the aim of study, information about types and features of present land and soil degradation had to be summarized. The authors have evaluated the information about land degradation in regulations of Latvia. They also examined international experience and had discussions and interviews with competent specialists in public institutions of Latvia (Ministry of Agriculture, Ministry of Environmental Protection and Regional Development, State Plant Protection Service, etc.). The study was conducted as a part of municipal and state institutions competent specialists' survey to find out the opinion of respondents on land degradation types, identification and prioritization of degraded land areas and information about the maintenance of degraded territories.

Knowledge and impressions obtained during planned study trip in Poland and Germany on regeneration of brownfields have been used as well. There general scientific methods of theoretical research: analysis and synthesis, induction and deduction, as well as monographic method have been used.

The **object** of research is degraded build-up area. Processes of land degradation can express in different ways. At the moment in Latvia does not exist accepted on governmental level

classification of brownfields. Public discussions on proposals of classification of types of land degradation and methods for its evaluation have been opened by Cabinet of ministers in 2019 (Table 1).
Table 1 shows that degraded build-up territories are one of the types of land degradation and they can be divided into three sub-types: degraded residential or public build-up, industrial and military territories. In all cases there are located abandoned buildings, constructions or other objects that are not managed and endanger human health or life due to their physical wear and tear or harm the environment.

Table 1

Classification of types of land degradation
(draft, developed by Cabinet of Ministers of Latvia)

Type of land degradation	Sub-type of land degradation
Degraded build-up area	Degraded residential or public build-up area
	Degraded industrial area
	Degraded military territory
Degraded mineral extraction site	Non-recultivated mineral extraction site
Waste disposal at non-designated for this purpose sites	Waste disposal, preservation and storage in non-designated for this purpose sites
Land pollution	Pollution of the territory by hazardous substances
Spread of invasive plants	Territory infested with invasive plants

To determine degraded build-up area it is necessary to define characteristic features (table 2).

Table 2

Features characterising degraded build-up areas

Sub-type of land degradation	Feature of land degradation
Degraded residential or public build-up area	Territory on which are located abandoned or incompletely used residential buildings or public buildings which do not fulfil their intended function, or which are not managed, or endanger human health or life due to their physical wear and tear, or harm the environment
Degraded industrial area	Territory on which are located abandoned or incompletely used production facilities where economic activity has been suspended, or they do not fulfil its intended function, or they are no longer managed, or endanger human health or life due to their physical wear and tear, or harm the environment
Degraded military territory	Territory on which is located abandoned military object, which do not fulfil its intended function, or is no longer managed and endanger human health or life due to physical wear and tear, or harm the environment

Results and Discussion

It can be concluded that in the world, especially in Europe, the issue of brownfield regeneration began to play a prominent role in development programs in the end of last century. Already almost for 50 years solutions with international approach has taken place and theory and experience of brownfields regeneration has been developed. They are linked to wide range of issues of sustainable urban and regional development. Regeneration of brownfields strengthens the vitality and efficiency of urban area.

It can be also concluded that brownfields are rapidly developing in process of social and economic changes. Symptoms of chronic unemployment and social stratification of society always have very negative economic and physical impact on the territory. In Eastern Europe in post-industrial period brownfields developed due to transformation of industrial environment. In post-industrial society much less space is needed for production, but much more for services, consumption and entertainment (Juozapaviciute, 2016). Examples of post-industrial transformations can be found in Latvia, too.

Reuse of brownfields has significant impact on sustainable development because it meets all three of its objectives: improvement of economy, social cohesion and environment. When economic activities return to degraded areas, these areas have been significantly improved and therefore greenfield areas are preserved. New activities taking place on former brownfields create new opportunities for public, increase employment, income, etc. Remediation of brownfields can also improve social cohesion, prevent risks to the environment, protect cultural and historical values and improve quality of life. The contrast between modern and historic, creating new tower of views from which a view of the historic castle is open, is showed on fig.1.

Fig.1. Park for recreation and entertainment near Bauska castle

Renovation of brownfields has positive impact on real estate prices. Further savings are achieved through the opportunities offered by existing resources and infrastructure (buildings, energy, sewerage networks, etc.) and transport options. Planning taking into account public needs can maximize investment in brownfield redevelopment also for builders and landowners. Extraordinary residential complex "Gypsum Factory" is located on the bank of Daugava River and has wonderful panorama to Old Riga (fig.2).

Fig.2. Arrangement of residential and office spaces in old abandoned factory in Riga

One of the main drivers of brownfield regeneration is the economic revitalization of the urban area and potential profits. The role of brownfields in supporting economic development and competitiveness in Europe has become increasingly important. Most often this is case in traditional former industrial areas. Revitalization of brownfields affects different market areas: land market, real estate market, labour market, capital market, financial market, resources market; infrastructure market; innovation market. Analysing foreign experience, it can be concluded that aim is to develop sustainable localities with higher quality of life. One of the key elements of high-quality urban development is accessibility and good connection with open space (fig.3).

Fig.3. Arrangement of park for recreation and entertainment near railway station in Rezekne

Many of regenerated sites once have been an "engines" that facilitated the industrial revolution - coal mines, quarries and edges of channels. With the decline of heavy industry, often these territories became abandoned, sometimes dangerous.

There are many examples in the world with a long history and relevant experience, where public and commercial centres, museums and exhibition galleries, relax and recreation areas, amusement parks, sports centres etc. cultural objects for local public and visitors have been created. Often they change the habits of the city and people. The development of urban areas takes place on the basis of more efficient use of existing built-up land and with infrastructure for new construction, thus preventing new investments in the construction and maintenance of transport and other infrastructure (Kunc, 2014; Simion, 2016).

Getting acquainted with activities of several Eastern European countries in the regeneration of brownfields can be recognized several similar features. Major cities are undergoing major changes in functions. New activities take place in the premises of former industrial companies and in areas where military objects and railway lines were predominant. As a result, rehabilitation of brownfields became one of the first issues of territorial development along with changes in property rights after breaking off of industrial activity and real estate market reorganization after 1990.

More exposed to reconstruction are former production sites in industrial areas with good location, where it was easier and cheaper to reconstruct or completely demolish the buildings. The changes are also characteristic for less favoured areas of industry, where typical phenomenon is continuous preservation of previous buildings, simply replacing their earlier functions with commercial, warehouse and logistics functions. In many abandoned industrial and infrastructure territories the preserving industrial buildings and structures as monuments of the era and their use for cultural, educational and tourism purposes have been observed (Juozapaviciute, 2016; Platonova, 2017).

Summarizing and analysing scientific publications on regeneration of brownfield sites and evaluating benefits from it, several regularities and variants of brownfield regeneration can be distinguished:

- arrangement and construction of shopping centers;
- arrangement of science and technology parks;
- preservation of industrial heritage;

- development of cultural, educational and business centres;
- arrangement of residential and office spaces in old abandoned industrial buildings;
- arrangement of parks for recreation and entertainment, amusement and sports activities, etc.

Conclusions

In large cities of Europe are undergoing major functional changes. In post-socialist countries these changes have taken place in shorter period of time than in Western Europe. For reconstruction more exposed have been former manufacturing sites with good location.

Arrangement and construction of shopping centres is one of widely used forms of abandoned brownfields in Eastern Europe. New science and technology parks promote innovations, research and development, and support start-ups. Protection of historic buildings and monuments is a case of transformation and replacement of architecture heritage, because existence of an industrial culture has been the driving force of the economy since the Industrial Revolution.

Reuse of brownfields has the significant impact on sustainable development – improvement of economy, social cohesion and environment.

HABITAT TYPES OF EUROPEAN IMPORTANCE ON THE JAHORINA MOUNTAIN (BOSNIA AND HERZEGOVINA)

Natasa MARIC, Sladjana PETRONIC, Vesna TUNGUZ

Faculty of Agriculture, University of East Sarajevo, East Sarajevo, Bosnia and Herzegovina
*Corresponding author: natasa.bratic@yahoo.com

Abstract

The paper presents types of habitats of Jahorina Mountain which are of European importance. The review is made on the basis of studies of flora and vegetation and the Guide of the types of habitats according to the EU Habitats Directive. Research was carried out in the period of 2015-2016. Taking plant material and making phytocoenological recordings were done at different habitats. Identification of species was based on floristic literature. Phytocoenologically recordings were made by the method Braun-Blanquet. During the research the following habitats have been isolated: 4060 - Alpine and Boreal heaths, 6230 - Species-rich Nardus grasslands, on silicious substrates in mountain areas (and submountain areas in Continental Europe), 6410 - Molinia meadows on calcareous, peaty or clayey-silt-laden soils (*Molinion caeruleae*), 6430 - Hydrophilous tall herb fringe communities of plains and of the montane to alpine levels, 6510 - Lowland hay meadows (*Alopecurus pratensis*, *Sanguisorba officinalis*), 6520 - Mountain hay meadows, 7110 - Active raised bogs, 7120 - Degraded raised bogs still capable of natural regeneration, 7220 - Petrifying springs with tufa formation (Cratoneurion), 9140 - Medio-European subalpine beech woods with Acer and *Rumex arifolius*, 9410 - Acidophilous Picea forests of the montane to alpine levels (*Vaccinio-Piceetea*). The aim of the paper is to present a habitat in Jahorina that is significant for Bosnia and Herzegovina and the European Union.

Key words: *habitat, Natura 2000, Jahorina*

Introduction

The Jahorina Mountain is located in the central part of Bosnia and Herzegovina, southeast of Sarajevo. The Jahorina Mountain range is determined with coordinates 43˚ 39´ to 43˚ 47´ north latitude and 18˚ 31´ to 18˚ 43´ east longitude. It belongs to continental Dinarides with the direction of the main ridge from northwest to southeast. Jahorina massif is long about 30 km, with the highest peak Ogorjelica (1916 meters above sea level). In geological terms Jahorina is composed of a variety of rocks of Paleozoic, Mesozoic and Permkarbon Triassic age. The base consists of Carbon and Permian sandstones and shales, and above them there are Mesozoic Triassic limestones. From the land, on carbonate surface, the following have been developed: lithosols, organogenic and organomineral calcomelanosol, calcocambisol, luvisols, and on a silicate substrate: brown podzols, podzols, swampy gley peat and ranker. The lowest altitude position is in the climate which is temperate continental, in a central part of Jahorina is subalpine climate, and in the highest mountain areas is alpine continental climate (Petronic et al., 2009).

Because of the negative anthropogenic impact, natural habitats are destroyed on a daily basis, and many species die out. Connecting protected areas of Bosnia and Herzegovina in the European network of protected areas Natura 2000 is aimed to prevent the loss of biodiversity, preserve the habitat of endangered species and ensure their long term survival. For Bosnia and Herzegovina, WWF MedPO started a project to support the implementation of the European ecological network Natura 2000 in 2007. Based on the literature data, the research of authors, supported by The European Union, made the Habitat Types Guide of BiH according to the EU Habitats Directive (Milanovic et al., 2015). The aim of this paper is to present types of habitats in the area of Jahorina Mountain, which are significant for Bosnia and Herzegovina and the European Union.

Materials and methods

Floristic and vegetation research on areas are carried out from 2015. to 2016. Taking plant material and making phytocoenological recordings were done at different habitats. Identification of species was based on floristic literature (Javorka et Csapody, 1979; Beck, 1903 and 1927; Josifovic ed. 1970-1977). Phytocoenologically recordings were made by the method Braun-Blanquet (1965). During allocations European significant habitats on the Jahorina Mountain used data research of flora and vegetation and Guide to the types of habitats according to the EU Habitats Directive (Milanovic et al., 2015).

Results and Discussion

Based on explored flora, vegetation and habitats, according to the Review of the Habitats Directive of the European Union, the following habitats were isolated (table 1).

Table 1. Overview of habitat areas of Jahorina

Code	Name of habitats
4060	Alpine and Boreal heaths
6230	Species-rich Nardus grasslands, on silicious substrates in mountain areas (and submountain areas in Continental Europe)
6410	Molinia meadows on calcareous, peaty or clayey-silt-laden soils (*Molinion caeruleae*)
6430	Hydrophilous tall herb fringe communities of plains and of the montane to alpine levels
6510	Lowland hay meadows (*Alopecurus pratensis*, *Sanguisorba officinalis*)
6520	Mountain hay meadows
7110	Active raised bogs
7120	Degraded raised bogs still capable of natural regeneration
7220	Petrifying springs with tufa formation (Cratoneurion)
9140	Medio-European subalpine beech woods with Acer and *Rumex arifolius*
9410	Acidophilous Picea forests of the montane to alpine levels (*Vaccinio-Piceetea*)

4060 - Alpine and Boreal heaths

Alpine and Boreal heaths represent the stands of low, bushy and patchy shrubs of subalpine and alpine belt of the Eurasian Mountains. The communties of mountain pine, nowdays are limited on narrow belt of the highest dinaric mountains (Redzic at al., 2008). They are characterized with a very dense cover of characteristic species, usually up to 50 cm high. They usually occur as a result of the cessation of grazing on the subalpine grasslands and represent successive transitions to the bushes of mountain pine or vegetation of subalpine forests (Milanovic, 2015). Geological foundation are either carbonate or silicate rocks. Soil belongs manly in the class of humus-acumulative ones, which is black earth, rendsine and ranker (Redzic at al., 2008).

The degradation of forest vegetation of the highest parts of the Jahorina, from 1600 m to the peaks of the mountain, occurred in the ancient past, and this place was named Gola Jahorina (figure 1). Alpine and Boreal heaths on Jahorina were developed in the zone of mountain pine (*Pinus mugo*). The vegetation of mountain pine was retained on a small number of sites (Trijeska, Lokvansko brdo and Stjeniste) in extremely small areas. Surfaces under mountain pine have been cut down in the past and turned into spacious pastures (Bjelcic, 1966).

In deep and acidic soils of these natural successions dominate *Vaccinium myrtillus* in community *Hyperico maculati-Vaccinietum myrtilli* (Lakušić et al. 1979) Surina 2013, *Hyperico grisebachii-Vaccinietum myrtilli* (Lakušić et al. 1966) Surina 2013, while on the shallow soil on the carbonates there are comon Juniper communities (*Juniperus communis*) *(Arctostaphylo-Juniperetum nanae-intermediae* Stefanovic 1964 and *Sempervivo schlechani-Juniperetum alpinae* Bjelcic 1966) and *Arctostaphylos uva-ursi (Arctostaphyletum uvae-ursi Lakušić* et al. 1979). On wet recess there are community with *Salix silesiaca* (Bjelcic, 1966).

Figure 1. Gola Jahorina

6230 - Species-rich Nardus grasslands, on silicious substrates in mountain areas (and submountain areas in Continental Europe)

Species-rich Nardus grasslands are dry to mesophilic. They develop on acidic soils of Atlantic, subatlantic and boreal lowlands, hills and mountains, but in the southern part of Europe only occur on the mountains. In these grasslands is dominated *Nardus stricta* and other acidophilic species. They are typical for silicate massifs, but also occur on carbonates, only on flatlands and valleys, where the soil is deeper and more acidic, and the influence of the substrate is isolated or limited. They are mainly formed as a result of the shrinkage of subalpine forest or shrub vegetation, because the cattle are glad to graze and have plenty of food, but they are often so impoverished that they become almost monotypical. These monotypic grasslands can not be included in this type of habitat (Milanovic, 2015).
Species-rich Nardus grasslands on Jahorina belong to association: *Aurantiaco-Nardetum strictae* Ht 1960, alliance: *Jasionion orbiculatae* Lakušić 1966, order: *Seslerietalia comosae* (Sim.) Lakušić 1966 and class: *Caricetea curvulae* Br.-B. 1948.

6410 - Molinia meadows on calcareous, peaty or clayey-silt-laden soils (*Molinion caeruleae*)

The habitat includes meadows of *Molinia caerulea* from the lowland to the mountainous belt, which developed on wet, basic, neutral to acidic soils, mainly poor nitrates (figure 2). They usually occur by natural or artificial drying of peat bogs and by cutting of forest vegetation on acidic soils and slightly sloping slopes. Fertility reaches into the late summer and maintained by regular mowing or annual burning.
Purple moor meadows are very heterogeneous and should be observed in the proper interpretation of the habitat. Purple moor stands out as a dominant species in several types of lawn, and only some of them can be included in this habitat. In addition, the genus *Molinia* encompasses more similar species, which make ecologically and physiologically different

lawns. This habitat type includes Central European meadows of alliance *Molinion caeruleae* W. Koch 1926, which are rarely found in our conditions and are found mainly in the mountain range of silicate massifs. These are secondary constructions created by the cutting of forest vegetation on the gentle slopes with very deep, in springs extremely humid, acidic soils. These lawns are mowing once in the late summer and dont give good food for cattle, because they are abandoned and left to heal or held by burning before the end of the vegetation season (Milanovic, 2015). In the area of Saracevo polje, on wet meadows, there are few stands where dominated purple moor (Petronic i Pavlovic, 2012).

Figure 2. Molinia meadows on Jahorina

6430 - Hydrophilous tall herb fringe communities of plains and of the montane to alpine levels

Hydrophilous tall herb fringe communities belonging to the class *Betulo-Adenostylete* Braun-Blanquet 1948, which develop from montane to alpine levels, are commonly observed on humus and humid soils. They follow the edges of forests, forest cleanings, water flows, etc. (Muratovic, 2015).

On Jahorina they are classified in 4 order (*Atropetalia belladonnae* Vlieg 1937, *Betuletalia* Lakušić et al 1978, *Adenostyletalia* Br. 1931 and *Pteridetalia* Lakušić et al., 1978) and 6 alliance (*Atropion belladonnae* Br.-Bl. 1930, *Sambuco-Capreae capsules* Tüxen & Neumann ex Oberdorfer 1957, *Betulion verrucosae* Lakušić et al 1978, *Adenostylion alliariae* Br. 1925, *Petasition* Lakušić et al. 1978 and *Pteridion aquilini* Lakušić et al. 1978) and 8 associations (*Telekietum peciosae* Treg. 1945, *Salicetum incanae* Jov. 1963, *Capreeto-Populetum tremulae* Glišić (1950) 1975, *Adenostylo-Doronicetum* Ht 1956, *Deschampsietum subalpinum* Ht 1956, *Petasitetum albi* Ht 1956, *Pteridietum aquilini* Lakušić 1975, *Aegopodio-Petasitetum hybrids* R. Tx.) (Petronic et al., 2009).

The habitat is characterized by the nitrophilic ruderal vegetation of the order *Glechometalia hederaceae* R. Tüxen in Brun-Hool et R. Tüxen 1975 and *Convolvuletalia sepii* Tüxen 1950, and excludes communities in which prevails alpine dock (*Rumex alpinus*) (Muratovic, 2015).

6510 - Lowland hay meadows (*Alopecurus pratensis*, *Sanguisorba officinalis*)

Lowland hay meadows are maintained by a constant anthropogenic influence. In Bosnia and Herzegovina, they develop in the valley, upland and mountain areas and belong to alliance of *Arrhenatherion* Koch 1926, *Cynosurion* Tüxen 1947 and *Calthion* Tüxen 1937 (Muratovic, 2015).

In the area of Jahorina there is a vegetation of alliance *Arrhenatherion* and *Cynosurion*. From the vegetation of alliance *Arrhenatherion elatioris* the most common community is *Arrhenatheretum elatioris* Tx. 1937, which occupies the lowest habitats on flat surfaces (Petronic and Pavlovic, 2012).
Vegetation of alliance *Cynosurion* involves the mesophilic meadows in the lower areas caused by degradation of oak forests. On Jahorina there is an association *Bromo-Cynosuretum cristati* H-ić 1930 which differentiates into subassociations of *holcetosum lanati* and *brometosum racemose* (Petronic and Pavlovic, 2012).

6520 - Mountain hay meadows

Mountain hay meadows are covered by alliance of *Polygono-Trisetion* Braun-Blanquet et Tüxen ex Marschall 1947 n. inv. and *Poion alpinae* Oberdorfer 1950, and on the territory of Bosnia and Herzegovina there is endemic alliance *Pancicion* Lakušić 1966 (Muratovic, 2015). The vegetation of mountain hay meadows on Jahorina belongs to class of *Arhenatheretea* Br.-Bl. 1947, order *Arrhenatheretalia* Pawl. 1928 and endemic alliance *Pancicion* Lakušić 1966 which differentiates on two endemic associations *Pancicion-Lilietum bosniacae* Bjelcic et Lakušić 1969 and *Alchemillo-Crepidetum bosniacae* Bjelcic in 1967. These communities build a large number of mesophilic species among which a significant number are endems (Petronic and Pavlovic, 2012).
On Jahorina association *Alchemillo-Crepidetum* bosniacae occupies fewer areas. It is developed in the lower part of the subalpian belt. It is mainly used as a pasture because it contains a lot of valuable species in terms of feeding cattle (Petronic and Pavlovic, 2012).

7110 - Active raised bogs

The raised bogs in B&H occupy small areas but in their specificities they represent a unique but little known value. Since they were formed during the glacial period, they are categorized as glacial relics. Relative to the worldwide distribution of raised bogs, they are located at the southern border of their areal, indicating their high isolation and vulnerability (Barudanovic et al., 2017).
Natural or semi-natural majority ombrotrophic elevated peat complexes on peat substrate. Often the raised surface is developed, or dome, with levels of water that is considerably higher than the groundwater level in the environment, which receives water exclusively from atmospheric precipitation. This raised bogs complex is characterized by the dominance of moss from the genus *Sphagnum* spp., and includes all zones lying within retention zone of water. The necessary prerequisite for the development of bogs formations is the high amount of rainfall (active bogs) (Djug and Milanovic, 2015).
In the syntaxonomic view vegetation belongs to class *Oxycocco-Sphagnete* Br.-Bl. et Tx. 1943 order *Sphagnetalia fusci* Tx. In 1955. On Jahorina, in the area of Dugo polje, there is alliance of *Sphagnion fusci* Br.-Bl. 1920, which includes the associations of *Sphagnetum fusci* Luq. 1926 and *Sphagnetum medii* Käsn. et al. 1933. Active raised bogs are very rare and poorly explored in BiH, and often have a transitional character.

7120 - Degraded raised bogs still capable of natural regeneration

These habitats include degraded raised bogs which are under negative influence (on the hydrological regime or exploited) but still capable of natural regeneration. Stages of their degeneration are recognized by colonization of species *Molinia caerulea* and other species that make changes to the trophic regime from oligo-distrophic conditions to mezotrophic and eutrophic conditions. Regeneration ability means that it is possible to restore the hydrological regime, after which the native vegetation can be expected to recover for about 30 years. Plant species that are typical for raised bogs such as moss (*Sphagnum* spp.) represent a significant part of vegetation with significant presence of species characteristic of the degradation stages (*Molinia caerulea* and other) (Djug and Milanovic, 2015).

7220 - Petrifying springs with tufa formation (Cratoneurion)

Petrifying water sources that are rich in potassium bicarbonate and where the sediment sits right next to the spring in the forest or open areas. There are frequent mosses which belong to alliance of *Cratoneurion commutatum* W. Koch 1928. This type of habitat includes the main streams where the tuff is formed and is characterized by the presence of tufa formations. It is necessary to include all zones that are directly related to the source as well as the zones inhabited by relevant vegetation (Cratoneurion), even where it extends from sources to the upper streams of the watercourse (Đug, 2015).The spring of the Paljanska Miljacka (figure 3) is located on the sedimentary deposits, represents the hydrological value. Downstream from the source, about 200 m, there is a waterfall on Paljanska Miljacka. The sedentary area at Paljanska Miljacka is about 400 m downstream from the spring and is active. Rich populations of the genus *Cratoneurion* have been developed on it. This type of habitat is distinguished by the presence of a yellow-orange blanket which is made of moss *Cratoneuron commutatum* and *Cratoneuron filicinum* (Petronic and Pavlovic, 2012).

Figure 3. Petrifying springs with tufa formation on Jahorina

9140 - Medio-European subalpine beech woods with *Acer* and *Rumex arifolius*

Subalpine forests with *Acer pseudoplatanus* are a permanent climaregional stage in western Dinarides in BiH. The mild slopes of the subalpine belt are matured, and happiness is a little lower, on flat terrain and deep plains of obstructed glacial lakes (lakes), where the secular succession gradually shifts to the climaregional community of the mountain forest. The dominant species is mainly *Acer pseudoplatanus*, and there are more beech and spruce trees on the floor of the trees. In eastern Dinarides, there are similar subalpine forests with *Acer heldreichii* ssp. *visianii*, *Cicerbita pancicii* (Brujic, 2015).

In Jahorina they are subalpine mountain forests of beech and mountain maple *Aceri heldreichii-Fagetum* Jov. 1957 (*Aceri visiani-Fagetum* Fuk. And Stef. 1958) - subalpine beech forest with Greek maple. In the Jahorina area in mixed deciduous-coniferous forests above 1300 m there is an endemic species of maple *Acer heldreichii* subsp. *visianii*, known as the mountain maple. It is significantly and prominently represented along the streams and the road of Pale - Jahorina, the sites Mali and Veliki javor. In the highest part of the forest zone, have been developed subalpine beech forests with maple trees (*Aceri-Fagetum subalpinum* Fuk. Et Stef. 1958 and *Aceri visianii-Fagetum Fuk* 1969. They are not a continuous belt, they are often degraded with individual but numerous old trees of maple (*Acer heldreichii* subsp. *visianii* and *Acer pseudoplatanus*) (Petronic and Pavlovic, 2012).

9410 - Acidophilous Picea forests of the montane to alpine levels (*Vaccinio-Piceetea*)

Subalpine spruce forests
In the area of Jahorina, *Aceri visiani-Piceetum subalpinum* Stef. 1970., this habitat occupies a cooler and colder position under the limestone ridge where deeper clayey soil formed, such as pseudogley or sour brown soil (distric cambisol). This community is conditioned by orographic (microclimate) - edaphic and does not make the altitude belt here, it is already included in the belt of the subalpine beech at an altitude of 1600-1750 m (Petronic and Pavlovic, 2012).
Frosty spruce forests
Piceetum montanum illyricum Horv. et al. 1974 - the frosty forest of spruce, often azonal and extrasonal, orogens. This frosty type of spruce forest is represented on several sites with smaller areas on Ravna planina (Careve vode), best developed in the area of the Dvorista. It is distinguished by specific relief, curvature and depression, with sour brown and brown subsoil that is formed on verphic (quartz) pedestrians (Petronic and Pavlovic, 2012).
Secondary spruce forests
Abieti-Piceetum silicicolum Stef. 1960 in the Jahorina (figure 4,5) is a widespread forest of fir and spruce. It was developed mainly in the severely northern exposures, mainly on the verphic peaks of sour brown and brown subsoil, with the appearance of raw humus. There are also on the verphic clays, in deeper illimerized or poorly clad soil. The larger areas are located in the area of Vrhpraca, less on Ravna planina and above Pale towards Begovina. It occupies a wide altitude range of 1000-1600 m above sea level (Petronic and Pavlovic, 2012). The leading environmental pressures in B&H are inadequate and uncontrolled deforestation (especially coniferous forests). Total logging creates imbalances in the ecosystem and landscape zones, landslides and soil displacements, floods, aerial pollution, loss of resources, forest timber, fertile humus, etc., which leads to loss of diversity (Barudanovic et al., 2015).

Figure 4,5. Conifer woods on Jahorina

Conclusions

Connecting protected areas of Bosnia and Herzegovina in the European network of protected areas Natura 2000 is aimed to prevent the loss of biodiversity, preserve the habitat of endangered species and ensure their long term survival. For Bosnia and Herzegovina, WWF MedPO started a project to support the implementation of the European ecological network Natura 2000 in 2007. The aim of this paper is to present types of habitats in the area of Jahorina Mountain, which are significant for Bosnia and Herzegovina and the European Union. During the research the following habitats have been isolated: 4060 - Alpine and Boreal heaths, 6230 - Species-rich Nardus grasslands, on silicious substrates in mountain areas (and submountain areas in Continental Europe), 6410 - Molinia meadows on calcareous, peaty or clayey-silt-laden soils (*Molinion caeruleae*), 6430 - Hydrophilous tall herb fringe communities of plains and of the montane to alpine levels, 6510 - Lowland hay meadows (*Alopecurus pratensis*, *Sanguisorba officinalis*), 6520 - Mountain hay meadows, 7110 - Active raised bogs, 7120 - Degraded raised bogs still capable of natural regeneration, 7220 - Petrifying springs with tufa formation (Cratoneurion), 9140 - Medio-European subalpine beech woods with Acer and *Rumex arifolius*, 9410 - Acidophilous Picea forests of the montane to alpine levels (*Vaccinio-Piceetea*).

ANALYSIS OF DROUGHT IN NEGOTIN LOWLAND FROM THE ASPECT OF PLANT PRODUCTION

Enika GREGORIĆ*, Gordana MATOVIĆ, Vesna POČUČA

University of Belgrade, Faculty of Agriculture, Belgrade, Serbia
*Corresponding author: enikag@agrif.bg.ac.rs

Abstract

The research covered drought analysis in Negotin lowland from plant production issues point of view. Monthly data for the period 1961-2010 from the weather station Negotin were used for the study. Data were analyzed in two sections; first thirty and the last twenty years. Mean air temperature, precipitation, potential evapotranspiration, number of ice days and number of tropical days were processed. For the drought indices, the Standardized Precipitation Index (SPI-6) for September 30, the Walter diagram, the De Martonne index, the Climatic precipitation deficiency and the Aridity index were used. In comparison of the second with the first period, an increase in mean air temperature (1°C for annual temperature and 1.2°C for growing season) and decrease in precipitation (4% for both annual and growing season) were observed. The average climatic precipitation deficit was 375mm, without any significant difference between two periods of research. The average number of tropical days was significantly higher (>50%) in the second study period compared to the first, while the average number of ice days did not show a significant difference. SPI-6 for 30th September indicate 6 dry growing season during the first thirty and 4 in the other twenty years of research period. Aridity index showed a higher frequency of occurrence of semi-arid growing season in the second period of research (every other year) than in the first period (every third year). The Walter diagram and the De Martonne-index pointed to the emergence of drought and the need for irrigation during July, August and September. The forecast indicated further increase in air temperature and decrease in precipitation for the analyzed area. The study conclusion is that in order to secure agricultural production, efforts must be made to find solutions for increasing of the irrigated surfaces in this area.

Keywords: *drought, drought indices, lowland, Negotin, Serbia.*

Introduction

The Negotin lowland is characterized by a very specific climate, the most continental in the whole of Eastern Serbia, with the most pronounced average annual amplitudes and the most pronounced absolute amplitudes of air temperature (Rakićević, 1976). The summers are fierce, with temperatures above 40°C, and cold winters (up to -30°C). The highest precipitation (over 50% of the total annual sum) fall during the summer half of the year (Rakićević, 1976). However, despite this statement, August and September are the least rainfall (RHMZ). The unfavorable rainfall and high summer temperatures have influenced the fact that Negotin lowland is classified as the driest areas in Serbia (Radić, 2017). Climate projections for the future in this area are also not favorable for crop production. An increase in air temperature and decrease of precipitation are expected (Vuković et al., 2018). The frequency of drought, duration and their intensity are the parameters on which the degree of vulnerability of agricultural production depends. In the Negotin lowland area, agricultural production occurs mainly in rainfed conditions, which means that is directly dependent on climate conditions. This production is of great importance for the population of the Negotin lowland, to which agriculture is often the only way of generating income. The aim of this paper is that with use of different Drought indices to analyze the phenomenon of drought in Negotin lowland in the last fifty years, to determine the eventual trend of an increase or decrease in individual indicators of drought and thereby determine their impact on plant production and the need for irrigation.

Materials and methods

The Negotin lowland is located in the eastern part of Serbia, on the triple border of Serbia, Romania and Bulgaria. It is surrounded by mountain ranges (Miroč, Crni Vrh and Deli Jovan) from the north and west.

Monthly climate data for a period of 50 years (from 1961/62 to 2010/11) were taken from the National Hydrometeorological Service of Serbia, from the Negotin weather station. Drought analysis was performed based on the following parameters: mean annual air temperatures and mean air temperatures in the growing season (April-September); annual precipitation and precipitation in the growing season; number of tropical days (Tmax> 30^{o}C) and number of ice days (Tmax <0^{o}C). The annual data discussed in this paper reflect the hydrological year, from October to September of the next year. Drought Indices are determined on an annual basis and/or for growing season. The Standardized Precipitation Index (SPI-6) for September 30 (McKee et al., 1993; Zarch et al., 2015; WMO, 2016), Walter diagram (Walter et al., 1975; Stricevic, 2007), De Martonne Index (De Martonne, 1926; Stričević, 2007; Zambakas, 1992), Climatic precipitation deficiency (Spasov, 2003) and Aridity Index were calculated (UNEP, 1992). Potential evapotranspiration calculated using the FAO method Penman Monteith (Allen et al., 1998) was used to determine the Climatic precipitation deficiency, and Thornthwaite method (Thornthwaite, 1948; Kafle and Bruins, 2009) was used for the Aridity Index.

Results and discussion

The fifty-year analysis (1961/62-2010/11) shows that mean daily air temperature (Tmean) in the Negotin area is 11.5^{o}C during the year, and 18.8^{o}C during the growing season (Tab.1), with an average of 37 tropical days. The average annual precipitation is 635mm, of which 323mm are on average during the growing season. In the last two decades, annual precipitation was lower by 4% than in the previous period. Ruml et al., 2016, analyzing the climate of Serbia in the period 1961-2010, came to the conclusion that Negotin is one of the four meteorological stations in which the greatest decreasing trend in precipitation in Serbia is registered, and is <10mm per decade. Growing season precipitation (323mm) as the income of water and the needs of the reference plant species for water (ETo = 698mm), make the average climate precipitation deficit of 375mm. The division of the investigated period in the

Tab. 1. Mean air temperatures (Tmean), precipitation (P), potential evapotranspiration (ETo), number of ice days, tropical days and average climatic precipitation deficit (P-ETo) in growing season (April-September) at Negotin in period 1961/62-2010/11.

Period	Tmean (^{o}C)		P (mm)		ETo (mm)		Ice days (days)	Tropic.days (days)	P-ETo (mm)
	Hydr. year	Grow. season	Hydr. year	Grow. season	Hydr. year	Grow. season			
1961/62-1990/91	11.1	18.3	646	328	908	703	20	31	-374
1991/92-2010/11	12.1	19.5	619	315	882	691	19	47	-376
1961/62-2010/11	**11.5**	**18.8**	**635**	**323**	**898**	**698**	**20**	**37**	**-375**

first thirty and in the second twenty years shows that in the last 20 years (1991-2010) there was an increase in the average daily temperature compared to the previous period, by 1.0^{o}C per year, ie by 1.2^{o}C during the growing season (Tab.1). This result is complemented by the results of the analysis of extreme air temperatures in Serbia which were got by Ruml et al., 2016. Namely, for the same period of research, the authors noted a statistically significant trend of increasing both the minimum and maximum temperatures in Negotin. This trend of temperature increase has also been reflected in the increase in the length of the growing season, which is statistically significant in the period 1980-2010, and is 22days (Ruml et al., 2017). The rise in mean air temperature during the growing season, in Negotin is shown by the normalized deviation of mean air temperature (NDTmean) (Figure 1).

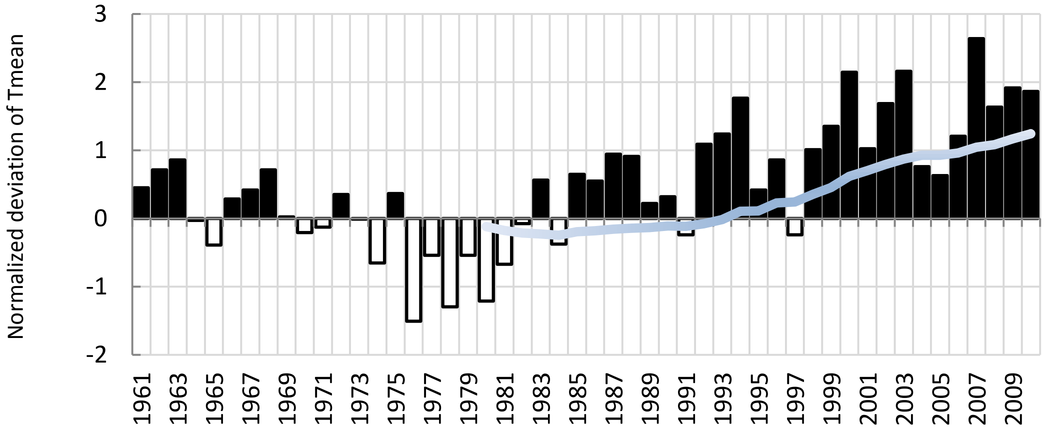

Figure 1. Normalized mean air temperature deviation (NDTmean) during the growing season (April-September) with a mowing average in Negotin lowland

The average number of tropical days is also significantly higher (> 50%) in the second study period compared to the first (Tab.1), while the average number of ice days does not show a significant difference.

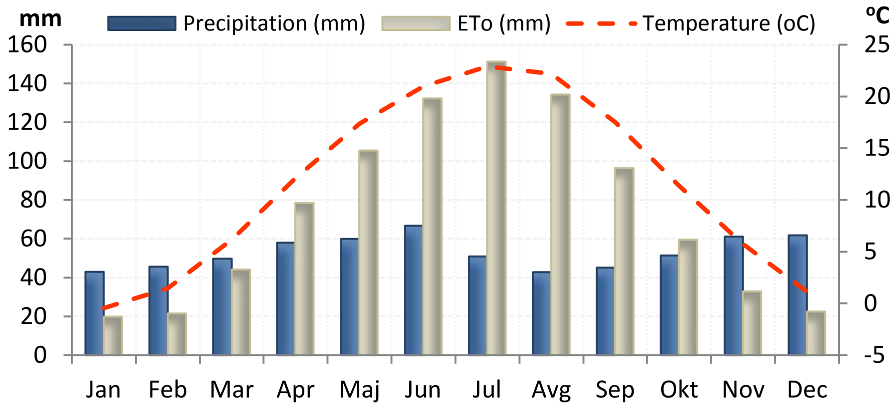

Figure 2. Mean monthly (1961-2010) air temperatures, precipitation and potential evapotranspiration in the Negotin lowland

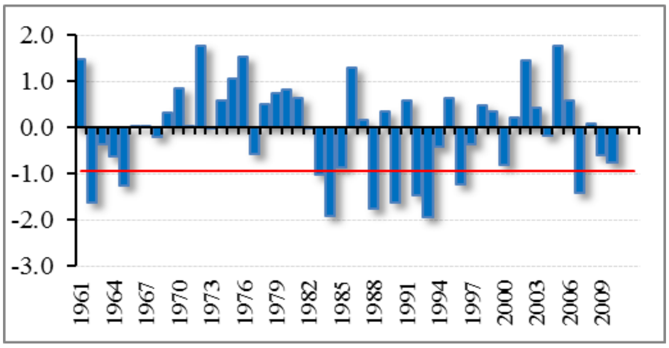
Monthly distribution shows that June is the most rainy month, with an average precipitation of 67 mm (Figure 2). Maximum precipitations during this month were recorded in 1969 and amounted to 197 mm. The minimum rainfall in August is on average 43 mm. Six times during the fifty-year period, August was characterized by less than 5 mm precipitation. A small amount of precipitation during the summer months is at a disagreement with the high demand of plants for the water during that period. ETo, as an indicator of the potential water expenditure, ie the need for water of a reference plant species, is 375mm for the entire growing season. The highest values of ETo were in July (151mm), so the climatological deficit water of that period was 100mm in average and in August 91mm (Figure 2). Climatological deficit greater than 350mm was recorded in Serbia next to the Timocka Krajina (to which it belonging to the Negotin lowland) and in Banat, as well as the extreme south of Serbia (Spasov et al., 2003).

Moisture conditions in Negotin lowland, shown by the Standardized Precipitation Index (SPI-6) for 30th September, indicate 6 dry growing season during the first thirty and 4 in the other twenty years of research period (Figure 3) .



Moisture conditions	**SPI Value**
Exceptional drought	≤ -2.326
Extreme drought	-2.326 to -1.645
Severe drought	-1.645 to -1.282
Moderate drought	-1.282 to -0.935
Minor drought	-0.935 to -0.524
Near normal	-0.524 to +0.524
Slightly increased moisture	+0.524 to +0.935
Moderately increased moisture	+0.935 to +1.282
Considerably increased moisture	+1.282 to +1.645
Extremely wet	+1.645 to +2.326
Exceptionally wet	≥ +2.326

Figure 3. Moisture conditions during the growing season (April-September) for the period 1961-2010 in Negotin lowland, based on the Standardized Precipitation Index (SPI-6) for 30^{th}September

The Walter diagram (Figure 4) drawn on the basis of average 50-year values (1961-2010) points to droughts in July, August and September, with the most pronounced in August.

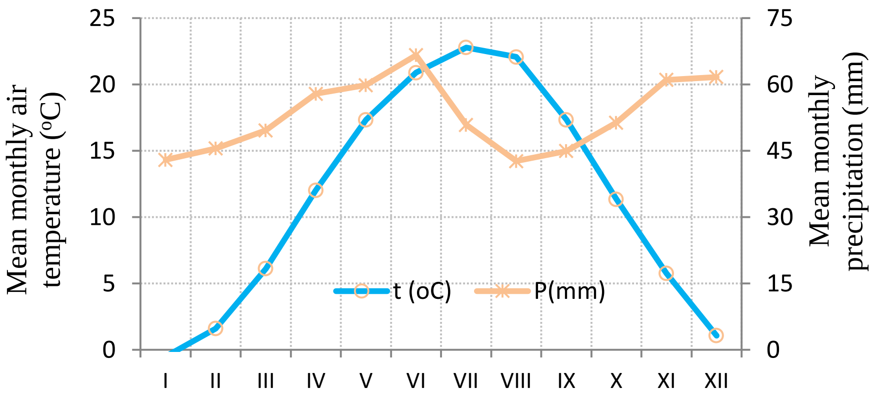


Figure 4. Walter diagram for Negotin lowland (1961/62-2010/11)

The De Martonne index calculated on an annual basis shows that the Negotin area (Ia = 29.5) belongs to the humid condition. However, the values of this index at the monthly level (Tab. 2) indicate the need for irrigation (Im < 20) during July, August and September. As well, in Leskovac lowland, using the same index, the need for irrigation during July and August was determined (Idrizović et al., 2018).

Tab. 2. De Martonne index calculated on the 1961-2010 database for Negotin lowland

1961-2010	Jan	Feb	Mar	Apr	Maj	Jun	Jul	Avg	Sep	Okt	Nov	Dec
Im	54.2	47.1	36.9	31.5	26.3	25.9	18.6	16.0	19.7	28.9	46.4	66.9

The aridity index (at annual level) is 0.71, which, like the Walter index, classifies the climate as humid (AI>0.65). However, AI for the period of the growing season (average 1961-2010) is 0.46, which indicates semi-arid conditions. A higher incidence of semi-arid growing season (AI=0.2-0.5) was observed in the last two decades of research than in the previous period (Figure 5).

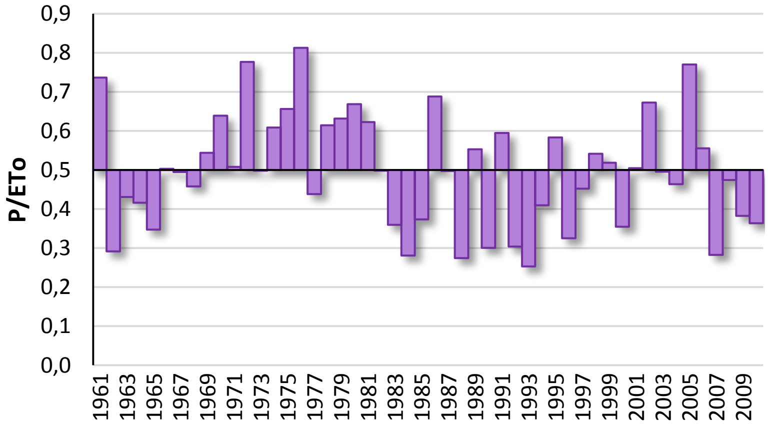

Figure 5. Aridity index (P/ETo) calculated for the growing season (April-September) in Negotin lowland

Conclusions

If the fifty-year research (1961/62-2010/11) was divided into the first (1961/62-1990/91) and the second (1991/92-2010/11) period, the analysis of the climate parameters of the Negotin lowland shows the following:

- The mean air temperature increase in the second period is recorded in relation to the first. Annual T are higher by 1°C, and growing season T is 1.2°C.
- The average number of tropical days is significantly higher (> 50%) in the second study period compared to the first one, while the average number of ice days does not show a significant difference.
- Reduction of annual and growing season precipitation is recorded in the second period compared to the first one, by 4%
- Climatological deficit of precipitation occurs in the growing season. The average is 375mm, with no significant difference between the two research periods. The highest climatic precipitation deficit is in July (100mm) and August (91mm).
- SPI-6 for 30th September indicate 6 dry growing season during the first thirty and 4 in the other twenty years of research period.
- Aridity index shows a higher frequency of occurrence of semi-arid growing season in the second than in the first period of the research.
- The Walter diagram indicates the occurrence of drought in July, August and September.
- De Martonne-index points to the need for irrigation during July, August and September.
- The results show that climatic conditions for plant production are worse in the last twenty years than in the previous thirty. Projections of climatic conditions in the future show further increase of air temperature and decrease of precipitation in this area, so conditions are expected in which agricultural production will be even more threatened. Therefore, the need for irrigation will be even greater.

Abstract

Aquaculture in the world and in Bosnia and Herzegovina is the fastest growing food production sector. The high nutritional value of fish meat, which is also rich in proteins, high-value fats, minerals and vitamins, is also a challenge in respect to a more intensive production of salmonid species in Bosnia and Herzegovina and in the Balkans. As the production is closely tied to the reproductive abilities of fish and animal population as a whole, our research studies compared the intensity of oogenesis and spermatogenesis in rainbow trout in various rearing environments, with a special emphasis on water temperature and oxygen saturation at the time of fishing. The research is one of the guidelines of how to intensify the production of rainbow trout while providing the most favorable living conditions and a faster growth of fish population, contributing to the faster production and market placement without undermining the fundamental postulates of the natural environment.

Key words: *rainbow trout*, *oogenesis*, *spermatogenesis*, *microenvironment conditions.*

Introduction

Hydro resources of Bosnia and Herzegovina belong to the basins of the Adriatic and Black Sea. They cover 20,000 km of rivers and tributaries, 400 ha of lakes and accumulations and 1,400 m of the sea coastline. The special potentials of aquaculture in Bosnia and Herzegovina include a high-quality and clean water, non-infected fish species in the controlled farming conditions, open waters, a high-quality base stock of fish, hatcheries and other fish farming objects. As an agricultural branch, the aquaculture in our country can produce high amounts of various species and categories of fish. If Bosnia and Herzegovina is to keep up with the rest of the world in terms of industrial economic growth, it needs to increase significantly the fish diversity, quality and total production. The most important fish species reared on the trout farms across the country is the rainbow trout *Oncorhynchus mykiss* (Walbaum, 1792). Besides the fact that farming of this fish stock is attractive to a large number of producers, and given its high-yield possibility, another trait is its tolerance to the varying microclimatic conditions of environment. The rainbow trout is reared in concrete or cage systems and can yield between 100,000 and 500,000 kg of trout per hectare of the pond (Hamzić, 1993).
Making a right selection of the base material under the intensive farming secures high production parameters of the offspring (Korjenić, 2010). The intensive production of the rainbow trout (*Oncorhynchus mykiss*) requires meeting several factors to allow for the most favourable conditions for the life and fast growth of fish population, i.e., to contribute to a faster achievement of the planned production and market-placement of the final product. Producers must provide the highest-

quality genetic potential of fish, high-quality feed in line with the age categories, health and veterinary control and physical and chemical parameters of water quality, with a sufficient amount of water supplied to fish-farm, water temperature, concentration of dissolved oxygen in water and pH of water, as the most important ones (Aganović, 1979; Treer *et al*., 2001; Ćuk *et al*., 2006; Katavić, 2009). Minor changes in the keeping and feeding disturb the exploitation of the biological potential of fish, and in case of exceeding certain limits, they even endanger the physiological functions, i.e., they lead to health disorders (Jeremić *et al*., 2004). Our studies tried to examine and bring closer the optimal microenvironment conditions favouring a more intensive oogenesis, i.e., spermatogenesis in the rainbow trout *Oncorhynchus mykiss* (Walbaum, 1792).

Material and methods

The material for our research was sampled from three fish farms in Bosnia and Herzegovina:

- Royal-fish farm located on the Jablanica lake (Donja Jablanica), hydro-accumulation on the river Neretva;
- Magazin MAPRIM located on the Ramički creek (Pazarić-Resnik) that flows into the river Bosna, and,
- Eko-projekt located on the river Krupica (Jeleć-Miljevina), which together with Govza flows into the river Bistrica and subsequently into the river Drina.

The research was conducted during the spawning period, in November and December. The male and female samples of the rainbow trout were sexually mature and between 2 and 5 years of age. Due to the relatively large samples and for the purpose of an easier manipulation of the fish samples and duration of measurement, the fish were anaesthetized using Benzoak solution. A total of 40 specimens (26 females and 16 males) from the three fish farms were used in the morphological and histological studies of the gonads. The gonads were separated into plastic bottles and then fixated using 10% formaldehyde. They were transported to the laboratory for further analysis. Prior to moulding, the samples were dehydrated by immersing them in a series of increasing concentrations of alcohol. First, the samples were placed in alcohol solution with concentration of 70% for two days, after which they were transferred into alcohol solution with concentration of 96% concentration for one day and, in the end, they were placed in 100% alcohol for one day. Following this procedure, the samples were transferred into a mixture of 100% alcohol and toluol for two hours, and after that only in toloul for another four hours. The samples thus prepared were left in paraffin I for five hours, and then in paraffin II for twelve hours. After this, the moulding with paraffin blocks was completed. The sample processing from fixation to moulding with paraffin, was carried out on a rotational tissue processor (MICROM model STP 120). After the moulding, the samples were cut using digital microtome LEICA RM 2145, several serial cuts from 0.5 to 1.5 micrometre thick. A total of 400 preparations of 80 samples (40 left and 40 right gonads) were prepared. The cuts were placed on glass slides and deparaffinized by immersing them in a series of decreasing concentration of alcohol. After that, the cuts were stained using haematoxylin eosin, covered with a coverslip and fastened with Canada balsam. The examination of the histological preparations was done using a light microscope equipped with camera MOTIC TYPE 102M, under magnification of 100, 200 and 400x. The analyses of histological structures were carried out using a special program Motic Images Plus 2.0 ML. The microscopic examination included analysis of the gonads in females and males during the spawning period, monitoring the developmental phases and degree of gamete maturation at various fish farms. Water temperature (°C) was measured by the same instrument with an inbuilt thermometer. Oxygen solubility (mg/l) in water was measured by an oximeter Multi 340i/SET (Germany) according to the reference method ISO 5814:1990. A probe was immersed into the water rendering the values of the dissolved oxygen.

Results and discussion

Temperature and photoperiod play a big role in the control of the reproductive cycle (Taranger & Hansen 1993; Pankhurst *et al*., 1996; Davies & Bromage 2002). The uniformity of the water temperature allows for a proper diet, normal metabolism of substances and thus achievement of the desired production results. Farmed rainbow trout receives feed most intensively at the water temperature of around 10 °C, but the best degree of the feed utilisation is achieved at 9 °C (Korjenić, 2010). Ideal water temperatures in salmonid farming (regardless of the production orientation) should be between 9 and 12 °C, with smaller deviations, and the best growth in the fish between 6 months of age and its table size is reached at the water temperatures between 10 and 16 (Mulabdić, 2007). As such water temperatures are usual for the springs of mountain streams and some shorter streams, it becomes a fundamental requirement when selecting the location and projecting the salmonid economy to build such economies in the spring areas of the streams, mostly 500 m to 1000 m downstream. The spring and well waters have constant temperatures throughout the year (between 9 and 12 °C); they are perfectly clean; they are not susceptible to pollution and they are most suitable for supplying the salmonid economy. But, river waters are significantly richer in dissolved oxygen; they contain higher amounts of dissolved salts and they almost never contain a surplus of gasses for example, carbonic acid, nitrogen compounds, etc. (Korjenić, 2010). The optimal temperature in the cage system is between 15 °C and 20 °C, whereby its further growth during summer periods is not desirable for longer periods and can lead to death of fish Pillay, 1996; Mulabdić, 2007). The optimal concentrations of the available oxygen for fish is one of the basic factors that affects and defines the capacities of production (Mulabdić, 2007; Arnautović 2007; Ćirić, 2013). The lack of the sufficient amounts of oxygen causes impairments and imposes various limitations on the living and production conditions. Salmonid species require certain amounts of oxygen dissolved in water, which is closely tied with the temperature of water in which fish live. Needs for oxygen are smaller at lower temperatures than at higher temperatures. The need for certain amount of oxygen depends on the fish species, sexual maturity and its activity. Disruptions in the production on salmonid fish farms can be caused by a decline in the concentrations of dissolved oxygen below 6 mg/l, while the desirable values for a normal functioning of the fish farm are between 8 and 12 mg/l (Ržaničanin *et al.* 1982; Treer *et al*., 1995; Boyd & Tucker, 1998; Jeremić, 2003; Ćuk *et al.*, 2006). The morphological and histological description of the gonads included examination of 40 pieces of fish between two, three and four years of age, due to a more credible monitoring of the developmental stages and degree of maturation of the gametes at various fish farms.

The histological studies of the ovaries involved sexually mature specimens between two and five years of age, during the spawning time. The studies show that, given the different farming environment, there are certain discrepancies in the histological structure of the ovaries. The histological analysis of the ovaries of the specimen from the Royal fish farm (location Donja Jablanica) determined that there was a large number of the primary yolk oocytes (Image 1). This developmental form of the oocytes shows a clear homogenous basophilia of the cytoplasm-ooplasm, and the nucleus is surrounded by several nucleolus (even up to 20) that are varying in size and that are located at the edge of the nucleus membrane, while the entire form is surrounded by zona radiata composed of the granulosa and theca cells. Given the presence of the yolk granules (rich in protein), we can determine that it is a previtellogenic phase of the development. Besides these developmental stages of the oocytes, we observed that the same ovaries had a small number of the secondary yolk oocytes (Image 2), preovulatory follicles (Image 3) as well as postovulatory follicles (Image 4).

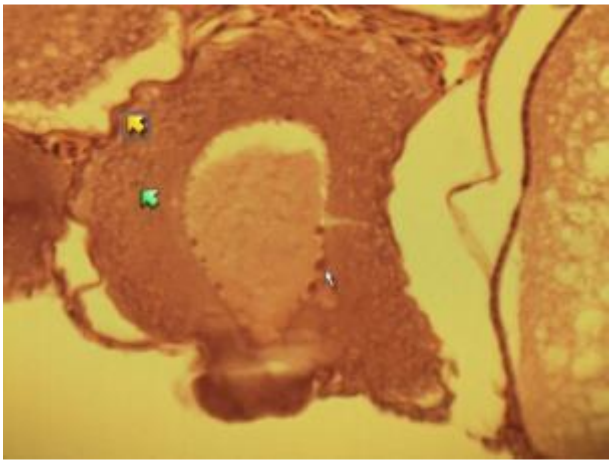

Image 1. Primary yolk oocyte: the green arrow indicates the yolk granules; the white arrow indicates the nucleoli; the yellow arrow indicates the zona radiata (HE X 400)

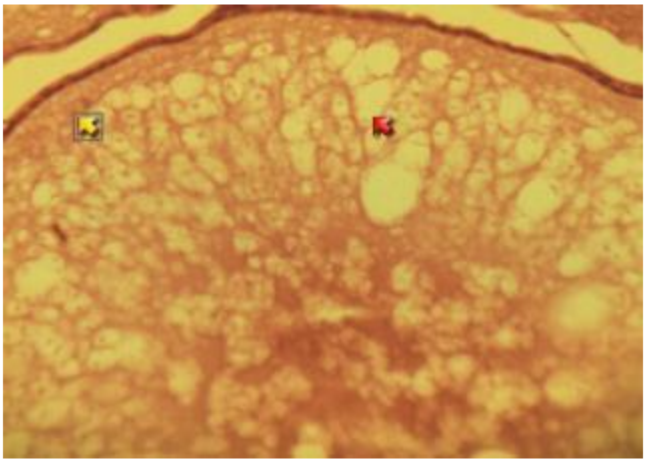

Image 2. Secondary yolk oocyte: the red arrow indicates the vacuoles; the yellow arrow indicates the yolk granules (HE X 400)

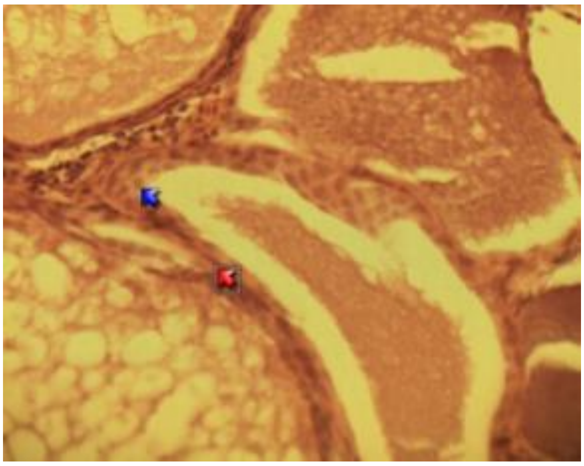

Image 3. Preovulatory follicle: the blue arrow indicates granulosa cells; the red arrow indicates theca cells (HE X 400)

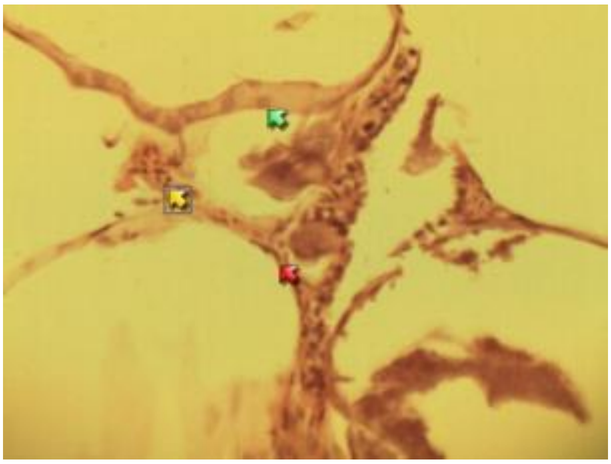

Image 4. Postovulatory follicle: the green arrow indicates granulosa cells; the red arrow indicates theca cells; the yellow cells indicates blood vessels with visible erythrocytes

The presence of secondary follicles indicates that the oocytes are in the vitellogenesis phase. Almost entire ooplasm is filled with yolk granules and fat vacuoles. The oocytes are surrounded by zona radiata and follicular epithelium (theca follicles) in the form of low-prismatic cells. Preovulatory follicles are characterised by migration of the nucleus towards the periphery, which occurs immediately before maturation. The yolk granuloses are clearly visible (fusion occurs) and very basophilic; the cytoplasm of the granulosa cells is lighter and have the ball-shaped nuclei, while the nuclei of the theca cells are elongated, darker and have a darker cytoplasm. The studied histological preparations of the ovaries of the specimen taken from the Royal fish farm show a visible presence of postovulatory follicles, however, to a lesser extent than in the ovaries of the specimen from other fish farms. The postovulatory follicles show the presence of granulosa, theca lutein cells, degraded follicles and blood capillaries with free and elongated erythrocytes of the clearly visible basophilic nuclei.
The conditions at the Royal fish farm (Donja Jablanica) were as follows: water temperature was 8^0 C; the water pH value was 8.15; and oxygen solubility was 8.27 mg/l. The fish were reared in the cage systems. We observed that the nuclei on some histological preparations migrated towards the periphery and that there was fusion of the yolk granules that appeared as one compactness and a distinctive basophilia, which indicated the immediate maturation – pre-maturation (Image 5 and 6).

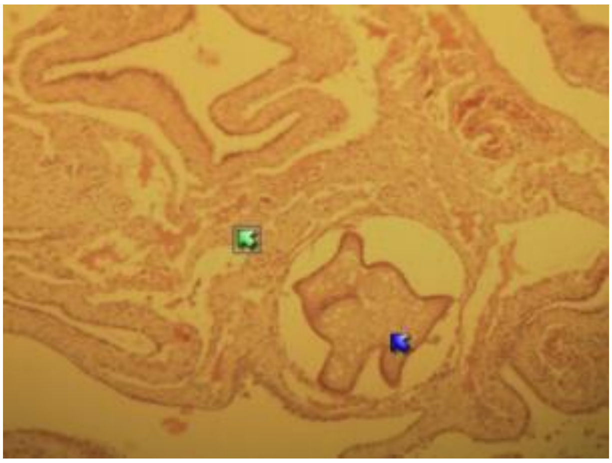

Image 5. Pre-maturation and ovulation; the blue arrow indicates the pre-maturation oocytes; the green arrow indicates the postovulatory follicle (HE X 200)

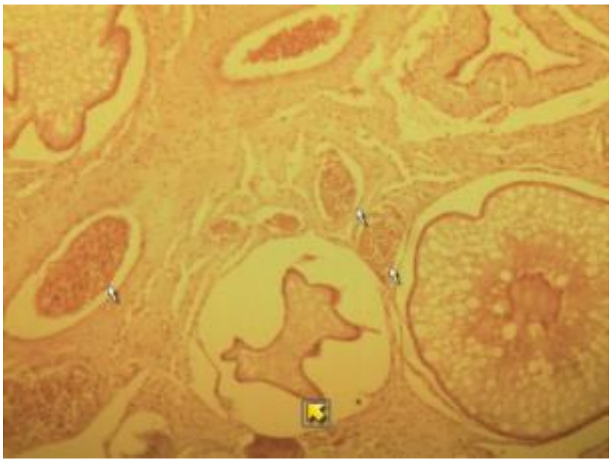

Image 6. Oocytes immediately before maturation-the yellow arrow; the white arrows indicate blood vessels in the places of degraded follicles (HE X 200)

However, the largest number of the histological preparations of the ovaries from the studied location, showed the presence of postovulatory follicles and clearly visible large granulosa cells of the ball-shaped nuclei, somewhat darker theca cells, and abundance of the sections of blood vessels – capillaries, oval lumens filled with erythrocytes.

The water temperature at the time of sampling was 7^0 C; oxygen solubility was 10.5 mg/l, the water pH value was 7.8; the Eko-projekt fish farm is located at the latitude of 760 m, which probably contributed to this picture of the oogenesis intensity. We can conclude that the oogenesis of the specimen from this fish farm, when compared to other two farms, at the same period of the year, during the spawning, in November, was at the very peak, given a significant presence of the mature oocytes. The fish from the Eko-projekt farm (at the Jeleć-Miljevina site) were farmed in the spring water concrete ponds with a raceway system. The studied samples showed a small number of oocytes in the pre-maturation phase (Image4). The oocytes are clearly visible on the histological preparations, considering that they were extremely large and surrounded by the granulosa and theca cells. They are fully filled with yolk granules, while a smaller number of vacuoles are visible on the periphery. A very small number of mature oocytes is what draws attention while studying the samples of the ovaries in the specimen taken from this fish farm. The conditions at the Magazin MAPRIM farm (Ramički potok-Pazarić) located at the latitude of 653 m were as follows: the water temperature was 11° C; the water pH value was 8,3 and solubility of oxygen was 10 mg/l. The fish at the Magazin MAPRIM farm were reared in the concrete ponds. We can conclude that the histological picture of the ovaries of the specimen taken from the Magazin MAPRIM farm (Ramički potok -Pazarić) is characterised by all phases of oogenesis (Image 7).

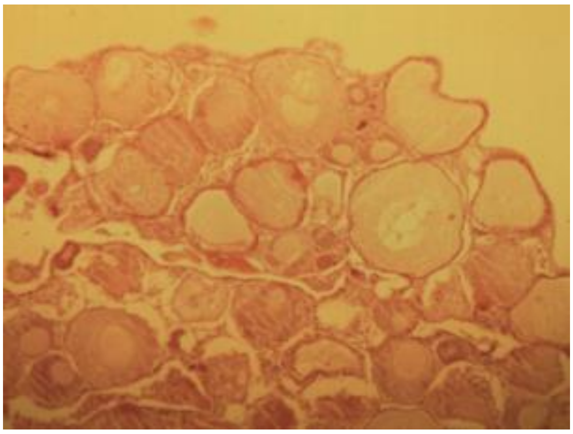

Image 7. General image of the ovaries of the specimen taken from the Magazin MAPRIM farm at the time of spawning (HE X 200)

The histological analysis of the ovaries of the rainbow trout sampled from different fish farms characterised by different microenvironment conditions showed that the fish from the Eko-projekt farm (Jeleć-Miljevina site) had the oogenesis of the highest intensity. The conditions at this site were optimal for oogenesis (pond farming with a raceway system (spring water), located at the latitude of 760 m, the water temperature was 7° C, the water pH value was 7.8 and oxygen saturation was 10.5 ppm). Having studied the histological structure of the testicles of the rainbow trout from different locations during the sexual season we can conclude that the microstructure is more or less equal.By comparing the results of the histological studies of the testicles of the rainbow trout from three fish farms in BiH located at different watercourses and with different microclimatic farming conditions, we can freely conclude that there are certain discrepancies in the intensity of spermatogenesis. Considering that the studied testicles were sampled during the spawning time, we expected that the overall histological picture would be uniform. However, it is evident that, in addition to other factors, the water temperature of 7° C at the Eko-projekt farm and 11° C at the Magazin MAPRIM farm contributed significantly to the intensity of spermatogenesis. The histological studies of the testicles of the fish sampled from the Eko-projekt farm, which had the lowest temperature during the sampling, and the water pH value of 7.8, showed an intensive spermatogenesis and presence of all cells of the developmental phases, especially spermatocytes, spermatids and spermatozoa, and a clearly noticeable lumen of the seminal walls which contained some spermatozoids (Image 8). Interstitium, i.e., the wall of the lobes on the analysed samples, was quite thin and discontinuous in certain places.

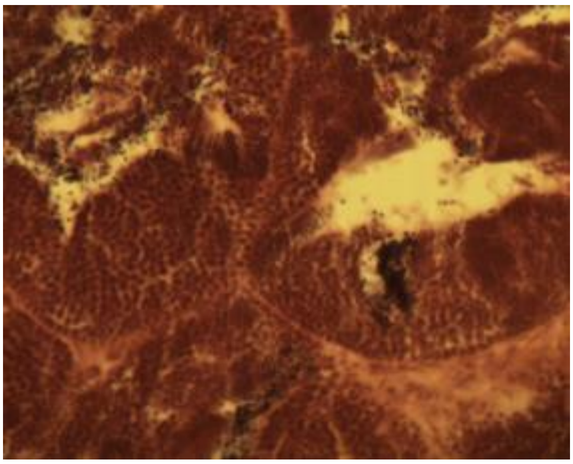

Image 8. Spermatogenesis: Eko-projekt fish farm (HE X 400)

The testicles of the rainbow trout fished from the Royal-fish farm, where the water temperature at the time of sampling was 8° C and the water pH value was 8.15, showed a discrepancy in the histological structure relative to the other two fish farms. Parenchyma of the seminal ducts contained abundance of spermatozoa, while the lumen of the seminal ducts was not notable. Spermatids were observed at certain places along the side of the seminal ducts, however in smaller numbers relative to spermatozoa and other cells of the spermatogenesis. The wall of the seminal ducts was thin and well-preserved, with a clearly noticeable lobularity (Image 9).

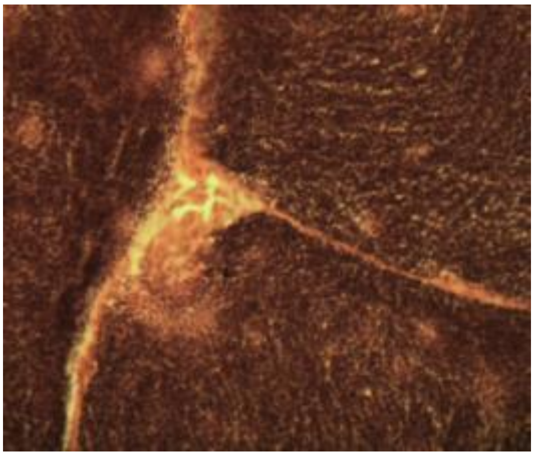

Image 9. Spermatogenesis: Royal-fish farm, (HE X 400)

The testicles collected from the specimen from the Magazin MAPRIM farm showed a higher intensity of spermatogenesis relative to the specimen collected from the Royal-fish farm, and a lower intensity of spermatogenesis relative to the specimen taken from the Eko-projekt fish farm. The water temperature at the time of sampling was 11° C, the highest water pH value was 8.3 and solvability of oxygen was 10 mg/l. Spermatogonia A and B, spermatocytes, spermatids and for the most part spermatozoa are present along the walls of the seminal ducts. The wall of the seminal ducts is continuous and well-preserved with visible sections of blood vessel.

Based on our histological research and microscope elaboration of the organs, we can determine with certainty that the most intensive spermatogenesis was at the Eko-projekt farm, given the presence of cells of all developmental phases, which was likely due to the water temperature of 7° C and pH value of 7,8 and solubility of oxygen in the water, which was 10.5 mg/l. The samples were taken from the pool environment with a flow-through spring water.

Conclusion

Considering the growing trend of the rainbow trout production in our country, it is necessary to typify the histological structure of the reproductive organs, to assess differences regarding the changed living conditions in order to provide useful information about the biological aspects of reproduction and to improve certain conditions to achieve a more productive spawning and farming. It is expected that the results of the study will have an applicative significance and that they will serve to improve the rainbow trout production both in the concrete and cage ponds.

Abstract
The aim of this research was to determine the quality of the soil and Fe, Cu and Zn content by the help of physico-chemical analysis at different areas of Herzegovina region (Bosnia and Herzegovina). The increased presence of the investigated elements has negative influence and the accumulation of it in the cultivated cultures is directly brought into the chain of nutrition, which results in their accumulation in the human organism as the final consumer. The research was carried out at three sites of Mostar, and from each of them, samples were taken from two different depths, from 0 to 30 cm and from 30 to 60 cm. The highest presence of Fe was found at the Salakovac site (42.447,11 mg/kg), where an increase of 37% was observed at the first depth, up to 42% at the second depth of testing, compared to MAC. Cu was above the limit values only at the site of Vrapcici, while Zn was measured in the highest values at the Salakovac site, at the first depth of the test (177,36 mg/kg). It can be concluded by comparing localities that Dubrava site is unloaded with the content of the examined elements, and it is considered acceptable for the cultivation of various herbal crops without fear for the health of final users. On location Salakovac recorded increased values of Fe in both depth testing, as well as increased concentration Zn on the first depth. This can cause long-term negative effects on the plants, but also human health. The Soil at the Vrapcici site contained higher concentrations above the permissible values of all tested elements which is the most polluted of these three explored sites. It can be said that represent great risk to human and animal health that consume the cultures cultivated on this land.

Keywords: *iron, copper, zinc, soil, MAC*

Introduction
The land, as a loose surface of the Earth's crust, is the basis for plant production, and it is necessary to examine its quality. Agricultural land is particularly vulnerable to degradation, given the numerous, often radical, technical-technological interventions in plant cultivation and thus become a potential source of environmental contamination. Rational use of these surfaces can reduce the risk of both the production of health defective food and groundwater contamination.

Most of the pollutants that are considered to be contaminants are the natural components of soil and groundwater, although they are often found only in traces. Determination of the total content of heavy metals in the soil is a basic indicator for the determination of the degree of pollution, although long-term risk assessments and direct impacts of pollution are based on their bio sensitivity and/or mobility (Salomons, 1995).

Natural and synthetic organic matter in the land is mainly degraded by microbiological and chemical, light photo chemically. If the intake of substances, even hardly degradable, is greater than their exposure by flushing, disintegrating or digging, the deposition occurs in the soil. Dangerous loads may increase to such an extent that they can permanently endanger natural soil flow.

According to Maxymiec (2007), heavy metal toxicity is one of the major forms of abiotic stress, which results in different impacts on animal and plant health, and therefore on humans.

The effect on plants, as the author believes, may be the result of their direct adverse effect on the membranes and the photosynthesis apparatus, leading to inhibition of organic matter synthesis and plant aging stimulation, which is the most exogenous external indicator of plant stress.
The term heavy metal is in principle used for metals and semi-metals that are related to environmental pollution and toxicity phenomena, but also to some elements that are essential to low concentrations in cells (Gratão et al., 2005). According to Dučić and Polle (2005), Cu is a major contaminant that occurs in the environment due to anthropogenic activity, especially due to the long-term use of Cu-based fungicides (Diaz et al., 2001).
In the research on adsorption of Cu, Cd, Ni, and Zn in individual and multi-metal solutions of agricultural and forest land (Sprynskyy et al., 2011), significant differences in the absorption capacity of the examined soil were demonstrated. The largest absorption of the investigated elements is in agricultural land, followed by surface forest land, and deep forest land. Agricultural and deep soil adsorb Cu, Zn, Ni, and Cd, while for surface woodland adsorption is Cu, Ni, Zn, then Cd.
Heavy metals such as cadmium, mercury, nickel, lead, uranium, copper, iron, manganese, cobalt, zinc, and similar metals are toxic substances that are included in the nutrition chain that pose a high risk for long-term biodiversity. The risk may have different forms: worsening of human, animal or plant health, damage to structures or contamination of ground or surface waters that are in contact with soil. The effect of toxic metals depends on the form in which the contaminant is found, further affecting its behavior in the soil. The mobility of contaminants depends on the pH value and the type of soil. For instance, As and Se are more mobile in alkaline pH, while Hg, Pb, Cd, and Zn are more mobile in acid pH soil (Adriano, 1986, Alloway, 1990).
The literature suggests a very wide variety of biological functions of zinc as a biogenic element and its participation in various biochemical processes (Deighton and Goodman, 1995; Chaney, 1992). Zinc and its compounds are irritant to the skin and mucous membranes of the respiratory and digestive tract, damage the liver, kidneys, myocardial, lymphocytic and neutrophil granulocytes, central and peripheral nervous system, pancreas, and carbohydrate metabolism, protein, and fat.

Material and Methods

The subject of this study is to determine the concentration of investigated metals in the land at three sites in the wider area of Mostar municipality. The research methodology was carried out in the following phases: selection of sampling sites, taking representative soil samples, preparing samples for analysis, physical-chemical soil quality analysis, laboratory analysis of Fe, Cu and Zn content.
The soil was sampled using standard methods using a chromium-plated probe, by taking five individual samples per parcel diagonal, which were collected in an average sample, an average mass of about 2 kg. The soil was sampled with two different depths of 0-30 cm and 30-60 cm. Six soil samples were prepared, analyzed on basic soil quality indicators, especially on the metal content of the study: Fe, Cu, and Zn. Sampling was carried out at the time of vegetation in 2012. The sampled soil was air dried for a month without the presence of direct light. After that, each individual sample was triturated in an auspicious advance and sifted through a 2 mm plastic drill bit, squeezed into paper bags and sent to the laboratory for further analysis.
Laboratory soil analyzes included the following parameters: pH in H_2O and n-KCl, hygroscopic humidity, humus content, carbonate content, physiologically available K_2O, and P_2O_5, determination of Fe, Cu and Zn content.

The pH values in H_2O and n-KCl were determined electrochemically. Electrometric determination of soil pH is based on measuring the potential difference between two electrodes immersed in a soil suspension. By the methodology, it is customary to determine pH in the soil suspension supernatant.
Determination of total nitrogen was made using the Kjeldahl method. The method is based on the destruction of the soil sample with sulphuric (H_2SO_4) acid, in the presence of a catalyst and at elevated temperature. Concentrated sulfuric acid destroys organic compounds wherein the organic compounds of nitrogen are reduced to ammonia.
Hygroscopic humidity was determined by weighing the soil sample (about 2 g) measured in the cauldron before and after drying. Humidity is determined by placing a certain amount of soil in a pot and heating to 105 ° C and drying until all the water has evaporated. The content of hummus was determined by a colorimetric method. The method is based on the wet burning of soil organic matter, using concentrated H_2SO_4 and potassium dichromate as a strong oxidizing agent. The content of carbonate in the soil was determined by a calcimeter, volumetric by Scheibler. The carbonates are destroyed by hydrochloric acid with the release of carbon dioxide, the volume of which is measured by a calcimeter at the current temperature and atmospheric pressure. The content of metals in soil samples was made by the Atomic Absorption Spectrophotometer (AAS) method using the flame technique or graphite excitation technique. This method is one of the most commonly used methods for determining the number of elements in a sample. When the characteristic wavelength of light passes through the sample, there is some absorption by the free atoms of the element whose content is determined. A hollow cathode lamp emitting intense monochromatic radiation serves as the radiation source.

Results and Discussion

The results obtained are shown in the tables. Table 1 shows the results of soil analysis on basic physicochemical parameters, while Table 2 shows the content of investigated elements (Fe, Cu, and Zn) in the explored soil.

Table 1. Physical-chemical analysis of the soil

Locality	Depth (cm)	pH-value in (±0,01)		% Nitrogen content	% Phosphorus content /100g land	% Potassium content/100g land	% Humus content	% Hygroscopic humidity
		H_2O	n-KCl					
Dubrave	0 - 30	7.50	6.70	0.21	6.50	10.4	1.24	2.38
	30 - 60	8.12	7.20	0.23	9.15	14.8	1.20	2.21
Vrapčići	0 – 30	7.55	6.65	0.22	6.15	14.1	4.31	4.98
	30 – 60	7.72	6.90	0.17	5.15	12.6	1.63	4.74
Salakovac	0 - 30	7.21	6.40	0.21	4.80	9.50	2.85	4.45
	30 - 60	7.75	6.95	1.15	9.70	13.8	3.79	5.33

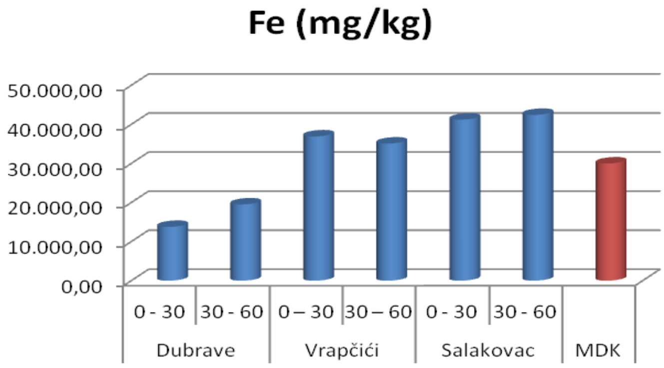
According to pH values in water as shown in the table 1, it is slightly alkaline soil and the values range from 7.21 to 8.12.
The values in n-KCl ranged from 6.40 in Salakovac, while the highest values were found at Dubrave's land, at the depth of 7.20. According to the values of pH in n-KCl, it can be concluded that the investigated land at the sites Vrapčići and Salakovac is classified as a weak acid and the plot from the location of Dubrava to neutral.

The content of nitrogen is quite balanced, and the largest quantity is at Salakovac at a different depth and is 1.15.
According to the nutrient content, all three sites can be classified as unfruitful land.

Table 2. The content of investigated elements

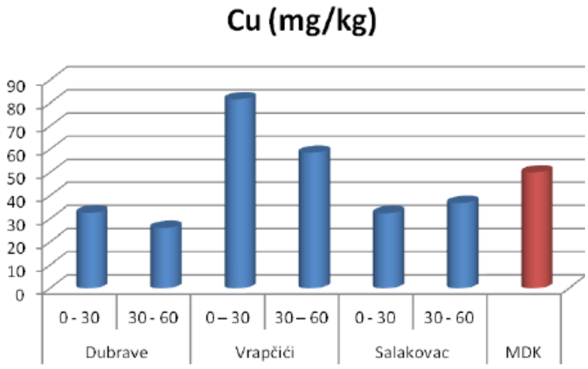
Locality	Depth (cm)	Fe (mg/kg)	Cu (mg/kg)	Zn (mg/kg)
Dubrave	0 - 30	13.774.85	32.56	90.20
	30 - 60	19.529.71	25.97	78.71
Vrapčići	0 – 30	36.934.41	81.58	159.67
	30 – 60	35.103.81	58.43	165.52
Salakovac	0 - 30	41.225.29	32.36	177.36
	30 - 60	42.447.11	36.75	99.22
MDK		30.000.00	50.00	100.00

According to the results of the content of the investigated metals (Table 2), it can be concluded that the Dubrava site is not polluted. At the site of Vrapčići, all the samples showed an increase of the investigated elements irrespective of the depth from which the sample was taken. The locality of Salakovac had increased values in three out of six samples in comporison to MAC.
The amounts of iron present were above the permitted limit values in a total of four samples at the locality of Vrapčići and Salakovac, the copper content was increased in two samples in locality Vrapčići, while the amount of zinc was above the maximum permissible concentration in three samples in locality Vrapčići and locality Salakovac.

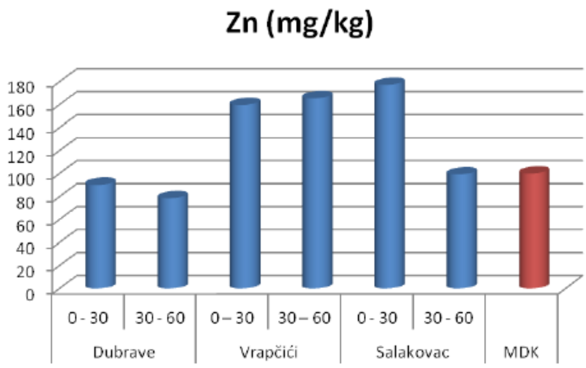


Graph 1. Content Fe in the explored soil

Iron has the highest values in the Salakovac site and its volumes are as high as 37% at the first depth and 42% at a second depth greater than the maximum permissible concentrations. Not negligible values of this element were found in the locality of Vrapčići, where an increase above MAC of 23%, at the first depth and 17%, was also noted at the second depth of the test.



Graph 2. Content Cu in the explored soil



Graph 3. Content Zn in the explored soil

The content of the copper found only at the Vrapčići location was above the limit values, and an increase of 64%, at the first depth and 17% at the other depth was noted.
The largest presence of zinc was recorded at the Salakovac site, where concentrations of this element were increased by 77% above allowed at the first depth, while its contents at the second depth were very close to the limit values. At the Vrapčići site, the zinc content was above MDK at both depths of the study. At the first depth, the presence was increased by 60%, while at the other depth was increased by 66%.
The presence of iron on two sites was larger in the deeper layers of the soil, the copper content was also in two locations somewhat larger in the surface layer of the soil, while the zinc content was also present at two locations somewhat in the first depth of the test.

Conclusions

According to the results of physicochemical analysis based on the parameters of soil quality, the following can be noted:
- all explored soils at pH in the H_2O are slightly alkaline,
- the explored soils are rich in nitrogen,
- the content of phosphorus and potassium is quite low so that the land can be classified as poorly supplied by these elements.

According to the content of the investigated elements in the investigated sites, the following observations have been made:
- the Dubrave site is unburdened with the contents of the explored elements so it is considered acceptable for the cultivation of different herbal cultures without fear of life and health of end consumers,
- In the Salakovac site, 50% of the samples had values greater than allowed, Fe content at both depths and Zn content at the first test depth, which could have a negative effect on plants, but also on human health,
- the Vrapčići site contains large quantities of all the investigated elements, which is the most polluted by the three localities and can be said to pose a high risk to human and animal health that consume crops grown on this soil,
- the amounts of the iron present are quite high and in four samples are found above MAC. The highest values were obtained at the Salakovac site with as much as 37%, at the first depth, and 42%, at a second depth, higher than the maximum permissible concentrations,
- the copper is only at one location above the limit values, that is on the Vrapčići location it was above the limit values, where the 64% increase at the first depth and 17% at the second depth was noted,
- at the Salakovac site, the concentrations zinc were increased by 77% above the permissible value at the first depth, while its contents at the second depth were very close to the limit values. The Zn content at the Vrapčići site was above MAC at both depths, at the first depth

the presence was increased by 60% and at the other depth the increase by 66%. Such land is considered to be highly risky for growing plants.

By comparing the sites with each other in all analyzes it can be stated that according to the pollution can be compared:

- Vrapčići the worst soli quality all three investigated elements above MAC were found at both depths, iron by 23% and 17%, copper of 64% and 17% and zinc by 60% and 66%.
- Salakovac is a plot on which the Fe concentration above MAC was detected at both depths, Zn at the first depth of about 77% above MAC and at a second depth at the MAC limit itself, while amounts of Cu were present below MAC
- Dubrave at which site Fe, Cu, and Zn were present below MAC for both investigated depths.

AGRICULTURE AND CLIMATE CHANGE IN THE REPUBLIC OF SERBIA

Dragana DROBNJAK*, Nenad KATANIĆ

Ministry of Agriculture, Forestry and Water Management, Belgrade, Republic of Serbia

Abstract

Climate change is one of the greatest global challenges of our time. The consequences of this change are potentially so far-reaching and serious that every country must do its part to help stabilise our planet's climate. In the area of agricultural production, which accounts for about 10% of the total gross domestic product of the Republic of Serbia, the entire national economy is very sensitive to all factors that affect agriculture. There is no doubt that climate change will affect the quality and quantity of yields of major crops in Serbia, as well as the variability of yield which will be more pronounced each year. According to climate change scenarios, which predict a further rise in greenhouse gas (GHG) concentrations, we can expect more frequent occurrences of extreme weather conditions, drought and then reduction of the amount of summer precipitation in particular, the increased number of dry days and days with extreme temperatures in the individual sub-periods of vegetation (high spring and summer temperatures), warmer winters with a lower number of frostless days. Therefore, intensive studies are conducted and introduced in preventive and alternative ways in the production process to combat extreme weather conditions. Through customed agricultural techniques and the application of complex agro-technical measures, it is possible to mitigate, though not completely exclude the negative impacts of climate change on the yield of cultivated plants.

Keywords: *climate change, GHG, agriculture, adaptation measure, Serbia*

Introduction

Climate change projections estimate the increase in frequency and intensity of natural hazards, such as floods and droughts as well as in terms of scope and duration. A substantial number of studies predict increase in intensity and frequency of flooding, particularly in the winter season. Climate change is expected to affect water resources. An assessment on the effects on water resources indicates a general decrease of water flow at the national level of 3 percent per 10 years, caused by a decrease in annual precipitation (Djurdjevic, 2015). However, at the same time the number of extreme weather events, including heavy and excessive rainfall is expected to increase due to climate change. According to the INFORM Risk Index of 2019, Serbia is highly exposed and vulnerable to natural hazards (www.inform-index.org, 2019). The major natural hazards to which the country is exposed to include, among others, (flash and river) floods, storms, drought, landslides and earthquakes. As well as epidemic livestock diseases and the emergence of pests, which may cause significant damages and losses to people and animals.

Agriculture is a highly important economic sector for Serbia, as it accounts for about 8.2 of the total Gross Domestic Product (GDP) (Worldbank, 2019). Agricultural products account for over 20 percent of national exports. Its main export products include, among others, maize, wheat, apples and frozen raspberries.

In some regions of Serbia, agriculture is a core economic activity and most of the residents depend on it for basic livelihoods, for instance the southern and southeastern regions of the country are among the poorest, while the Vojvodina region in the north is relatively more endowned as it is largely based on the developed food and agriculture industry as it is rich in fertile loamy loess soil.

The natural potential for development of agricultural production is significant. Climatic conditions are favourable and Serbia is endowned with considerable water resources for further development of its agriculture production. More than half of the country's territory is classified as agricultural land (4.867.000 ha) with the area of utilized agricultural land to be 3.438.130 hectares (Statistical Office of the Republic of Serbia, 2018).
With regard to resources, food production, technological development and the environment, a lack of adequate responses to the effects of climate change is seen as well as a lack of systemic solutions. Among the key principles to achieve this vision is 'sustainable agriculture', which is viewed as one of the main principles for implementing this agricultural policy as agriculture is still one of the most important economic sectors in the rural areas. Disaster risk reduction is not included among the strategic goals, rather 'sustainable resources management environmental protection' and in particular the sustainable usage of available natural resources through e.g. responding to climate change, protecting the agricultural land, lowering greenhouse gas emissins, enhancing biodiversity and rural areas protection and so on (Ministry of Agriculture, Forestry and Water Management, 2014).
Climate change related measures are included, such as educational and public awareness raising programmes on the issue and effects of climate change, the establishment of greenhouse gas (GHG) inventories for agriculture and forestry, plans that contain emission reduction and climate change adapation measures, improvement of manure and organic waste management, more efficient use of nitrogen fertilizers, promotion of organic farming, and research and development promotion on new crop varieties and livestock breeding.

Expected climate change - climate change scenarios in the Republic of Serbia

During the period 1960-2012, significant increase of daily mean temperature, as well as in daily maximum and daily minimum temperatures was observed in Serbia with an average trend of 0.3°C increase per decade and on annual level. Eight out of ten hottest years ever recorded were observed after 2000.
Climate scenarios predict a plausible temperature rise in the near future. Under A1B scenario for 2011-2040 and 2041-2070 it is likely that the temperature will rise by 0.5-0.9 °C and 1.8-2.0 °C respectively. According to A2 scenario the expected temperature rise is 0.3-0.7 °C in 2011-2040 and 1.6-2.0 °C in 2041-2070. By the end of the century (2071-2100) the predicted change in temperature obtained by A2 scenario is 3.6-4.0 °C, and according to A1B scenario it will be 3.2-3.6 °C. It is expected that warming will be most pronounced in the summer and fall season, with the temperature rise over 4.0 °C by the end of the century. For the period 2011-2040 both scenarios predict precipitation changes that are positive compared to the base period, and that will be decreasing toward negative values by the end of the century. Under A1B scenario, projected precipitation changes for the end of the century range from +5% to -20%, and from +20% to -20% according to A2 scenario. The negative trend is most expected during the summer season. By the end of the century, the number of frost days will have reduced to the level when it can be considered a rare event. The number of summer days will have increased by 20 – 30 days (A2 scenario). The number of days with tropical nights, will have increased by over 20 days by the end of the century. During the second half of the century the length of the growing season will have extended by over a month. Longer periods of drought are to be expected, lasting for over one month, according to the both scenarios (Ministry of Environmental Protection, 2017).

Agriculture and climate change in the Republic of Serbia

In recent years, agriculture in Serbia has suffered significant losses due to adverse weather conditions and distinctive climatic anomalies. The most important include the damage arising from the effects of drought, spring frosts, hale, storms and floods. Since 2000, Serbia went through several episodes of severe drought, which resulted in significant losses. Extreme droughts were recorded in the years 2000, 2003, 2007, 2011 and 2012 (Republic Hydrometeorological Service of Serbia, 2019). Although rarely characterized as drought, lack of precipitation in the period from October to February may also adversely affect the yield of winter crops, such as sugar beet, rapeseed and others. Furthermore, during the vegetation period high temperatures and the higher intensity of solar radiation also have significant adverse impacts. They cause damage to the fruits and leaves, but also to the trunk and the bark of trees. These changes were observed especially during 2007 and 2008.

On the other hand, the emergence of a very warm period during the late winter and early spring, followed by freezing temperatures and frosts, is especially dangerous for the early varieties of fruits as well as vine and some agricultural crops due to early start of the growing season, which becomes interrupted by low temperatures.

Impact of climate change on plant growth dynamics (crop phenology)

Due to warmer winters and fewer frost days in February and March, flowering should occur earlier, as should maturity, owing to higher temperatures in April-May-June. This shift is nearly negligible to 2030, but may bring the entire vegetation cycle forward by about 20 days to 2100.

Detailed analysis of the impact of such temperature changes on physiological and biochemical processes (that determine plant growth dynamics) have shown that climate change will bring the crop growth season forward by about 20 days to 2100. These changes in phenology can affect yields and the timing of farming operations, but may also produce a second harvest.

Impact of climate change on yields and year-on-year yield fluctuations

Extreme weather events, especially drought and greater numbers of dry days, as well as days with extreme temperatures, will exert a decisive influenceon the yields of key crops under climate change conditions.There is no doubt that climate change will influence mean crop yield levels and year-on-year yield fluctuations. In other words, all of Serbia will be affected by changes to agro-climatic conditions, in particular rising temperatures and lower summer precipitation levels, which will reduce crop yields in the absence of adaptation measures.

Impact of climate change on the appearance of pests and diseases

Climate change increases the complexity of the integrated plant management system by promoting uncertainty in the plant-pest-environment triangle. Studies have shown that, in our region,thermophile insects are expected to shift to higher altitudes and increase their number of generations. A movement of these species' ranges northwards is also to be expected. Estimates to 2055 indicate northward shifts of between 3ºin the case of Ostrinianubilalis (European corn borer) to 11ºfor Lobesiabotrana (European grapevine moth) (UNDP, 2015). All crops (both winter and summer ones) will be affected by changing patterns of pests and disease driven by increasing temperatures and changing precipitation regimes, which will particularly increase vulnerability to pests (thermophile insects). Vulnerability of each particular crop and region depends primarily on the relevant crop acreage in each region, crop management, and crop rotation (e.g. these changes will particularly affect maize in Vojvodina and Mačva, sugar beet in Vojvodina, and orchards in the Kruševac region, Vojvodina, and elsewhere in Serbia, excepting mountainous regions).

Adaptation measures

Observed climate changes lead to changes in the environmental, social and economic indicators, i.e. to changes in the overall conditions in which contemporary society lives across the globe and also in Serbia. It is believed that if further changes remain within the limits which have been determined as the goal, the mitigation of negative consequences will be possible through the appropriate and timely measures of adaptation to changing climatic conditions. On the other hand, in the case of continued uncontrolled rise in global temperatures and changes in other elements of the climate system, the consequences will be on a significantly higher scale, while adaptation will require additional efforts and additional financial investments, which can significantly slow down and hamper the progressive development of society. The aim of adaptation is to reduce the potential negative effects of climate change via planned change in the natural and socio-economic systems and to maintain the functioning of the system, or if possible, to improve efforts where such potential exists (Ministry of Agriculture and Environmental Protection, 2015).

There is no doubt that climate change will influence the quantity and quality of yields of staple crops in Serbia, both in terms of mean crop yield levels and year-on-year yield fluctuations. All of the above bear out the urgent need for adaptation. In the Second National Communication of the Republic of Serbia, a series of adaptation measures to changing climatic conditions was listed for the agriculture sector.

Extreme droughts in recent years in the territory of Serbia has been very common (Stricevic *et al.*, 2011; Stricevic and Djurovic, 2013), so that irrigation is imposed as a measure to mitigate losses, in addition to the introduction of new hybrids and varieties tolerant to drought or by using other methodologies which help achieve a more efficient use of water. Irrigation in the climatic conditions prevailing in our country is an optional measure, because crop production can take place relatively successfully with the available natural supply of water, especially when it comes to agricultural crops. Users are not obliged to use any or to pay expenses related to irrigation, even though they have that option. That problem can be twofold: the monetization of bringing water to the plot and the profitability of irrigation on the land if there are not enough interested farmers for irrigation. Previous studies (www.water.worldbank.org, 2019) have shown that irrigation can be profitable if at least 60% of the total number of owners/users use the irrigation system in the irrigated area.

Drainage systems (dewatering) may prove to be especially important if in future climatic conditions there is an increase in shortterm episodes of intense precipitation which is indicated in the future climate change scenarios. Even though the analysis indicates that the climate will be warmer and drier, drainage channels should be maintained regularly, because in drier climates more intense precipitation can be expected with increased risk of flooding.

Adaptation to climate change in agriculture shall primarily include the following priority actions: Changes of plant species and assortments in the sowing structure of sowing in relation to the expected changes in the phenology of plants, Introduction and use of species and varieties/hybrids more tolerant to stressful conditions, Work on the selection, breeding and creation of tolerant genotypes, Increase the representation of growing winter crops, Adapting the basic treatment systems, Adequate rational fertilization, Change and improvement of the treatment system with the aim of improved moisture conservation (application of reduced treatment systems), Changes in time and sowing density, Monitoring and adapting to the new invasive thermophilic invasive pests and diseases (adapted to drought conditions).

Conclusions

The Republic of Serbia has established an important component of the institutional and legal framework for fighting climate change. At the same time, there is still a need for

improvement, as well as capacity building and expanding the knowledge of responsible and competent institutions, both at the national and local level, and among the general public.
The multi-sectoral nature of climate change and the current level of knowledge and awareness certainly indicate the need for systematic and continuous activities to raise awareness of this issue among the general public. As a result of the joint work of the Ministry of Agriculture, Forestry and Water Management of Republic of Serbia and the Food and Agriculture Organization of the United Nations (FAO), brochures "Good agricultural practices and technologies for mitigating the effects of natural disasters in corn production in Serbia" and "Good agricultural practices and technologies for mitigating the effects of natural disasters in soybean production in Serbia" (www.minpolj.gov.rs). The brochures are aimed at agricultural advisory bodies, those employed in the sector farmers, and the broadest interested public.
There is no doubt that climate change will influence the quantity and quality of yields of staple crops in Serbia, both in terms of mean crop yield levels and year-on-year yield fluctuations. All of the above bear out the urgent need for adaptation.

EFFECTS OF DRAINAGE AND RUNOFF ON THE PRODUCTIVITY OF THE LAGOON OF GHAR El MELH (TUNISIA)

Mohamed Salah ROMDHANE*, Chiheb FASSATOUI, Amel BEN REJEB JENHANI

Research Unit Aquatic Ecosystems and Resources, National Institute for Agricultural Sciences University of Carthage, Tunis Tunisia
*Corresponding author: ramadhanms@gmail.com

Abstract

The Ghar El Melh lagoon, Ramsar site and Ramsar City (Tunisia), is a coastal quaternary lagoon edified by the flood and sediments discharge of Mejerdah River and the marine swell. This lagoon maintains hydrological exchanges with the inland waters issues through river and channels, and the marine water across an evolving inlet. The aim of this work focused on how the inland water arrival, strongly linked to the agricultural activities and rainfall regime, may affect the fisheries productivity of the lagoon. In fact from the inland side, 2 rivers and 2 channels discharged into the lagoon the drainage water of more than 2280 ha of irrigated areas. The lagoon communicates with the sea through a naturel outlet of 70 m large and around 0.8 m depth. The yearly balance of water exchange revealed that the lagoon received 4.5 mm^3 of runoff water and 5.7 mm^3 of agriculture drainage waters. The daily tidal exchanges amounted to 3.1 mm^3, ensuring a water renewal time of 8.2 days. These inputs varied strongly with the rain season and the tidal range. The fisheries of the lagoon were directly regulated according to this hydrodynamic characteristics and balance: fish recruitment, trophic and genetic migrations etc. Thus the annual production of fish, dominated by European eels and mullets, seemed to fluctuate according to the years: 64 ± 22 tons per year during the period 2008-2017, the eels production was 8 times greater with runoff and drainage spill (24.10 ± 15.19 ton/year) (Kruskal-Wallis test: $p < 0.001$). However, that was not the case for mullet. The organic and mineral load of these waters may be directly implicated in the irregularity of catches, knowing that the total nitrogen can reach 2.67g/m^3 in the drainage waters.

Keywords: *coastal lagoon, rainfall, water exchanges, fisheries, Tunisia*.

Introduction

Ghar El Melh lagoon is located at the north-western part of the Tunisia (37°08'N 10°10'E), this coastal first-line lagoon cover an approximate area of 2600 hectares, separated from the sea by a sandy coastal strip and communicate throw an intermittent naturel channel of 70m as maximum large. The average depth of the lagoon is 1 meter, water salinity ranges from 25.0 to 46.0 psu and surface water temperature varies between 18.5 and 27.4 °C (Romdhane et al., 2019). A considerable supply of freshwater in this lagoon is observed during the rainy season (September-April) by the flood throw River and channels which overflows. The lagoon was often enriched with nutrients, which provided by the drain of an active agricultural surrounding area. In fact, the main activity linked to this lagoon are based on traditional fisheries coupled with multi agriculture uses from extensive to intensive systems. The fishing yields seem to be widely linked to the rainy or drought cycles and water issues and qualities. In this work we try to explain how the inland water arrival, linked to rainfall regime and agricultural activities affect the global fisheries productivity and the specific catches in the lagoon.

Materials and methods

The analysis is based first on hydrological parameters of rivers and canals that flow into the lagoon, hence we consider the volumes and quality of the drainage and runoff. Secondly we couple the meteorological data series covering the last 5 years, the data mainly cover the average monthly rainfall during the period 2013 to 2017 (INM 2019) and the total and specific fishing data with a complete time series of statistical data obtained over the last ten years for the period from 2008 to 2017 (DGPA2018). The data were structured to obtain mean yearly landings, by dry (April to August) and wet season (September to March), and by major fishing species in the region (particularly European eel and mullets productions). On the basis of these collections, descriptive statistical analyzes were carried out to connect the hydraulic variables (rainfall, inlet and outlet waters) to lagoon production in order to establish possible relationships between them. Principal component analysis (PCA) was applied to classify major fish species according to their relative fishing production during the study period. The non-parametric Kruskal-Wallis test (Kruskal and Wallis, 1952) was used to compare mean fishing productions over time and seasons.

Results and Discussion

The lagoon receipt in fact from the inland side, 2 rivers (Kherba and Nechma) and 2 channels (Mabtouh and Charchara) discharged into the lagoon the drainage water of more than 2280 ha of irrigated areas. The yearly balance of water exchange reveals that the lagoon receives around 4.5 Mm^3 of runoff water with 4.0 Mm^3 during the wet seasons and 0.5 Mm^3 during the dry season. The agriculture drainage release yearly 5.7 Mm^3 of wastewater, about 3.5 Mm^3 during the wet season and 2.2 Mm^3 during the dry season with respectively 2.3 and 7.25 mg l^{-1} of suspended matter charge . The effects of the irregularities of dry and wet seasons are clearly observed in this lagoon (Moussa et al., 2005). Sea side, the lagoon communicates with the sea through a naturel outlet of 70 m large and around 0.8 m depth. The daily tidal exchanges is ranged to 3.1 Mm^3, ensuring a water renewal time of 8.2 days. These inputs vary strongly with the rain season and the tidal range, so we considers yearly the succession of a dry and a wet season (Table 1).

Table 1. Mean hydrological data and fish yields during the last decade (2008-2017)

Parameters	Dry season	Wet season
Rainfall (mm)	47.9	477.5
Runoff (Mm^3)	0.5	4.0
Drainage (Mm^3)	2.2	3.5
Suspended matter (tons)	5.06	25.38
Tidal exchanges (Mm^3)	465	651
Nitrogen input (tons)	5.8	3.1
Total captures (tons)	16.9	47.1
Eels (tons)	3.4	24.1
Mullets (tons)	0.9	0.9
Mullets juvenile (tons)	4.8	6.6

The fishery of the lagoon is directly regulated by the hydrodynamic characteristics and balance: fish recruitment is enhanced by the water flow and water level at the outlet, best recruitment is observed up to 0.5 ms^{-1} current speed and 0.9m of water level, high turbidity disturb larval recruitment. the trophic and genetic migrations are also conditioned respectively by the nutriments levels who enhance the primary production and the physiological cycle of each species. Finally the fishing effort act as regulatory factor of the productivity of the lagoon. Thus the annual production of fish, dominated by European eels and mullets (adult and juveniles), seems to fluctuate according to the years around 64 ± 22 tons per year, mean value during the period 2008-2017. Such effects are widely observed in the coastal areas and lagoons (Garali et al., 2009). The organic and mineral load of these waters may be directly implicated in the irregularity of catches, knowing that the total nitrogen can reach 2.67 g m^{-3} in the drainage waters (Figure 1).

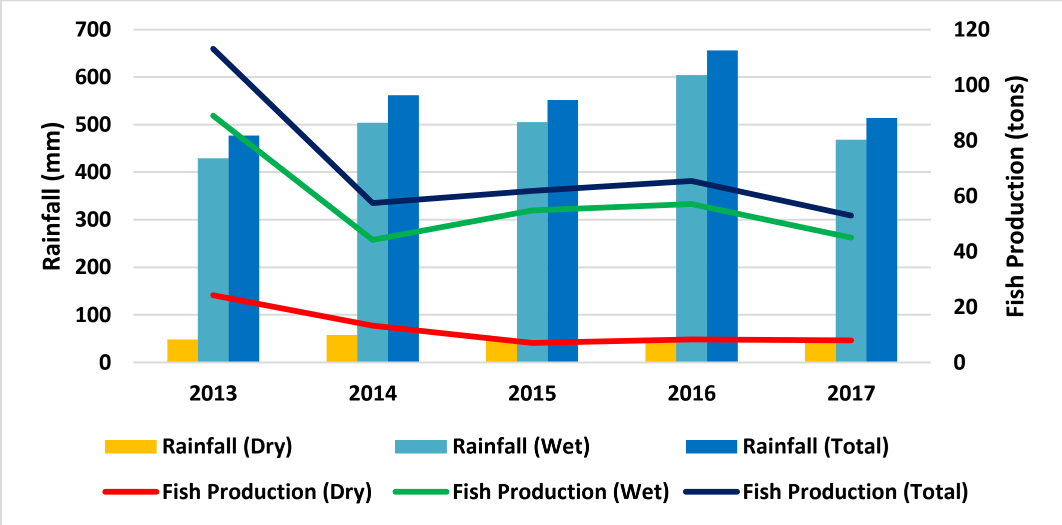

Figure 1. Evolution of the hydrological parameters and the fishery characteristics.

To better characterize the landings of total fish production and by major species (European eels and mullets) in Ghar El Melh lagoon, we carried out a PCA taking into account the year of landings of each fish category as variables and wet and dry seasons as factors (Figure 2). According to the PCA results, it appears that European eel follows closely the distribution of total fish production. However, an agglomerative distribution was observed in mullets totally independent of the seasons.

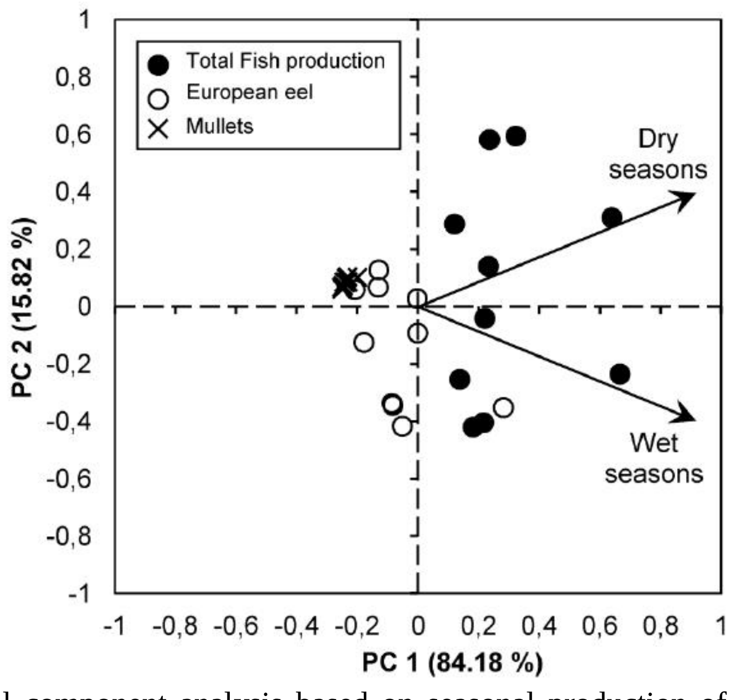

Figure 2. Principal component analysis based on seasonal production of total fish species, European eel and mullets in Ghar El Melh lagoon during the period 2007-2017.

When we compare fishery production for each season separately during the period from 2007 to 2017 in Ghar El Melh lagoon, similar tendency was observed as PCA output. The landing quantities of the total fish production, European eel and mullets in Ghar El Melh lagoon according to wet seasons and dry seasons are shown in Figure 3.

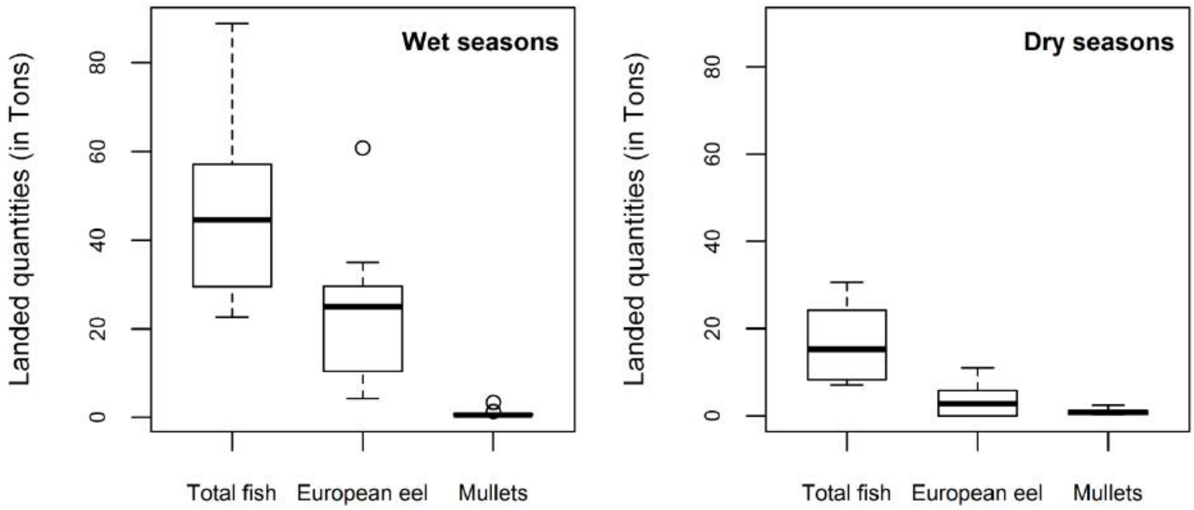

Figure 3. Box-plots indicating the landing of total fish production, European eel and mullets according to the seasons Wet in the right and dry in the left (period 2007-2017). The box portion of the plot represents the interquartile range from the first to the third quartile and the line drawn through the box represents the median. The vertical whiskers extend to the highest and lowest values in the dataset, excluding outliers, which are marked as open circles.

Hydraulic variables, mainly runoff, water exchange and seawater, are important abiotic factors that influence the production of European eels in the Ghar El Melh lagoon (Table 2). This production is 8 times greater in the wet season (24.10 ± 15.19 ton/year) than in the dry season (3.44 ± 3.62 ton/year) (Kruskal-Wallis test: $p < 0.001$). However, it seems that these factors have no effect on the stability of mullet production over the year (mean production during wet season: 0.93 ± 0.87 ton/year; mean production during dry season: 0.93 ± 0.60 ton/year; Kruskal-Wallis test: $p = 0.762$).

Table 2. Kruskal-Wallis test results comparing annual landing quantities (mean ± standard error) for total fish production, European eel and mullets between wet and dry seasons in Ghar El Melh lagoon during the period 2007-2017.

	Mean annual landing quantities in wet seasons (in tons)	Mean annual landing quantities in dry seasons (in tons)	Statistics of Kruskal-Wallis	*p*-value	significance
Total Fish	47.082 ± 19.566	16.857 ± 7.746	10.566	0,0011	**
European eel	24.100 ± 15.627	3.441 ± 3.623	11.147	0,0008	***
Mullets	0.930 ± 0.866	0.932 ± 0.695	0.091	0,7623	ns

From the nutrient point of view, it seems that there is a gradation of nutrient loading that increases from the natural watershed to the urbanized watershed and through the watersheds occupied by intensive agriculture (Deslons-Paoli, 1996). Till nowadays the nutrient inputs play a major role to maintain the lagoon productivity, hope that, phytosanitary products and uses and spill still under control.

Conclusion

The yearly total fisheries landing in the lagoon, is widely related to the hydrological balance of lagoon environments expressed by direct rainfall inputs, hydrological inputs, runoff, infiltration, drainage and evaporation is inevitably under seasonal influence. The dominant fish species (eels and mullets) may be used as indicators of the regularity of the water balance. In fact the large liquid and solid flows from the catchment area to the lagoon are accompanied by a transfer of significant quantities of suspended solids and nutrients, in their particulate and dissolved form, which can influence the productivity of the highly exploited lagoon and consequently the socio-economic situation of the region.

Abstract

Mercury (Hg) is a heavy metal, designated as a pollutant in the environment, due to its harmful effects on biota. Mercury pollution is a significant global concern, not only due to its increased levels in the environment, but also due to its toxic effect on human health across the food chain. The aim of this study was to determine the content of Hg in agricultural soils and main field crops. Total number of 84 bulked soil samples were taken (0-30 cm depth) from agricultural land. At the same plots, 84 plant crops (11 species – used as food and feed) were taken during the vegetation season 2018. The samples were analyzed for total Hg content using Direct Mercury Analyzer DMA 80 Milestone. The obtained results of Hg content in soil were within interval 0.003-0.37 mg kg^{-1}. The average concentration of Hg was 0.08, with median 0.06±0.06 mg kg^{-1}. Obtained values of Hg in soils were below maximum allowable concentration (MAC) and this interval is complied with the most cited range in soils up to 1 mg kg^{-1} without known nearby contamination sources. It was found that Hg content is positively correlated with pH value, slit soil fraction, and $CaCO_3$. The obtained results of Hg content in plant – field crops, were within interval 0.0001-0.9087 μg kg^{-1}. Obtained maximum value is still far lower than MACs for feed and food. According to the average Hg content in plant species, obtained results were classified from highest to lowest, respectively: bean, alfalfa, maize, soybean, rapeseed, sunflower, barley, pepper, wheat, rye and tomato.

Keywords: *Mercury, Hg, Soil, Heavy metals, Field crops.*

Introduction

Mercury (Hg) has been listed as a high priority pollutant by many international organizations due to its mobility and persistence in the environments and high toxicity to organisms (Jiang et al., 2006). A global response to solving this problem has been finalized by the adoption of the Minamata Convention on Mercury. The Minamata Convention on Mercury was approved and signed in Geneva in 2013 and entered into force in 2017. It is an international treaty designed to protect human health and the environment from the harmful effects of mercury (UNEP, 2019). Control and monitoring of anthropogenically introduced Hg throughout its life cycle is the key factor in fulfilling the obligations set by the Convention, and the Republic of Serbia is a signatory country to the treaty.

Mercury is a metal that easily changes the aggregate state, it is volatile at 20^0C, and migrates easily through the environment and builds compounds of different toxicity to biota. Natural sources of mercury released to the atmosphere include volcanoes, evaporation from soil and water surfaces, degradation of minerals and forest fires (Ottesen et al., 2013). The burning of fossil fuels, metal mining and industrial activities, such as ore processing and cement production, particularly coal and oil combustion and gold production, are the major anthropogenic sources of Hg release. Over the past several centuries, mining has been the dominant anthropogenic source of Hg (Amos et al., 2015). Soil contamination with mercury due to mining was studied worldwide (Odumo et al., 2014). More directly, soil contamination can be the result of liquid or solid Hg sources disposal, such as accidental spilling, mine tailings, landfills, polluted sewage sludge, etc. (Leterme and Jacques, 2015).

Hg in soil occurs in several ionic species and it is susceptible to transformations through the various processes. Mercury could be introduced and accumulated in soil through various pathways. On the other hand, Hg from soil could be released into the atmosphere, thus soil becomes an important source of Hg (Shi et al., 2013). Methylmercury (MeHg) is bioavailable and can be bio-accumulated within food webs. Many studies have confirmed Hg biomagnification in the food chain (Krasinska and Falandysz, 2015).
The aim of this study was to determine the content of Hg in agricultural soils of central Serbia region and main field crops.

Material and Methods

Study was conducted as part of the Project: "Global assessment of the tolerance of field crops on dangerous and harmful substance in agricultural soil and irrigation water", which is supported by the Ministry of Agriculture, Forestry and Water Management of the Republic of Serbia in 2018.

Sample collection and processing

Field activities were carried out during the second half of 2018. The locations of collected samples of agricultural land are shown in Figure 1 and belong to 6 statistical districts of the Republic of Serbia: East, Bor, South, West, Belgrade and Central District. Total of 84 bulked soil samples were taken from topsoil 0-30 cm using a probe drill. One composite soil sample represented 15-25 subsamples from production plots (up to 5 ha area).
During field activities, total of 84 samples of plant material were taken also. Field and industrial crops were sampled after harvest as an average sample of seed from observed plot. Plots with forage crops were sampled immediately after cutting, as an average sample of aboveground part of alfalfa. Vegetable crops were collected as fresh samples of fruit (tomato and pepper), while bean was collected at the stage of mature seed as part of crops consumed in human diet. Samples of pepper and tomato were transported to the Laboratory in refrigerator cars.

Laboratory analysis

The pH value in 1:5 (V/V) suspension of soil in 1 mol/L KCl and water was determined using glass electrode according to ISO 10390 (2010). The carbonate content ($CaCO_3$ content) was determined according to ISO 10693 (1995) volumetric method. The organic matter content was measured by oxidation using the sulphochromic oxidation method by ISO 14235 (1998). Particle size distribution was determined in the <2 mm fraction by the pipette method (Van Reeuwijk, 2002). The size fractions were defined as clay (<2 μm), silt (2-20 μm), fine sand (20-200 μm) and coarse sand (200-2,000 μm).The soil and plant samples were analyzed for total mercury content using Direct Mercury Analyzer DMA 80 Milestone.

Statistical analysis

Data were statistically processed by analysis of the main descriptive parameters and correlation coefficients ($p \leq 0.05$) using STATISTICA for Windows version 12 (Dell Inc. 2016).

Results and Discussion

Mercury in soil

Obtained values of total mercury content in this study vary in a wide interval, from 0.003 to 0.37 mg kg^{-1}. The results fall into the interval that is most often cited for mercury content in the soil without a known nearby source of pollution, and which amounts to 0.01–1 mg kg^{-1} (Shi et al., 2013). Median value of mercury in this study is 0.06 mg kg^{-1}±0.06 (Table 1), which also complies with the most cited mercury content in worldwide soils of 0.06 mg kg^{-1} (Adriano, 2001). Obtained values match with national average for China soils of 0.065 and Liaoning Province of 0.064 mg kg^{-1} (Shi et al., 2013).

Based on analyses of 1,370 samples of agricultural soil of Vojvodina, median for this province of the Republic of Serbia is of somewhat lower value and amounts to 0.05 mg kg-1 (Ninkov et al., 2017). High variation of coefficient of variation CV (72.5%) points out high heterogeneity of tested soil samples (Table 1); but this value is lower than the obtained for studies in Vojvodina (CV=119.9%).

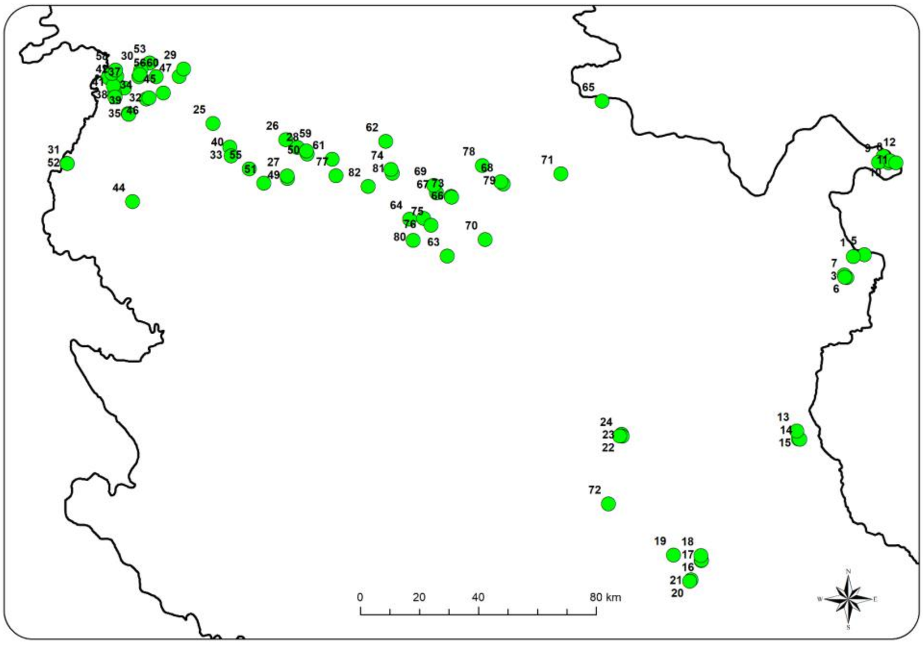

Figure 1. Layout of 84 taken soil and field crop samples in central Serbia

Based on GEMAS project (Ottesen et al., 2013), where 2,148 agricultural soil samples from a large part of Europe were analyzed (33 countries, 5.6 million km^2) at an average density of 1 sample site/2,500 km^2, median for mercury for agricultural arable land amounted to 0.03 mg kg^{-1} (Ap horizon, 0–20 cm). Median for Central Europe, where the Republic of Serbia belongs, amounted to 0.05 mg kg^{-1}. It was determined within GEMAS project that the values of Hg in Central Europe are the highest, compared to Scandinavia, Baltic Countries and Southern Europe. On the map of Hg distribution across Europe (Ottesen et al., 2013), part of Serbia, which is the subject of present study, ranged from 0.0476 to >1 mg kg^{-1}, while obtained values in our study are somewhat lower, i.e. Hg content in 25-75% percentiles were from 0.04 to 0.09 mg kg^{-1} (Table 1).

Mercury concentrations in soil of the United States of America ranged from 0.0091 to 0.37 mg kg^{-1} (Shacklette and Boerngen, 1984 *in* Wentz et al., 2014), similar to present research. Studies have shown that mercury concentrations in surface soil in the east part of USA are typically about twice those in the west part (Gustavsson and others, 2001 *in* Wentz et al., 2014). High mercury concentrations in the Eastern USA generally reflect greater rates of atmospheric mercury deposition in this region (Wentz et al., 2014).

Content of Hg in all tested samples was below the threshold of 2 mg kg^{-1}, which is the maximum allowable concentration (MAC) for agricultural soils as prescribed by the laws of the Republic of Serbia (OG 23/1994). There is only one sample which is above of threshold limit of 0.3 mg kg^{-1} according to Decree on Limit Values in soil (OG 30/2018). The obtained results also indicated that the measured levels of Hg in the soil are not limiting factors for safe food production in Serbia.

Table 1. Statistical summary of total mercury content (mg kg $^{-1}$) in agricultural soils

Statistical parameters	Value
Number of samples	84
Minimum value	0.003
Percentiles 25%	0.04
Median	0.06
Percentiles 75%	0.09
Maximum values	0.37
Average	0.08
Standard deviation	0.06
Coefficient of variation (%)	72.47

Silt fraction content was in significant positive correlation with Hg content, while there were no positive statistically significant correlations with other soil fractions content (Table 2). Generally, as for the other elements, heavier soils have higher Hg content and lighter soils have lower Hg content. Mean concentrations of Hg in podzols, sandy soils and desert sands is 0.06, while the mean concentration in loamy soils is 0.13 mg kg^{-1} (Hooda, 2010). In general, clays present negative charges, tend to undertake sorption of cations, and are associated with Hg retention in soil. It was found that mercury and mercury salts can adsorb strongly to soil particles, particularly clay minerals and iron oxides within neutral pH range (He et al., 2015). According to Roulet et al. (1998), the fine fraction (<63 μm) was two to seven times more concentrated in Hg than the medium (63-210 μm) and coarse (> 210 μm) fractions. However, some studies found no statistically significant differences that indicated a direct influence of clay contents on Hg concentrations in soil (Odumo et al., 2014).

Table 2. Correlation coefficients between content of mercury (mg kg^{-1}), various size soil fractions (%) and basic soil chemical properties

	Coarse sand %	Fine sand %	Silt %	Clay %	pH in H_2O	pH in KCl	$CaCO_3$ %	Organic matter %
Hg	-0.065	-0.083	0.220*	-0.040	0.262*	0.274*	0.634*	0.175

clay (<2 μm), silt (2-20 μm), fine sand (20-200 μm), coarse sand (200-2,000 μm)
* p≤0.05, significantly correlated

According to the established correlations shown in Table 2, Hg content was in statistically significant positive correlation to pH value (both, active in H_2O and substitution in 1MKCl, acidity), and $CaCO_3$ content, while statistically significant correlation was not found with organic matter content. In the previous studies (Rodriguez Martin et al., 2009; Ninkov et al., 2017) negative correlation between pH value and Hg content was established. The both listed studies were on alkali soils, while observed soils in present research were mainly acidic soils with median value of pH 5.41±1.21. In the study of Rodriguez Martin et al. (2009), negative correlation of Hg with $CaCO_3$ was found, while in some studies (Rodriguez Martin et al. 2013; Ninkov et al., 2017) significant correlation between $CaCO_3$ and Hg content was not found.

Statistically significant correlation was not found between organic matter and Hg content, which is the opposite of previous studies (Rodriguez Martin et al. 2009, 2013; Shi et al. 2013; Ninkov et al., 2017). The strong link between Hg concentration and organic material content was also confirmed in study of Ottesen et al. (2013), especially in the relatively high Hg levels in the Scandinavian soils.

Mercury in plant materials

As the result of high sensitivity of Direct Mercury Analyzer that was used in present study, mercury was detected in all samples of plant material, but in very small concentrations. The highest value in the study was 0.9 μg kg^{-1} in maize (Table 3). This value is still 10 times lower than allowed for animal feed, which, according to the Rulebook on the quality of animal feed (OG 39/2016), amounts 0.1 mg kg^{-1}. According to Rulebook on food (OG 90/2018), the limit for mercury content in fresh fruit and vegetables is 20, and for cereals and flour 30 μg kg^{-1}, while values obtained in present study are far lower (Table 3). According to the average Hg content in plant species, obtained results were classified from highest to lowest, respectively: bean, alfalfa, maize, soybean, rapeseed, sunflower, barley, pepper, wheat, rye and tomato (Table 3).

Statistical importance was not determined in the relation of Hg content in the soil and plant material. The majority of observed samples included the seed that plant protects from accumulation of harmful substances as its own generative part. Besides, observed vegetables and alfalfa were exposed to atmospheric deposition of Hg. Results of Niu et al. (2013) study indicated that Hg concentrations in the leaves of lettuce, radish, alfalfa and perennial ryegrass were the function of air Hg concentrations and time.

Table 3. The concentration of Hg in plants (μg kg^{-1} of originally fresh matter)

μg kg^{-1}	wheat	barley	maize	soybean	sunflower	rapeseed	alfalfa	tomato
N	17	5	26	6	10	3	12	2
Min.	0.0001	0.0150	0.0001	0.0001	0.0001	0.0001	0.2818	0.0001
Max.	0.0552	0.0504	0.9087	0.0679	0.2252	0.0580	0.8519	0.0001
Average	0.0122	0.0285	0.0507	0.0322	0.0286	0.0307	0.5296	0.0001

N number of samples

N=1: Rye 0.0001; pepper 0.0131; bean 0.8416 μg kg^{-1}

Conclusions

The obtained results of Hg content in the soil were within interval 0.003-0.37 mg kg^{-1}. The average concentration of Hg was 0.08, with median 0.06±0.06 mg kg^{-1}. This interval complied with the most cited range in soils up to 1 mg kg^{-1} without known nearby contamination sources. It was found that Hg content is positively correlated with pH value, slit soil fraction, $CaCO_3$. The obtained results also indicated that the measured levels of Hg in the soil are not the limiting factor for safe food production in Serbia. The obtained results of Hg content in plant – field crops, were within interval 0.0001-0.9087 μg kg^{-1}. Obtained maximum value is still far lower than maximum allowable concentration for feed and food. According to the average Hg content in plant species, obtained results were classified from highest to lowest, respectively: bean, alfalfa, maize, soybean, rapeseed, sunflower, barley, pepper, wheat, rye and tomato.

Abstract
This paper presents the variation of soil structure along the foot and toe slopes of Mt. Vukan, East-Central Serbia. The analysis of aggregate size distribution and structure indices were conducted by means of soil units, characteristic soil horizons and elevation differences along the study area. Soils of Great Field located at different elevations were found to have significant variation in ASD and soil structure indices. Topsoil horizon of Eutric Cambisols have higher MWD after dry sieving, but at the same time it has the highest variation in MWD after wet sieving, indicating low water stability, which is opposite to the coefficient of aggregability. We share an opinion that change in MWD better depicts soils structure stability to water. The results of correlation analysis indicated that clay content is correlated more to structure indices compared with SOM content. SOM is significantly correlated with ASD and soil structure indices only in Calcomelansols, whereas the significant correlation of clay content and soil structure is more evident in Eutric Cambisols and Non-calcaric Chernozems, compared with other soil units. Soil structure variation along the lowest chain of Catena might be strong, and that it has to be analyzed from the point of view of soil unit and their corresponding soil horizons.

Keywords: *Soil structure, aggregate stability, aggregate size distribution, structure indices*

Introduction
Soil aggregation is one of the most promising indicators of soil quality, although quantitatively not always perfectly defined. It refers to natural organization of soil particles into various forms as a result of pedogenic processes. Soil structure is formed with the involvement and interaction of physical, chemical, mineralogical, and biological factors, the role of which depends on the soil type and the organization level of the soil particles (Alekseeva et al., 2009). Soil aggregates behave variously in respect to water impact and mechanical pressure. Aggregate stability depends on internal cohesiveness between constituent colloidal particles, among which the most important binding agents are humic substances, sesqui-oxides, Ca^{++} ions, clay minerals, calcium carbonate, earth worms and funghi. Soil structure degradation produce a decrease of soil porosity and infiltration, favors soil crusting, enhance reducing conditions, impede seedlings growth, favors runoff and water erosion, leads to water logging. There is no universally accepted way to measure soil structure (Diaz-Zorita et al., 20012). Common method used to analyze soil structure in Serbia is Savvinov's method (Savvinov, 1931).
Aggregate size classes and their distribution is one of the most important soil property, because of its enrolment in soil fertility and resistance to erosion, compaction and sealing. Many indices worldwide obtained from the sieving analysis are used to describe soil structure and soil aggregability, such as structure coefficient (Shein et al., 2001), geometric mean diameter (Campbell, 1993), mean weight diameter (Hillel, 1993), or coeficient of aggregability (Vershinin, 1958). The importance of soils structure and their linkage and

homogenity with soil classification units are presented in Serbia by different authors (Djordjevic, 1993; Ciric et al., 2012).
The aim of this study is to: 1) to perform quantitative assessment of soil structure after dry and wet sieving by means of soil type, 2), to compute different indices of soil aggregation in order to assess stability of soil structure, 3) to find relation of soil structure with soil organic matter and clay content, and 4) to assess the impact of soil spatial position on aggregation.

Material and Methods

Site description

This study was conducted in the East-central Serbia about 100 km southeast of Belgrade. The study area called Great Field is located at the elevation between 175-210 m a.s.l. The area has temperate climate and presents the foot and toe slopes of mountain Vukan. Foot and toe slopes have uniform gradient of within the 2.5 km distance. Field crops production is presented more in the western part of the area, whereas the eastern parts are used mainly for grazing.

Soil sampling

Total number of 42 soil profiles was opened in respect to elevation alterations within the study area. Disturbed soil samples were taken approximately at 20 cm depth within the horizons. A total number of 161 samples characterized the whole area.

Basic soil analysis and soil classification

In the laboratory, the following measurements were conducted: particle-size distribution of the soils was determined by combining sieving and the pipette methods (Rowell, 1997); soil organic carbon concentration (SOC) was determined using the dichromate method (Rowell, 1997); SOM percent was calculated by multiplying %SOC by a factor of 1.724; total carbonate content was measured volumetrically after treatment with 6 N HCl (Nelson, 1982). The soils are classified according to national classification system (Skoric et al., 1985). General soil characteristics of the five soil units and their corresponding soil horizons are presented in Tab. 1. For additional details regarding the studied soils and further analytical data refer to Zivotic (2016, 2017).

Aggregate-size distribution and aggregate stability

Soil aggregation was characterized by the dry aggregate size distribution (ASD) after dry and wet sieving. Savvinov's method (Savvinov, 1931) uses dry and wet sieving procedures. As a result of dry sieving, eight classes of soil aggregates by size were determined: mega-aggregates (>10 mm), macro-aggregates (10–5, 5–3, 3–2, 2–1, 1–0.5, 0.5–0.25 mm) and micro-aggregates (<0.25 mm). As a result of wet sieving six aggregate size classes were determined: 3–2, 2–1, 1–0.5, 0.5–0.25 and <0.25 mm (micro-aggregates).

Structure indices

The results of dry and wet sieving were used to determine structure indices: coefficient of structure (Ks), dry mean weight diameter (dMWD), wet mean weight diameter (wMWD), and dry geometric mean diameter (dGMD), wet geometric mean diameter (wGMD) and coefficient of aggregability (Ka). Ks was calculated as the ratio between the content of the agronomically valuable fraction (0.25–10 mm) and the sum of aggregates higher than 10 mm and lower than 0.25 mm, after dry sieving (Shein et al., 2001). Soils with Ks value above 1.5 have a good structure, while those with Ks lower than 0.66 have with weak (bad) structure.
The MWD is the sum of the weighted mean diameters of all size classes, with the weighting factor of each class which is a proportion of the total sample weight. Both dMWD and wMWD were calculated by the following equation (Hilel, 2004):

$$MWD = \sum_{i=1}^{n} x_i \cdot w_i \qquad \text{Equation 1}$$

Where: xi is the mean diameter of any particular size range of aggregates separated by sieving, and w_i is the weight of the aggregates in that size range as a fraction of the total dry weight of the sample analyzed.
Geometric mean diameter was calculated as index of Mazurak (1950) after dry and wet sieving using following equation:

$$GMD = \exp\left\{\frac{\sum W_i \cdot \log X_i}{\sum W_i}\right\} \qquad \text{Equation 2}$$

Where: W_i is the weight of the aggregates of each size class (g) and X_i is the mean diameter of the i_{th} size class (mm).

Table 1. The mean (± standard deviation) values of and particle-size distribution, SOM content and $CaCO_3$ content in five different soil units and their characteristic horizons

Soil type*	Horizon designation*	Sand (%)	Silt (%)	Clay (%)	SOM (%)	$CaCO_3$ (%)
Colluvial Soils	A	26.8±12.0	46.8±3.7	26.4±9.6	3.17±0.61	19.5±21.6
Calcomelanosol	A	21.6±8.6	46.5±6.3	25.9±6.2	4.02±0.94	12.3±11.8
Calcaric Chernozem	A	26.8±7.4	48.5±3.2	24.7±8.2	3.65±0.43	19.7±12.9
	AC	31.6±11.5	45.9±6.8	22.6±8.3	2.64±0.62	30.7±19.5
	C	29.1±7.0	48.2±4.1	22.7±4.7	2.02±1.03	34.4±14.5

Eutric cambisol	A	15.3±2.7	52.2±4.0	32.6±3.8	2.36±0.61	-
	(B)	12.1±2.8	49.6±3.8	38.3±5.0	1.15±0.42	-

*according to national classification

Differences in MWD and GMD, after dry and wet sieving, were used to describe aggregate stability to saturated water conditions. High wMWD values imply greater aggregate stability, whereas high values of aggregates <0.25 mm implies low aggregate stability. Differences in the content of micro-aggregates between wet sieving and dry sieving was also used to express aggregate stability. Aggregate stability is expressed through coefficient of aggregability (Vershinin, 1958), as ratio of wet aggregates higher than 0.25 mm, and lower than 0.25 mm.

Statistical analysis
Descriptive statistic was used to present the results of soil structure for separate soil units. Six different elevations zones (180, 185, 190, 200, 205-210 m a.s.l) across the study area presented statistical treatments, whereas six profiles within the zone presented replications. The differences in soil characteristics within elevation groups were conducted by means of one-way ANOVA. The LSD test was used to assess the differences within the means of soil groups topsoil characteristics. Correlation analysis was performed to investigate the relationships between clay and SOM content and structure indices. The correlations were expressed as Pearson's linear coefficients with the indication of statistical significance (* for $P<0.05$, ** for $P<0.01$). All statistical analyses were performed using SPSS 18.0 software (SPSS, 1995).

Results and Discussion

Aggregate-size distribution and aggregate stability
Humus-accumulative horizons of Eutric Cambisols are characterized with the highest amount of aggregates >10 mm (58.7±13.7%), followed by their subsoil horizons (42.7±10.2%) and topsoil horizons of Non-calcaric Chernozems (42.2±7.2%). The lowest content of mega-aggregates is found in Calcomelanosols, 22.5±10.9%. The content of micro-aggregates in all

soil units is low. It is the highest in C horizon of Calcaric Chernozems, topsoil horizon of Colluvial Soils, and intermediate horizon of Calcaric Chernozems, 5.2±3.1%, 4.0±4.1%, and 3.3±2.1%, respectively. Ciric et al. (2012) found significant differences in ASD and structural indices among different soil types in Vojvodina. The lowest value of Ks is found in topsoil horizon of Eutric Cambisols, topsoil horizon of Non-calcaric Chernozems, and subsoil horizons of Eutric Cambisols, 0.8, 1.4 and 1.4, respectively. All the other soil horizons have coefficient of structure higher indicating good aggregation. MWD is different within soil units. It is the highest in Eutric Cambisols A horizon, (9.01±1.09 mm), followed by subsoil horizon of Eutric Cambisols, and topsoil horizon of Non-calcaric Chernozems, 7.76±0.85 and 7.70±0.59 mm, respectively. Calcomelanosols topsoil has the lowest MWD between soil units, 5.66±1.01 mm.

The results of wet sieving indicate the highest increase in the content of micro-aggregates in Non-calcaric Chernozems, whereas the lowest change was detected in topsoil horizon of Calcaric Chernozems, indicating the most stable structure. On one side, wMWD is the highest in topsoil horizon of Calcomelansols, which had the lowest MWD after dry sieving. On the other side, the lowest wMWD was found in the subsoil of Eutric Cambisols and in the A and AC horizons of Non-calcaric Chernozems, 1.44±0.31, 1.45±0.53, and 1.51±0.58 mm. These horizons had dMWD between 7–8 mm. Changes in MWD after wet sieving are presented in Fig. 1 below. Soil units presented on the right part of the figure exhibited higher changes in MWD. Soil units closer to dashed line exhibited lower changes. Calcomelanosols are followed by Calcaric Chernozems and Colluvial Soils by means of water stability. Located more on the right in the Figure 1 are Non-Calcaric Chernozems, and subsoil horizons of Eutric Cambisols, whereas topsoil horizon of Eutric Cambisols is located far away from the dashed line.

Ka values are high in all soil units described, ranging from 2.94 in C horizon of Calcaric Chernozems to 4.95 in A horizon of Eutric Cambisols. Coefficient of aggregability (Ka) results that we obtained does not correspond to the results of change in MWD after wet sieving. According to Ka, the highest values are found in Eutric Cambisols, which in turn have the highest change in MWD after wet sieving. Therefore, there is discrepancy among these indices. We share an opinion that change in MWD better present stability of soil structure.

Clay and SOM content vs. structural indices

The results indicate that SOM content and different structural indices have better correlation in Calcomelanosols compared with other soil units. SOM in Calcomelanosols has high positive correlation with content of water stable macro-aggregates (0,586**) and high negative correlation with content of water stable micro-aggregates (-0,601*). SOM is also positively correlated with the difference in the content of micro aggregates after wet sieving, and wMWD (0.629**) and Ka (0.722**). These significant correlations between SOM and structural indices of Calcomelnosols after wet sieving might be related to higher content of SOM in Calcomelanosols compared with other soil units. Similar findings about the correlation between SOM and soil structure after wet sieving was found in Serbia on Fluvisols (Gajic et al., 2010). On the contrary to their findings, SOM was not found to be correlated with dry micro-aggregates, whereas there were no significant correlation between SOM and dry mega-aggregates. In other soil units, significant SOM correlation with investigated structure indices is rare.

On the contrary to SOM content, clay content have shown much higher and more often correlations within different soil units. Clay content is highly negatively correlated with the content of micro-aggregates after dry sieving in Colluvial Soils (-0.842*), A horizon of Calcaric Chernozems (-0,609*), and C horizons of Non-calcaric Chernozems (-0.740*). Ks is positively correlated with clay content only in A horizons of Eutric Cambisols (0.514*). Clay content is highly negatively correlated with micro-aggregate content after wet sieving in Calcomelanosols (-0.478*), A horizon of Non-Calcaric Chernozems (-0.516*), AC horizon of Non-Calcaric Chernozems (-0.641**), and both horizons of Eutric Cambisols (-0.554* in A, and -0.812** in (B)). Clay content is positively correlated with dMWD in Colluvial soils (0.816*), AC horizons of Calcaric Chernozems (0.769*), and AC horizon of Non-calcaric Chernozems (0,459), whereas it is negatively correlated in A horizons of Eutric Cambisols (-0.560*). Clay content is positively correlated with wMWD in A horizons of Calcaric Chernozems (0.800**), A horizons of Non-calcaric Chernozems (0.579*), AC horizon of Non-calcaric Chernozems (0.678**), A horizons of Eutric Cambisols (0.493*) and subsoil horizons of Eutric Cambisols (0.641**). A positive correlation with Ka in A horizons of Calcaric Chernozems (0.808**), AC horizons of Calcaric Chernozems (0.781*), AC horizon of Non-calcaric Chernozems (0.556*), and subsoil horizons of Eutric Cambisols (0.843**) is found.

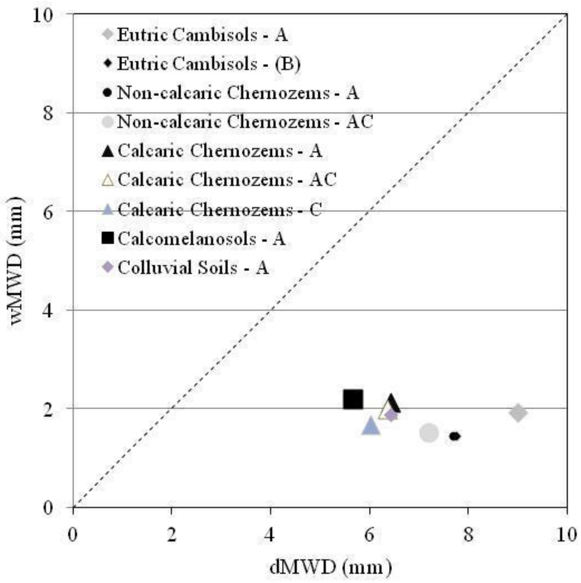

Figure 1. Scatter diagram of dMWD and wMWD of soil aggregates in five different soil units and their characteristic horizons

Changes in soil structure along the elevation changes

The spatial position of soils along the foot and toe slopes was found to be important for aggregation. There are significant differences between the content of micro-aggregates, mega-aggregates and several fractions of macro-aggregates between the soils along different elevations. These differences are mainly related to the presence of Eutric Cambisols as dominant soils on the lowest elevations and Calcomelanosols as the dominant soils at the higher elevation. Also, there is also significant difference in dMWD and dGMD between the same elevation positions. There are no significant differences between the soils at different elevations in respect to wet sieving.

Conclusion

Soils of Great Field located at different elevations were found to have significant variation in ASD and soil structure indices. These differences are mainly related to Eutric Cambisols found in the toe slopes and Calcomelanosols located at the foot slopes. Topsoil horizon of Eutric Cambisols have higher MWD after dry sieving, but at the same time it has the highest variation in MWD after wet sieving, indicating low water stability. The results of correlation analysis indicated that clay content is correlated more significantly to structure indices compared with SOM content. SOM is significantly correlated with ASD and soil structure indices in Calcomelansols, whereas, the correlation of clay content and soil structure is more evident in other soil units. The overall conclusion of this work is that soils structure variation along the lowest chain of Catena might be strong, and that it has to be analyzed from the point of view of soil unit.

COST AND ENVIRONMENTAL EFFICIENCY IN MEASURING THE ECO-EFFICIENCY PERFORMANCE OF WINTER TRITICALE PRODUCTION

Jerzy BIEŃKOWSKI, Małgorzata HOLKA

Department of Agricultural Production Systems, Institute for Agricultural and Forest Environment, Polish Academy of Sciences, Poznań, Poland

Abstract

Important issue in a sustainable production is a concept of eco-efficiency. Excessive application of agricultural inputs in fodder cereals production may affect both their economic performance and put an excessive pressure on the environment. The aim of the work was to estimate the eco-efficiency of winter triticale production by assessing the cost efficiency of applied inputs and the environmental efficiency. The research was carried out in a group of different types of farms located in two regions of Poland (Lubelskie and Wielkopolska), in the years 2017-2018. For efficiency measurement, the non-parametric Data Envelopment Analysis was implemented. The introduced model was focused on the input oriented efficiency that reflects the ability of using minimal amounts of inputs to obtain a given amount of output. Farms specialized in the milk farming reached the highest value of cost efficiency, while field crops farms displayed the full environmental efficiency. Cost efficiency of winter triticale production was higher in farms of lower economic size. Farms with higher environmental efficiencies were concentrated in groups of middle economic size. The results obtained suggest that the strategies of increasing the cost and environmental efficiencies of winter triticale production should be individualized dependent on the farming type and the economic size of farm. By applying DEA approach to the eco-efficiency analysis of winter triticale production, farms obtain an important source of information on an extent of indispensable changes with respect to improvement in cost efficiency and mitigation of their negative environmental effects.

Keywords: *Eco-efficiency, Cost efficiency, Environmental efficiency, Data envelopment analysis, Winter triticale*

Introduction

For a long time, one of the main objectives of agricultural policy in many countries was the increase in agricultural production. This increase was mainly due to the development of energy-intensive technology, use of mineral fertilization and plant protection products. It turned out, however, that the use of modern production factors on a wider scale results in an excessive burden on the environment. It is believed that maintaining further production growth without providing conditions for sustainable development will generate many ecological problems. The practical direction of implementing the idea of sustainable agriculture is the rational, economical use of agricultural production factors and at the same time exerting the lowest possible environmental pressure. Current views on sustainable agriculture assume equally important treatment of economic and ecological objectives. An operational way to achieve these goals is to carry out production tasks with the lowest cost and beneficial ecological effects. A useful tool for assessing and monitoring progress in the implementation of sustainable development principles is considered the eco-efficiency method (Huppes and Ishikawa, 2005, Kuosmanen and Kuosmanen, 2009). A multidimensional assessment of the effectiveness of inputs and environmental effects is possible by the use of non-parametric, Data Envelopment Analysis, DEA (Seiford and Zhu, 1999, Chen et al., 2005).

The purpose of the work was to assess the cost efficiency of the inputs used and environmental efficiency in the production of winter triticale in two different regions of Poland in farms representing various agricultural types of production and diversified economic size. The rationale for undertaking such assessment is that the triticale crop is an important Polish fodder plant being a component of compound feeds both for cattle and pigs. The widespread cultivation of this crop results from a good nutritional value of the grain and a suitability for cultivation on lower quality soils, compared to winter wheat.

Material and Methods

Data to the eco-efficiency analyses of winter triticale were collected during the years 2017-2018 among the group of 69 commercial farms, located at two provinces of Poland (Lubelskie and Wielkopolska). The surveyed farms with triticale cultivation represented different farming activities: milk farming, pig farming and field crops. They were differed in respect to the economic size, measured in the standard output units. Besides the monitoring of production costs, the analysis program also included the assessment of nitrate leaching, pesticide emission into the environment and ammonia emissions from mineral and natural fertilizers. The model described by van Beek et al. (2003) was used to calculate the nitrate leaching. The tier 1 default emissions factors from fertilizers were used to estimate ammonia emissions (IPCC, 2006). The quantities of pesticide emission have been determined following the method described by Margni et al. (2002).

The cost efficiency of winter triticale production was determined based on the DEA model, with input oriented approach and under the assumption of constant return to scale (Cooper et al., 2004). It is described by equations: (1a) - (1d). In the analysis, the following variables were taken into account on the input side of the model: direct costs including seeds, fertiliser and pesticide costs, maintenance and repair costs of machines and vehicles, labour costs and other costs including fuel costs, lubricants and service costs, expressed in PLN per ha. On the output side there was the variable of winter triticale value, as determined by sale prices (PLN/ha AL). The classic version of the DEA model was used, assuming that all factors of the input side are controllable, i.e. susceptible to changes, therefore they can be minimized. Finding the solution for this model involves searching for the possibility of radial, proportional reduction of all inputs without producing less output. In the model used, the goal is to indicate whether a given production volume can be realized with fewer inputs. This efficiency is relative and is determined in relation to the estimated frontier (best practices). The efficiency coefficients range from 0 to 1, $0 < \theta_o \leq 1$. An efficiency ratio of less than 1 means that it is possible to reduce inputs while leaving the output (production effect) at its current level. In the constructed model variable inputs are expressed in the form of costs, therefore the analysed technical efficiency can be characterized as cost efficiency (Chavas and Aliber, 1993).

DEA model describing the DEA model of efficiency (Cooper et al., 2004):

$$Min\,\theta_o, \qquad (1a)$$

$$Subject\ to:$$

$$y_o \leq \sum_{j=1}^{J} \lambda_j\, y_j, \qquad (1b)$$

$$\theta_o\, z_{io} \geq \sum_{j=1}^{J} \lambda_i\, z_{ij}, \quad i = 1,...,I, \qquad (1c)$$

$$\lambda_j \geq 0, \quad j = 1,...,J \qquad (1d)$$

where: θo = optimal, relative efficiency of object „o", yo – output value of object „o", yj – output value of object „j", j = farms (j = 1,...,J), zio – value of conventional ith input of object „o", zij = value of conventional ith input used by object „j", λ = nonnegative scalars.

The DEA model with identical structure as for cost efficiency was applied to calculate the environmental efficiency of the winter triticale production. The following variables, causing threats of environmental degradation, were introduced to the model: ammonia emission from mineral fertilization and manure (kg NH_3/ha AL), leaching of nitrates (kg NO_3/ha AL) and emission of pesticides to the environment (kg active substance/ha AL). The model assumes minimizing the values of indicators in relation to the unit of AL. By applying the DEA model of environmental efficiency, the possibility of equally proportional reduction in all environmental pollutants in relation to the efficient objects described as benchmarks is determined (De Koeijer et al. 2002). Both types of efficiencies are calculated by solving the linear programming task for each farm.

Results and Discussion

The cost and environmental efficiencies of winter triticale production in a group of farms located in two regions of Poland are shown in Figure 1.

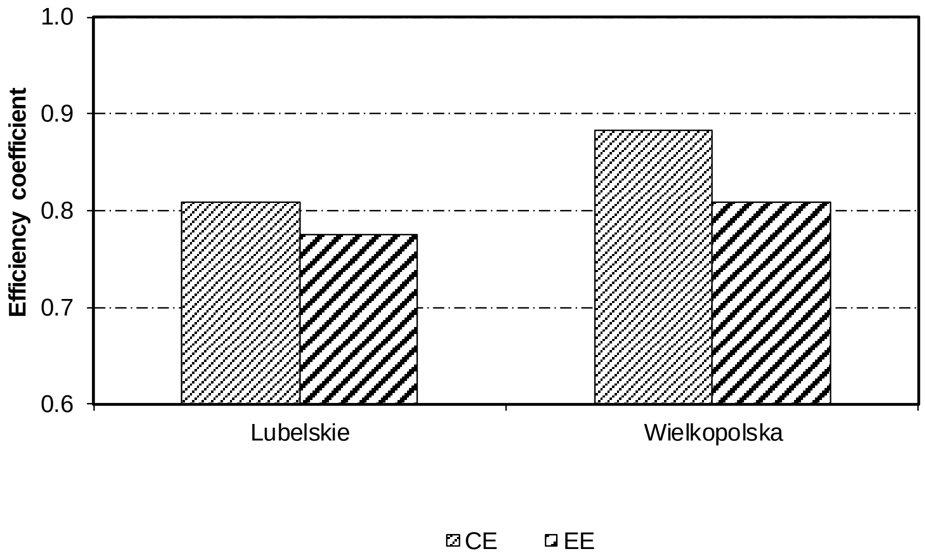

Figure 1. Cost (CE) and environmental efficiency (EE) for the analysed farm population in Lubelskie and Wielkopolska provinces.
Source: Authors' own calculations.

On average, farms from Wielkopolska province (Middle West region of Poland) achieved higher cost and environmental efficiency compared to farms from Lubelskie province (South East part of Poland). In the whole group, consisted of the analysed farms from both provinces, the average cost and environmental efficiencies of triticale production were equal to 0.845 and 0.792, respectively. Noticeable differences in cost and environmental efficiencies occurred between the identified agricultural types of farms (Figure 2). The highest level of cost efficiency of triticale cultivation was characteristic for farms oriented to milk production. The average value of the coefficient for this group was 0.884. The pig farms had an inferior cost efficiency of growing triticale by 6.7 percentage points. The lowest level of cost efficiency was achieved by farms of field crops type. The average efficiency for this this group was 0.742. This means that the cost of inputs for winter triticale production in this type of farms should be reduced by nearly 26 percentage points in order to be able to achieve the full efficiency while maintaining the current level of output value. On farms specializing in milk production, a simultaneous reduction of all costs by the average of the 11.6 percentage points would be sufficient to obtain the full efficiency of triticale production. It expected that an improvement in the cost efficiency of triticale will be one of the main factors determining

the ability to profitability gain of its production in the near future, increasing thus the competitive potential of triticale production in the Polish feed grains market.
The values of environmental efficiency coefficients for triticale cultivation in types of farms specializing in the production of milk and pigs were lower compared to the cost efficiency (Figure 3).
