PREFACE

The Faculty of Agriculture of the University of East Sarajevo (Bosnia and Herzegovina), the Faculty of Agriculture of the University of Belgrade (Serbia) and the International Centre for Advanced Mediterranean Agronomic Studies - Mediterranean Agronomic Institute of Bari (CIHEAM-Bari, Italy) organized the XII International Scientific Symposium “Agrosym 2021” on Jahorina mountain (East Sarajevo, Bosnia and Herzegovina). This year’s edition of Agrosym was organized for the first time in a hybrid format, in-person (250 participants) and virtual via ZOOM (450 participants), because of the prescribed restrictions due to the COVID-19 pandemic.
The 12th Scientific International Symposium "Agrosym 2021" made an important contribution to the agriculture practice in different fields e.g. plant production, animal husbandry, environmental protection, organic farming, forestry, and agro-economy. The Scientific Committee received 750 papers and after review, we accepted 695 papers; 159 for oral presentations and 535 for poster presentations, which addressed all the sessions of the symposium: plant production (43 oral and 167 poster presentations), plant protection and food safety (25 oral and 105 poster), environmental protection and natural resources management (24 oral and 86 poster), organic farming (6 oral and 37 poster), animal husbandry (24 oral and 69 poster), rural development and agro-economy (25 oral and 40 poster), forestry and agroforestry (12 oral and 33 poster presentations). The presented papers were submitted by about 2000 authors representing more than 80 countries worldwide.
We have had the opportunity to share new information on biotechnology, plant breeding and world markets during the COVID-19 pandemic in the plenary keynote session and many interesting research results and findings in parallel sessions. It can be pointed out that sustainable agriculture development must focus on building policies and practices at national and regional levels, with an emphasis on quality and greater diversity, followed by a demonstration of agronomic and economic viability, environmental protection and food safety, and social benefits, while fostering the convergence of rural and urban populations as well as closing the gap between producers and consumers.
AGROSYM 2021 has been a considerable undertaking from scientific, logistical and organizational points of view. Big thanks to all members of the Scientific Committee for their continued efforts and hard work, which made the symposium possible and successful. I would also like to thank my colleagues from the Organizing Committee, for all they have done to bring this event together, particularly the dean of the Faculty of Agriculture of the University of East Sarajevo, prof. Vesna Milic, as a host and chairperson, His Excellency, prof. Sinisa Berjan. Finally, I would like to thank all the authors, reviewers, session moderators and colleagues for their help in preparing and editing this book of proceedings. Special thanks also go to the organizers, partners and sponsors for their unselfish collaboration and comprehensive support.

Editor-in-Chief

PLANT PRODUCTION

INFLUENCE OF DIFFERENT FERTILIZATION MODELS ON THE MORPHOLOGY OF GALA SHNIGA APPLE LEAF (Malus domestica L.)

Dževad LAVIC

The Federal Institute for Agriculture Sarajevo, Butmirska cesta 40, 71210 Ilidža, Sarajevo, Bosnia and Herzegovina
*Corresponding author: dzevad.lavic@gmail.com

Abstract

In this research, the influence of different fertilization methods on the morphological characteristics of Gala Shniga leaf leaves in the agroecological conditions of Sarajevo during 2019 and 2020 was studied . The studies included dietary treatments : control variant (standard fertilization NPK 15-15-15); variant A foliar feeding (Yara Vita Universal Bio); variant B (KAN + NPK). The Gala Shing apple (Malus Domestica L.) originates from New Zealand and was obtained by crossing Golden Delicious and Kidd's Orange Red varieties. Generally speaking , the results showed that the new generation of fertilizers, as well as the method of fertilization through lists show the best results of morphological characteristics of leaf cultivars of apples. The results of the study showed that proper plant nutrition is one of the measures by which it is possible to achieve high yields and good quality of agricultural products. The leaf is the basic part of the plant that performs three very important functions: photosynthesis, transpiration and gas exchange. It also plays a big role in the nutrition of apple fruits. Of the necessary elements, the quality of apple fruits is most affected by: nitrogen, potassium, phosphorus, calcium, magnesium and boron. Their lack or excess can have a very negative effect on fruit quality.

Key words: *Apple variety, Gala Shniga , fertilization, leaf, morphological characteristics.*

Introduction

Apple (Malus domestica) is the most widespread fruit species in the world and belongs to the group of perennial woody plants from the rose family. It is a very important part of the daily diet. Known as a mother of all fruit, human kind used apple since ancient times in a variety of purposes, but most commonly as food, medicine and as a means of refreshment. Apple as a fruit species, in terms of fruit trade, is on the world market in third place, just behind citrus and bananas. It is one of the more commercial fruit species, which is why great attention is paid to improving its cultivation (Ubavić et al., 2001).

World apple production has increased slightly in recent years and 2018 amounted to 83,139,326 tons (FAO, 2018). The largest producers are China with 44, followed by EU countries with about 10, the United States with 4.7, Turkey with 2.8 and India with 2.3 million tons. In the EU, Poland leads in production with 2.9, Italy with 2.1, France with 1.4 million tons, and Germany with 990,000 and Spain with 550 thousand tons. The quality of fruits, their colour, taste, size, firmness is varietal characteristics of apples. The mentioned properties are also influenced by ecological factors, and especially agrotechnical measures, among which the influence of fertilization and its application in certain phenophases of apple growth and development should be emphasized. Depending on the dose and ratio of different fertilizers, nutrients may improve or in the case of improper application decrease the quality of fruit (Lukić, M. 2010). Thanks to the sunlight and mineral substances, plants produce food, not only for themselves but for all

living beings. The main organ for food production in plants is the leaf. The leaf is the youngest vegetative plant organ, responsible for the process of photosynthesis and the creation of organic matter. It means that development, yield and quality of the fruit and quantity are related to the development of leaf (Denffer and Ziegler, 1991). At one plant can be distinguished three categories of leaves: lower, middle and upper leaves. The middle leaves are the most numerous group of leaves. It includes green leaves in which photosynthesis is carried out. The most important for the plant is the middle (true) leaves (Janjatović, 1989). He says the leaves are composed of three parts: leaf blade (lamina), stems (petioles) and shelf (basis) leaf. The leaflet is the most important part of the leaf. It serves assimilation and transpiration. They have green colour and usually are flattened and expanded (Bacic, 2003). Types rate, size, and even the shape adapted to the exposure to the sunlight (Janjatović, 1989).
The total amount of organic fertilizers are limited, thus today in practice most common is the second type of fertilizer under the name of mineral fertilizers (Bulatovic, 1984). In relation to organic fertilizers, a mineral fertilizers are characterized by increased concentration of the nutritive elements. Thus, for example while 100 kg of manure on average contains 0.5 kg of nitrogen, 0.2 kg of phosphorus and 0.6 kg potassium, therefore a total of 1.3 kg of active substance, long 100 kg of mineral fertilizers eg. 15:15:15 contains 15 kg of nitrogen, 15 kg of phosphorus as P_2O_5 and 15 kg of potassium as K_2O, as a total amount of 45 kg of active nutrient substances (Ubavić et al., 2001). The leaves can develop in the spring, and arise from the leaf buds. Each type of plant has a different shape and size of leaves, but its role is always the same.

Material and method

Studies have been conducted during 2019 and 2020 on experimental test site of the Federal Institute for Agriculture in Sarajevo (Butmir) to the introduced planting of apple varieties Gala Shniga age of 16 years (Malus Domestica L.- cv. "Gala Shniga") per block system (10 trees per treatment). The tested apple cultivar was grafted on a weak vegetative substrate M9. The planting density is 1,300 trees/ha. Row spacing planting is 3,5 m spacing within rows was 1 m.

The study has represented the following treatments fertilization apples:
1) Control, standard variant of fertilization with NPK fertilizer 15-15_15 300kg/ha);
2) Variant A: foliar fertilizer - YaraVitaUniversal Bio (P_2O_5 - 35 g/l, K_2O - 60 g/l, B 0.2 g/l, Cu 1 - g/ l, Mn - 1.1 g/l, Mo - 0.3 g/l, Zn - 0.6 g/l);
3) Variant B: KAN (27% N) 400 kg/ha + NPK (15-15-15) 200 kg/ha.
Each variant of fertilization is covered by 10 trees, set by a random block system.
Control variant Standard- fertilization of NPK fertilizer and variant B, fertilizing with KAN + NPK are applied in early spring - March during both years of research.
Variant A fertilization with foliar fertilizer YaraVitaUniversal was applied four times during the growing season at intervals of after 15 days.
A certain number of leaves (medium - from the middle of the one - year increment) was taken for testing and further measurements.
The obtained results of measurement of parameters statistically the processed two-factorial analysis of variance using the software package SPSS 23.0 by ANOVA procedure, a difference mean of the tested LSD test.

Results and Discussion

Tab.1. The length of the leaf width of the leaf index of form, leaf area, leaf length stems depending on the year and fertilization ± s. deviation

variant of fertilization	Leaf length (cm)		Leaf width (cm)		Index form (L/W)		Leaf area (cm^2)		Leaf stalk length (cm)	
	2019	2020	2019	2020	2019	2020	2019	2020	2019	2020
Control	9.94 ± 0.11	10.8 ± 0.32	4.73±0.24	5.81±0.12	2.10±0.12	1.85±0.17	35.59±3.91	37.62±1.21	3.47±0.24	3.55±0.22
Variant A	13.36± 0.21	14.11± 0.16	6.92±0.13	7.54±0.19	1.9 ±0.19	1.87±0.16	67.33±3.71	77.82±2.32	4.15±0.31	4.28±0.19
Variant B	10.21±0.13	11.08± 0.19	5.83±0.19	6.33±0.21	1.75±0.23	1.75±0.11	44.64±5.46	52.60±6.19	4.10±0.33	4.36±0.14

Table 2. Analysis of variance for leaf length (cm) in relation to the method of fertilization and year

Source of Variation	*SS*	*df*	*MS*	*F*	*P-value*	*F crit*
Sample	139,6463333	2	69,82316667	6,14	0,00042	3,168246
Columns	10,25066667	1	10,25066667	4,77	0,08945	8,019541
Interaction	0,044333333	2	0,022166667	4,89	0,00242	3,168246
Total	149,9413333	59				

Observing the results of statistical analysis for leaf length, it is possible to notice that there are statistically significant differences in relation to the method of fertilization ($p < 0.05$). (Table 2.) Foliar fertilization shows the best results in terms of leaf length. When it comes to differences in terms of the year of the survey, we can argue that there are no statistically significant differences. Similar results came and Janjatović 1989, Denffer and Ziegler (1991), Ubavić et al. (2001), Bačić (2003), Lukić , M. (2010).

Leaf width

Table 3. Variance analysis table for leaf width in relation to the method of fertilization and year

Source of Variation	*SS*	*df*	*MS*	*F*	*P-value*	*F crit*
Sample	38.80133	2	19,40067	5,66	0,0001 2	3,168246
Columns	8,066667	1	8,066667	11,1	0,0007 9	4,019541
Interaction	0.937333	2	0.468667	6,42	0,0029 2	3,168246
Total	47.80533	59				

The results of statistical analysis for leaf width , possibly show that there are statistically significant differences in relation to the method of fertilization ($p < 0.05$). (Table 4.) We can claim that the best results are shown by foliar application of fertilizers. When it comes to differences in terms of the year of the survey, we can also argue that there are statistically significant differences in relation to the year of observation. Although Janjatović (1989), Denffer and Ziegler (1991), Ubavić et al. (2001), observed noticeable statistically significant difference,it is not so pronounced as in the recent research carried out by hand Bacic (2003) and Lukic, (2010).

Index form leaf shape

Table 4. Variance analysis table for index leaf form in relation to the method of fertilization and year

ANOVA

Source of Variation	*SS*	*df*	*MS*	*F*	*P-value*	*F crit*
Sample	0.525	2	0,2625	5,19	0,00065	3.168246
Columns	0.160167	1	0,160167	4,95	1,967	1,019541
Interaction	0.170333	2	0,085167	5,04	0,00021	3,168246
Total	0.8555	59				

Statistical analysis of data related to index form leaf, it shows there are statistically significant differences in relation to the method of fertilization (p <0.05). (Table 6.) We may claim that, unlike other observed traits, the best results are shown by the control group. The difference between the years of observation is not statistically significant. When it comes to research by other authors, similar results were obtained by Janjatović (1989), Denffer and Ziegler (1991), Ubavić et al. (2001). In some recent works of Bačić (2003), Lukić, (2010). different results were noted. Namely, in the works of mentioned authors, it was noticed that foliar fertilization gives the best results in terms of leaf index.

Leaf area

Table 5. Analysis of variance for leaf area in relation to the method of fertilization and year

ANOVA

Source of Variation	*SS*	*df*	*MS*	*F*	*P-value*	*F crit*
Sample	13413.62	2	6706.81	6.52	0.0003 2	3.168246
Columns	699.0507	1	699.0507	6.8	0.0007 9	4,019541
Interaction	188.5623	2	94.28117	9.17	0.0008 2	3.168246
Total	14301,23	59				

The statistical analysis of data on the leaf surface , showing statistically significant differences with respect to the method of fertilization (p <0.05). (Table 8.) We can claim that the best results are shown by foliar application of fertilizers. When it comes to differences in terms of the year of the survey, slightly better results were observed in 2020. Similar results were obtained by Janjatović 1989; Denffer and Ziegler, 1991; Ubavić et al., 2001; Bačić, 2003; Lukić, 2010.

Leaf stalk length

Table 6. Analysis of variance for leaf stalk length in relation to the method of fertilization and year

ANOVA

Source of Variation	*SS*	*df*	*MS*	*F*	*P-alue*	*F crit*
Sample	6,771	2	3,3855	1,03	0,179	3,168246
Columns	0.368167	1	0,368167	1,12	0,238	4,019541
Interaction	0.086333	2	0,043167	1,31	0,567	3,168246
Total	7,2255	59				

Observing the results of statistical analysis for leaf stalk length , we can claim that there are no statistically significant differences in relation to the method of fertilization ($p < 0.05$). (Table 6.) When it comes to differences in terms of the year of the survey, we can say that there are no statistically significant differences. Similar results were obtained by Janjatović 1989; Denffer and Ziegler, 1991; Ubavić et al., 2001; Bačić, 2003; Lukić, 2010.

Conclusion

Bearing in mind above-mentioned results, we may conclude that there are statistically significant differences in the method of fertilization in terms of length, width, index of form and surface sheet ($p<0,05$). Statistically significant differences between the ways of fertilization were not found when it comes to the length of the leaf stalk ($p>0,05$). The statistical differences between years of observation observed were found only at leaf area. On the basis of these results, we recommend foliar way fertilization and give him an advantage in relation to other modes of apple nutrition.

Abstract

Potato is a field crop which has a great significance in Bosnia and Herzegovina, however, the production is according to all indicators rather unstable and unreliable. Two-factorial trials were set up (of different combination of adsorbent and location) for examining the influence of location and super-adsorbents on morphological characteristicsof potato. The morphological characteristics monitored were as follows: plant height (cm) (measured from the ground surface to the top point of the plant); the number of sprouts; leaf surface per plant (m^2) with the help of leaf contour on paper method; new above-ground plant mass (g), leaf mass (g) and potato stem mass (g). The first factor consisted of 6 variants: control variant (A_0), superadsorbent (A_1), superadsorbent enriched with growth stimulants (A_2), superadsorbent enriched with microorganisms (A_3), superadsorbent enriched with microelements (A_4) and superadsorbent enriched with growth stimulants, microorganisms and microelements (A_5) in the quantity of 20 kg ha^{-1}. The trials were set up in East Sarajevo and Bijeljina. The main goal of this research was to determine the effect of super-adsorbent and area on morphological characteristics of potato. Through analysis of the results, it was determined that the use of different variants of adsorbent had great influence on the examined, while the influence of area had great significance for all the examined characteristics except for the number of stems per plant. The use of different variants of super-adsorbent in both areas had positive effect on morphological characteristics of potato, where the use of super-adsorbent enriched with growth stimulants, microorganisms and microelements is especially emphasised, while the variant in which super-adsorbents were not used (control variant) had poor results for the examined characteristics.

Key words: *superadsorbent, plant height, plant mass, assimilation surface area, stem number*.

Introduction

Climate change resulted in increased demand for water in agricultural production, affecting the development of various models with a view to preserving soil moisture and decreasing water consumption in agricultural production. Besides the continuous trend of air temperature increase, further rainfall shortage, accompanied by decreased soil moisture, have a significant influence on the uncertainty of agricultural production and considerable crop yield decrease per unit of area. Water conservation in agriculture can be achieved through use of various substances (polymers), which alter water and air properties, but also physical soil properties. The ultimate goal of the abovementioned substances, which started to be used in the 1950s, is the improvement of soil water regime. The use of these polymers improves aggregate stability, decreases soil compaction and erosion, and increases infiltration by 2,5 times (Sepaskhah and Bazrafshan-Jahromi, 2006), positively affects both physical and chemical soil properties, the contents of nutrients in the soil, microorganism activity in the soil, as well as soil productivity (Mann et al., 2011). Polymers, which are insoluble in water (hydrogels), were introduced in agricultural production in the 1980s. The use of hydrogel in soil increases the amount of available water and decreases plant stress, also affecting seed germination, plant growth and yield (Wallace and Wallace, 1986). Previous research demonstrated that not only does the use of polymer prevent agroecosystem pollution, but it also increases economic return for farmers (Islam et al., 2011a). By adding polymers to sandy soils, the efficiency of water consumption and compost in cultivated plants is increased (Bhardvaj et al., 2007; Islam et al., 2011b).

Matherial and methods

Two-factorial trials were set up for examining the influence of location and super-adsorbents on morphological characteristics of potato cultivars Agria. Factor A comprises 6 variants: control variant (A_0), superadsorbent (A_1), superadsorbent enriched with growth stimulants (A_2), superadsorbent enriched with microorganisms (A_3), superadsorbent enriched with microelements (A_4) and superadsorbent enriched with growth stimulants, microorganisms and microelements (A_5). in the quantity of 20 kg ha^{-1} (created at the Voronezh State Agrarian University named after Tsar Peter the Great). Factor B: locality B1 - on the territory of the city of East Sarajevo, altitude 550 m (43 ° 49'01 " NW and 18 ° 20'57 " EWD) on alluvial soil (fluvisol) and locality B2 - on the territory of the city of Bijeljina, altitude 90 m (44 ° 41 ′ NW; 19 ° 14 ′ EWD) on semi-glacial land (table 1).
The trials are set up in randomized block system with four replications of 53.333 plants per ha^{-1}. The area of the basic plot is 15 m^2 (four rows 5 m of length with 20 plants per row, at the distance between the rows of 0.75 m and between the plants in a row 0.25 m). Standard agrotechnical measures used in potato production were applied. The morphological characteristics monitored were as follows: plant height (cm) (measured from the ground surface to the top point of the plant); the number of sprouts; leaf surface per plant (m^2) with the help of leaf contour on paper method; above-ground plant mass (g), leaf mass (g) and potato stem mass (g). The trial in Bijeljina was set up on 24 March 2019. Potato started sprouting evenly on 13 April 2019, and flowering on 2 June 2019. The analysis samples were taken on 14 June 2019. The trial in East Sarajevo was set up on 25 April 2019. Potato started sprouting evenly on 15 May 2019, and flowering on 13 July 2019. Meteorological data on mean monthly temperatures, precipitation were taken over from the Republic Hydrometeorological Institute of Republic of Srpska and Federal Hydrometeorological Institute of Bosnia and Herzegovina, from the meteorological stations closest to the areas where field trials were conducted.
Examining the significance of differences between treatments were conducted with the help of analysis of variance (ANOVA). The significance of differences was tested with the help of Fisher's LSD test. STATISTICA 10 (StatSoft, Inc. Corporation, Tulsa, OK, USA), a statistical programme, was used for statistical processing.
Optimal pH value of the soil for growing potatoes is low acidic (from 6.0 to 6.5). Potato requires high soil permeability, as tubers are deformed in compact soil. Furthermore, it requires well-drained soil, while watered soils result in numerous physiological changes in tuber that become watery and are difficult to preserve (storage). In order for potato production to be successful,

organic matter contents, which enhances quality, structure and water-holding capacity, is very important (Baniuniene and Zekaite, 2008).

Table 1. Agrochemical analysis of the soil

Area	Depth (cm)	pH/KCl	Humus %	N %	Soluble P_2O_5 mg $100g^{-1}$	Soluble K_2O mg $100g^{-1}$
East Sarajevo	0-30	6.63	3.62	0.23	15.75	17.59
Bijeljina	0-30	7.16	4.12	0.27	>40	36,41

Besides soil fertility, meteorological factors such as, temperature, rainfall amount and distribution during potato vegetation period are also important. The growth and development, and thus yield and the quality of cultivated plants considerably depend on their effect. Little rainfall in the most critical stages of potato growth and development considerably decrease the yield, ruin tuber quality, which requires constant monitoring of soil moisture with the aim of providing timely soil moisture. When we also take high air temperatures in July and August into consideration, the general conclusion is inevitably drawn that besides high air temperatures and soil, one of the restrictive factors of growth and development of potato plants and tubers in the conditions of arid and semi-arid climate, is precisely insufficient amount and uneven rainfall distribution in vegetative period (Gvozden, 2016). Mean yearly temperature for East Sarajevo and the vicinity in 2019 was 11.7°C and it was higher than the multi-annual average (10.1°C), while the total rainfall amount was 850.5 mm, which is less than the long-term average (932 mm).

Table 2. Mean monthly air temperatures (°C) and rainfall amount (mm) during 2019 and the multi-annual average

	Year / Month		I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII	Average/ total
E.Sarajevo	2019	°C	-1.5	2.5	7.7	11.4	12.3	21.1	21	21	16.5	12.9	10.6	3.6	11.7
		mm	79.7	56.7	51.8	98.2	102.3	97.1	67.8	69.7	44.1	38	80.3	64.8	850.5
	1981-2010	°C	-0.1	1.4	5.3	9.9	15.0	17.7	19.8	19.7	15.1	10.9	5.2	1.1	10.1
		mm	67	63	71	78	73	94	72	70	86	85	91	85	932
Bijeljina	2019	°C	0.6	4.7	10.2	13.2	14.9	23.7	23.2	24.3	18.1	13.7	11.3	4.8	13.6
		mm	62.8	34.1	33.7	95.4	121	113	59.2	27	57.2	27.6	52.7	68.1	751.8
	1981-2010	°C	0.3	1.9	6.9	11.8	16.9	19.9	22.1	21.2	17.2	11.6	6.0	2.3	11.5
		mm	54.1	43.5	59.7	66.1	68.2	100	74.6	60.7	55.8	67.6	64	63.9	778.2

Mean yearly temperature for Bijeljina and the vicinity in 2019 was 13.6°C and it was higher than the multi-annual average (11.5°C), while the total rainfall amount was 839.4 mm, which is less than the multi-annual average (778.2 mm). Compared to multi-annual averages, the year of 2019 was characterised by higher temperatures and uneven rainfall distribution. It was only in May that there were lower temperatures in both areas, and which significantly affected slower potato germination in East Sarajevo. Rainfall shortage was reported in Bijeljina in July and August, and in East Sarajevo, the reported values were at the shortage limit in East Sarajevo in these months.

Results and discussion

The table 3 shows analysis of variance of the effect of the use of adsorbent and area on morphological characteristics of potato. The use of different adsorbent variants had a highly significant impact on the examined parameters, while the effect of area had high significance on all the examined characteristics, except for stem number per plant. The interaction adsorbent *x* area had high significance for the plant assimilation surface, plant mass, leaf mass and stem mass.

Table 3. The effect of adsorbent and area on morphological and productive potato characteristics

(*) statistically significant difference, (**) statistically very significant difference, (nssd) no statistically significant difference

Plant height

The average potato plant height, regardless of the application of adsorbent and locality, is 80 cm. The greatest plant height is in the variant where the super-adsorbent enriched with growth stimulants, microorganisms and microelements is used (88 cm).

Table 4. The average potato plant height depending on the adsorbent in chosen areas (cm)

Adsorbent / Area	A_0	A_1	A_2	A_3	A_4	A_5	Average
East Sarajevo (B_1)	54.25	62.75	69.25	72.25	75.50	78.25	68.71
Bijeljina (B_2)	71.00	87.75	98.50	94.00	98.75	97.75	91.29
Average	62.62	75.25	83.88	83.12	87.12	88.00	80.00

Adsorbent: Control variant (A_0); superadsorbent (A_1); superadsorbent enriched with growth stimulants (A_2); superadsorbent enriched with microorganisms (A_3); superadsorbent enriched with microelements (A_4) and superadsorbent enriched with growth stimulants, microorganisms and microelements (A_5).

The use of different variants of enriched super-adsorbent produced a significantly higher potato plant compared to the control variant (62.62 cm) and the variant in which super-adsorbent was used (75.25 cm). The obtained results are in harmony with the results obtained by Jahan et al. (2013) and Islam et al. (2011b), who, in multi-annual trials, had higher potato plants through use of adsorbents, and compared to control variants. Highly significant differences of plant height between the variant where super-adsorbent was used and the control variant were determined. Plant height in Bijeljina amounts to 91.29 cm, and in East Sarajevo 68.71 cm. These differences are highly significant. The obtained results are in accordance with the results that Lalić et al. (2019) obtained in their research.

Stem number

Stem number per plant varies considerably depending on variety, production conditions, the size of planted tuber, the number of sprouts per tuber and physiological ages of tuber (Khan et al., 2004; Momirović et al., 2016). Stem number per plant is a significant morphological property, as it affects the development of the above-ground mass, that is, assimilation surface area (Van der Zaag, 1992; Struik, 2007), the number of germinated tubers per plant, that is, total yield (Khan et al., 2004; Momirović et al., 2016). The average number of stems per potato plant, regardless of the application of adsorbent and locality is 4.69. The control variant had the smallest number of stems (3.38), and the largest super-adsorbent enriched with growth stimulants, microorganisms and microelements (6.38). The established differences are statistically highly significant, as well as the differences of other variants of super-adsorbents compared to the control variant. The number of stems per plant in Bijeljina is 4.96, and in East Sarajevo 4.42.

Table 5. The average number of stems per potato plant depending on adsorbent in chosen areas

Adsorbent / Area	A_0	A_1	A_2	A_3	A_4	A_5	Average
East Sarajevo (B_1)	3.75	4.25	5.25	5.25	4.50	6.75	4.96
Bijeljina (B_2)	3.00	4.00	4.25	5.00	4.25	6.00	4.42
Average	3.38	4.12	4.75	5.12	4.38	6.38	4.69

Adsorbent: Control variant (A_0); superadsorbent (A_1); superadsorbent enriched with growth stimulants (A_2); superadsorbent enriched with microorganisms (A_3); superadsorbent enriched with microelements (A_4) and superadsorbent enriched with growth stimulants, microorganisms and microelements (A_5).

These differences had no statistical significance. The obtained results are in accordance with the results that Lalić et al. (2019) obtained in their research.

Assimilation surface area

The average assimilation surface area of potato, regardless of the application of adsorbent and locality, is 0.447 m^2. The assimilation surface area of the plant ranged from 0.340 m^2 per plant (A_0) to 0.553 m^2 (A_5). These differences were statistically highly significant, as well as the differences between the variant A_5 and other combinations of super-adsorbent and differences between enriched super-adsorbents and super-adsorbent.

Potato cultivated in Bijeljina (0.540 m^2) had statistically considerably greater assimilation plant surface area compared to potato cultivated in East Sarajevo (0.354 m^2). These differences are highly significant. The greatest stem mass in both areas was in the variant A_5, and the smallest one in the control variant. The greatest assimilation surface area in both areas was in the variant A_5, and the smallest one in the control variant. The obtained results are in accordance with the results that Lalić et al. (2019) obtained in their research.

The use of various agrotechnical measures can affect the increase of leaf surface. In this research, the use of different adsorbent variant resulted in the increase of assimilation plant surface area. With the increase of assimilation surface area, there was also an impact on the increase of photosynthetic plant production and crop yield increase (Stoimenov and Kirkova, 2009).

Table 6. Assimilation surface area of potato plant depending on adsorbent in chosen areas (m^2)

Adsorbent / Area	A_0	A_1	A_2	A_3	A_4	A_5	Average
East Sarajevo (B_1)	0,286	0,324	0,344	0,361	0,363	0,449	0,354
Bijeljina (B_2)	0,394	0,464	0,593	0,571	0,558	0,657	0,540
Average	0,340	0,394	0,469	0,466	0,460	0,553	0,447

Adsorbent: Control variant (A_0); superadsorbent (A_1); superadsorbent enriched with growth stimulants (A_2); superadsorbent enriched with microorganisms (A_3); superadsorbent enriched with microelements (A_4) and superadsorbent enriched with growth stimulants, microorganisms and microelements (A_5).

Plant mass

Plant mass ranged from 365.5 to 896 grams. The use of super-adsorbent enriched with growth stimulants, microorganisms and microelements resulted in potato plants which, in comparison with other variants, had statistically considerably greater plant mass, while the control variant compared to the use of different super-adsorbent variants had statistically smallest plant mass. Highly significant variations of plant mass between super-adsorbent (A_1), super-adsorbent enriched with growth stimulants (A_2), super-adsorbent enriched with microorganisms (A_3) and super-adsorbent enriched with microelements (A_4) were determined. Plant mass in Bijeljina is 797.9 grams, and in East Sarajevo 464.3 grams. These differences are highly significant.

Table 7. The average potato plant mass depending on adsorbent in chosen areas (g)

Adsorbent / Area	A_0	A_1	A_2	A_3	A_4	A_5	Average
East Sarajevo (B_1)	398.3	393.0	381.0	528.9	423.2	661.4	464.3
Bijeljina (B_2)	332.6	642.1	756.7	1023.1	902.1	1130.6	797.9
Average	365.5	517.6	568.9	776.0	662.7	896.0	631.1

Adsorbent: Control variant (A_0); superadsorbent (A_1); superadsorbent enriched with growth stimulants (A_2); superadsorbent enriched with microorganisms (A_3); superadsorbent enriched with microelements (A_4) and superadsorbent enriched with growth stimulants, microorganisms and microelements (A_5).

The greatest plant mass in both areas was in the variant A_5 1130 g; 661.4 g, and the smallest one 332.6 g in the control variant (in Bijeljina), that is, 381 g in the variant A_2 in East Sarajevo. In the area in Bijeljina, and compared to the area in East Sarajevo, plant mass was greater in the variants in which different adsorbent variants were used, while plant mass was greater in the control variant in East Sarajevo, compared to Bijeljina.

Leaf mass

Leaf mass ranged from 215.27 to 492.89 grams. The use of super-adsorbent enriched with growth stimulants, microorganisms and microelements resulted in potato plants which compared to other variants had statistically considerably greater leaf mass, while the control variant compared to the use of different variants had statistically considerably smallest leaf mass. Highly significant leaf mass variations between super-adsorbent (A_1), super-adsorbent enriched with growth stimulants (A_2), super-adsorbent enriched with microorganisms (A_3) and super-adsorbent enriched with microelements (A_4) were also determined. Leaf mass in Bijeljina is 426.01 g, and in East Sarajevo 248.49 g. These differences are highly significant. In both areas, the greatest leaf mass was in the variant A_5 (658.46 g; 327.31 g), and the smallest one 179.60 g in the control variant (in Bijeljina), that is, 213.37 g in the variant A_2 in East Sarajevo. The obtained results are in accordance with the results which Lalić et al. (2019) obtained in their research. The use of different adsorbent variants in the area in Bijeljina resulted in determining a greater potato leaf mass, compared to East Sarajevo, while in the area in East Sarajevo, control variant had greater leaf mass, compared to the control variant.

Table 8. The average potato leaf mass depending on adsorbent in chosen areas (g)

Area \ Adsorbent	A_0	A_1	A_2	A_3	A_4	A_5	Average
East Sarajevo (B_1)	250.95	220.09	213.37	269.72	209.52	327.31	248.49
Bijeljina (B_2)	179.60	323.33	383.81	513.17	497.69	658.46	426.01
Average	215.27	271.71	298.59	391.45	353.60	492.89	337.25

Adsorbent: Control variant (A_0); superadsorbent (A_1); superadsorbent enriched with growth stimulants (A_2); superadsorbent enriched with microorganisms (A_3); superadsorbent enriched with microelements (A_4) and superadsorbent enriched with growth stimulants, microorganisms and microelements (A_5).

Stem mass

The average potato stem mass, regardless of the application of adsorbent and locality, is 293.84 g. Stem mass ranged from 150.19 grams to 403.12 grams. The use of super-adsorbent enriched with growth stimulants, microorganisms and microelements (403.12 g) and super-adsorbent enriched with microorganisms (384.55 g), resulted in potato plants that compared to other variants had statistically considerably greater stem mass, while the control variant compared to the use of different super-adsorbent variants had statistically considerably smallest stem mass.

Table 9. The average potato stem mass depending on adsorbent in chosen areas (g)

Area \ Adsorbent	A_0	A_1	A_2	A_3	A_4	A_5	Average
East Sarajevo (B_1)	147.38	172.93	167.64	259.15	213.68	334.04	215.80
Bijeljina (B_2)	152.99	318.79	372.89	509.96	404.42	472.19	371.87
Average	150.19	245.86	270.27	384.55	309.05	403.12	293.84

Adsorbent: Control variant (A_0); superadsorbent (A_1); superadsorbent enriched with growth stimulants (A_2); superadsorbent enriched with microorganisms (A_3); superadsorbent enriched with microelements (A_4) and superadsorbent enriched with growth stimulants, microorganisms and microelements (A_5).

Highly significant variations of stem mass between super-adsorbent (A_1), super-adsorbent enriched with growth stimulants (A_2) and super-adsorbent enriched with microelements (A_4) were also determined. Stem mass in Bijeljina is 371.87 g, and in East Sarajevo 215.80 g. These differences are highly significant. The obtained results are in accordance with the results that Lalić et al. (2019) obtained in their research. In both areas, the greatest stem mass was in the variant A_5, and the smallest one in the control variant.

Conclusions

The use of different variants of super-adsorbent in both areas had positive effect on the morphological characteristics of potato. What is especially emphasised is the use of super-adsorbent enriched with growth stimulants, microorganisms and microelements, where we had the best results for: plant height, the number of stems, plant mass, leaf mass, stem mass and leaf surface area per plant.

Adequate results of the examined characteristics were stated in the use of super-adsorbent enriched with microorganisms, while the results of the variant in which super-adsorbents (control variant) were not used were poor for the examined characteristics.
In the trials conducted in Bijeljina, due to more favourable agro-ecological conditions, better results were realised for the morphological characteristics of potato, and compared to East Sarajevo.

Abstract

The paper presents the results of studying the chemical composition of the fruit of autochthonous cultivars of apple from Sarajevo area during an one–year period (2020. year). Determination found that it was the fruit of the next cultivars: Funtaca, Sadicka, Ticimka, Staklara and Car Konstantin. Significant differences were found between cultivars in content of soluble dry matter, total sugar, invert sugar, saccharose, total acids and pH value of the fruit of autochthonous cultivars. The cultivar of Staklara had the highest content of soluble dry matter, total sugar, invert sugar and pH value of fruit. The highest content of saccharose was in fruit of cultivar Sadicka, while the cultivar of Ticiminka had the highest content of total acids. Significant differences were found between cultivars in content of macroelements and microelements (magnesium, manganese, copper, aluminum, and zinc), but significant differences were not found between cultivars in content of trace elements (lead, cadmium, and arsenic). The cultivar Staklara had the highest content of magnesium, manganese, while the highest content of copper, aluminum and zinc was in the fruit of cultivar Car Konstantin. The fruits of autochthonous cultivars of apple had the same content of lead (0.10 mg/kg), cadmium (0.05 mg/kg) and arsenic (0.30 mg/kg). The analyzed autochthonous cultivars of apple from the Sarajevo area can be of great importance for integral and organic production, but also as a hybridization starting material to produce new, better cultivar resistant to pathogens of plant diseases and pests.

Key words: *apple, autochthonous cultivar, chemical composition, Sarajevo area.*

Introduction

Autochthonous cultivars of apple are the result of a long process of selection by human and natural conditions, characteristic of the area in which they originated. Bosnia and Herzegovina is rich with autochthonous cultivars and populations of many species of fruit, thanks to the diversity of its edaphic, climatic and geomorphological conditions. However, old traditional cultivars have been neglected, although they represent an important part of our natural and cultural heritage. Old cultivars represent a rich source of genetic material, but some cultivars, also, have very positive traits (e.g. high and regular yield), which is very important from the aspect of cultivation (*Mitre et al.,* 2009), and can have a significant role in further selection. Autochthonous cultivars are gene donors that are responsible for specific traits: resistance to pathogens and pests, color, aroma, resistance to abiotic environmental factors, storage traits.

Autochthonous cultivars are distributed as individual trees or in smaller plantations in a large number of localities in BiH, especially in the areas of Central and Western Bosnia. Their fruits may not look aesthetically perfect compared to standard cultivars (*Bignami et al.*, 2003), but they are characterized by „specific" pomological properties and characterized by different fullness of taste, as well as the ratio of sugars and acids, while some cultivars have a particularly pronounced fruit aroma. The reason may be that most traditional cultivars have a balanced composition of nutrients and bioactive substances (*Feliciano et al.*, 2010).

On the other hand, the processing industry is interested in production these cultivars due to the possibility of growing them without protection or with reduced use of pesticides. (*Militaru et al.*, 2009; *Tomić et al.,* 2011). Also, some old cultivars of apple are used in breeding programs as gene donors responsible for specific traits: resistance to pathogens and pests, color, aroma, resistance to abiotic factors, storage traits, etc. (*Bignami et al.*, 2003).

The aim of this study was to determine the most important chemical composition of the fruit of autochthonous cultivars of apple in the Sarajevo area.

Material and methods

The study on chemical composition of the fruit of autochthonous apple cultivars in the Sarajevo area in Bosnia and Herzegovina was implemented during an one–year period (2020) on five autochthonous cultivars of apple: Funtaca, Sadicka, Ticimka, Staklara and Car Konstantin. Laboratory tests were performed in the laboratory of the Federal Institute of Agriculture Sarajevo–Butmir. Fruits for chemical characterization were sampled in the period of their full maturity.

The following parameters were determined from the chemical properties of the fruit:

- Content of soluble dry matter („Carl Zeiss" binocular refractometer);
- Content of sugars (total and invert) (Luff−Schoorl method (*Džamić*, 1989));
- Content of total acids (titration with 0.1 N NaOH in the presence of phenol–phthalein as an indicator, (*Džamić*, 1989);
- pH value (pH meter CyberScan 510);
- Content of mineral element (digestion under pressure BAS EN 15763:2011).

The obtained data for chemical properties are represented by the mean value for three replicates ± standard error, and were statistically processed by Fisher's model of analysis of variance (ANOVA), using the F–test (*Fisher*, 1953) for $R \leq 0.05$ and $R \leq 0.01$. When the F−test was significant, the testing of arithmetic mean differences was determined using the *Duncan's* multiple interval test for a significance level of $P \leq 0.05$.

Results and discussion

The quality of the fruit of apple is a combination of a large number of physical and chemical, external and internal properties of the fruit. Also, it depends on the interaction of several factors: genotype (cultivar and rootstock), pollinator, physical and chemical properties of the soil, nutrient content and water regime of the soil (*Tagliavini* and *Marangoni*, 2002; *Militaru et al.*, 2009). According to *Chun et al.* (2005) the most important parameters of fruit quality (dry matter content, content of sugar, content of total acids, organic acids, phenolic compounds), depend on the cultivar, but also on the agro–ecological conditions, growing conditions, agrotechnical and pomotechnical measures, storage. Fruit of apple contain up to 17.0% dry matter, from 6.84% to 8.04% of sugar and from 0.16% to 0.56% of organic acids (*Mratinić and Vulic*, 1988). Table 1. shows the most important chemical composition of the fruit (content of soluble dry matter, content of total sugars, content of invert sugars, content of saccharose, content of total acids and pH value) of the fruit of autochthonous cultivars of apple from sarajevo area. The content of soluble dry matter was from 12.69% (Ticiminka) to 15.82% (Staklara). Significant differences were found between cultivars in content of soluble dry matter (table 1). According to the content of soluble dry matter, the studied cultivars can be classified into cultivars with medium high to high content of soluble dry matter. According to *Božović et al.* (2015) the content of soluble dry matter in fruits was from 9.6% to 15.2%, while *Bostan* (2009) states the content of soluble dry matter in the fruits of the local cultivars of apple from 10.5% to 15.0%. The fruits of the cultivars Busuta and Pazarka had the content of soluble dry matter of 15.2% and 14.7%, respectively, and these cultivars can be good raw materials for industrial processing (*Božović et al.*, 2015). According to *Kulina et al*. (2018) the content of soluble dry matter ranged from 12.93% (Bjeličnik) to 16.15% (Ljepocvjetka). The highest content of soluble dry matter was in the fruits of the cultivars Zlatna zimska parmenka and Citronka (*Skendrović–Babojelić et al.*, 2014). According to *Skender et al.* (2008) the content of soluble dry matter was from 11.0% (Divljakinja) to 17.25% (Muškinja). The highest content of soluble dry matter was in the fruits of the cultivars Aleksandrija (16.0%), Rebraca (15.5%), Jolovaca (14.6%) and Dunjka (14.5%), which indicates that these cultivars can be used as a material in the processing industry (*Božović et al.*, 2013). The lowest content of soluble dry matter was 12.0% and was determined in four cultivars, while the highest content was 17.0%, and it was recorded in fruit samples in only one of cultivar (*Jakobek et al.*, 2020). The content of soluble dry matter is the result of agroecological, primarily climatic conditions, and deviations ours from the results of other authors may be a consequence of cultivar, rootstock, agrotechnical and pomotechnical measures, as well as growing conditions. The content of total sugars in the fruit was from 4.87% (Tičiminka) to 8.83% (Staklara). The lowest content of invert sugars was in the cultivar Car Konstantin (3.79%), while the highest content had the cultivar Staklara (5.97%). The content of sucrose was from 0.88% (Tičiminka) to 2.73% (Šadićka). Significant differences were found between cultivars in total sugar, invert sugar and sucrose (table 1). The lowest content of invert sugars was in the fruits of the cultivar Divljakinja (3.0%), while the highest content was in the fruits of the cultivar Petrovka (6.09%) (*Skender et al.*, 2008). Acids give the fruit a sour taste. During the ripening period, the fruits accumulate sugar and break down the total the fruits tastier. Adequate ratio of sugars and acids gives apple fruits a harmonious and refreshing taste, which is an important criterion when evaluating and consuming fruits (*Mišić*, 2002). The content of total acids was from 0.15% (Staklara) to 0.48% (Ticiminka). Significant differences were found between cultivars in content of total acids (table 1). According to *Kulina et al*. (2018) the content of total acids was from 0.43% (Petrovaca) to 0.71% (Sampanjka). The highest content of total acids had the cultivars Lijepocvjetka and Zlatna zimska parmenka, slightly less the cultivar Bozicnica, while the significantly lowest content of total acids had the cultivars Bobovec and Citronka (*Skendrović–Babojelić et al.*, 2014). The content of total acids in the fruit of cultivar Petrovka was 0.12%, while the highest content of total acids was in the fruit of cultivar Divljakina (1.02%) (*Skender et al.*, 2008). According to *Harker et al.* (2002) high content of total acids is the best indicator of sour taste, while high content of soluble dry matter is an indicator of sweet taste of fruit. The balance between sugar content and organic acids is very important in achieving a harmonized taste of fruit (*Hudina* and *Štampar*, 2000; *Bignami et al.*, 2003).

Table 1. Chemical composition of the fruit of autochthonous cultivars of apple (2020 year)

Cultivar	Soluble dry matter (%)	Total sugars (%)	Invert sugars (%)	Saccharose (%)	Total acids (%)	pH values
Funtaca	14,43 ± 0,01 c	6,48 ± 0,01 c	4,56 ± 0,01 c	1,82 ± 0,01 b	0,41 ± 0,01 c	3,29 ± 0,01 d
Sadicka	15,70 ± 0,01 b	8,36 ± 0,01 b	5,52 ± 0,03 b	2,73 ± 0,01 a	0,43 ± 0,01 b	3,26 ± 0,01 e
Ticiminka	12,69 ± 0,01 e	4,87 ± 0,01 e	3,94 ± 0,01 d	0,88 ± 0,01 d	0,48 ± 0,01 a	3,47 ± 0,01 c
Staklara	15,82 ± 0,01 a	8,83 ± 0,01 a	5,97 ± 0,01 a	2,72 ± 0,01 a	0,15 ± 0,01 d	4,37 ± 0,01 a
Car Konstantin	14,21 ± 0,01 d	5,21 ± 0,01 d	3,79 ± 0,01 e	1,35 ± 0,01 c	0,44 ± 0,01 b	3,70 ± 0,01 b

Mean values followed by the same letter are not significantly differ according to Duncan's test (P≤0.05)

Table 2. Mineral content of the fruit of autochthonous cultivars of apple (2020 year) (mg/kg)

Cultivar	Magnesium	Manganese	Copper	Aluminum	Zinc	Lead	Cadmium	Arsenic
Funtaca	32,54 ± 0,01 e	0,16 ± 0,01 d	0,47 ± 0,01 e	0,18 ± 0,01 e	0,12 ± 0,01 e	0,10 ± 0,01 a	0,05 ± 0,01 a	0,30 ± 0,01 a
Sadicka	39,98 ± 0,01 d	0,16 ± 0,01 d	0,82 ± 0,01 c	0,59 ± 0,01 c	0,33 ± 0,01 c	0,10 ± 0,01 a	0,05 ± 0,01 a	0,30 ± 0,01 a
Ticiminka	46,58 ± 0,01 c	0,22 ± 0,01 c	0,93 ± 0,01 b	0,21 ± 0,01 d	0,20 ± 0,01 d	0,10 ± 0,01 a	0,05 ± 0,01 a	0,30 ± 0,01 a
Staklara	54,30 ± 0,01 a	0,48 ± 0,01 a	0,55 ± 0,01 d	0,45 ± 0,01 b	0,43 ± 0,01 b	0,10 ± 0,01 a	0,05 ± 0,01 a	0,30 ± 0,01 a
Car Konstantin	54,19 ± 0,01 b	0,26 ± 0,01 b	0,96 ± 0,01 a	0,68 ± 0,01 a	0,88 ± 0,01 a	0,10 ± 0,01 a	0,05 ± 0,01 a	0,30 ± 0,01 a

Mean values followed by the same letter are not significantly differ according to Duncan's test (P≤0.05)

The lowest pH value was in the cultivar Sadicka (3.26%), while the highest was in the cultivar Staklara (4.37%). Significant differences were found between cultivars in pH value (table 1). pH value of the fruit of autochthonous cultivars of apple from Sarajevo area was in agreement with earlier studies of autors *Kulina et al*. (2018). According to *Jakobek et al.* (2020) pH value was from 2.4 (Crvenka) to 3.8 (Ivanlija).

The deviation ours results from the results of other authors can be explained as a consequence of the influence of cultivar, rootstock, agrotechnical and pomotechnical measures, meteorological conditions, but also the time of maturity.

The fruits of autochthonous cultivars of apple from Sarajevo area had eight mineral elements divided into three groups: macroelements (magnesium), microelements (manganese, copper, aluminum and zinc) and trace elements (lead, cadmium and arsenic) (Table 2). Magnesium (Mg) was the element with the highest content in the fruit of apple, followed by, in descending order: manganese (Mn) > copper (Cu) > aluminum (Al) > Zinc (Zn) > lead (Pb) > cadmium (Cd) > arsenic (As). The content of magnesium (Mg) was from 32.54 mg/kg (Funtaca) to 54.30 mg/kg (Staklara). The content of microelements was in the following intervals: manganese (Mn) − from 0.16 mg/kg (Funtaca and Sadicka) to 0.48 mg/kg (Staklara); copper (Cu) – from 0.47 mg/kg (Funtaca) to 0.96 mg/kg (Car Konstantin); aluminum (Al) – from 0.18 mg/kg (Funtaca) to 0.68 mg/kg (Car Konstantin) and zinc (Zn)– from 0.12 mg/kg (Funtaca) to 0.88 mg/kg (Car Konstantin). The fruits of autochthonous cultivars of apple had the same content of lead (0.10 mg/kg), cadmium (0.05 mg/kg) and arsenic (0.30 mg/kg).

Significant differences were found between cultivars in content of macroelements and microelements (magnesium, manganese, copper, aluminum and zinc), but significant differences were not found between cultivars in content of trace elements (lead, cadmium and arsenic) (table 2). Heavy metals (lead, chromium, nickel, etc.) are elements whose excessive accumulation in plant products can cause various side effects on human health (*Duran et al.*, 2008). The largest amount of heavy metals is absorbed by the root system, with the mechanism of uptake and accumulation depending on the pH value of the soil, absorption capacity, amount of CaCO3, distance from the source that emits unwanted metals, exposure time, etc. (*Osmanović et al.,* 2014). The accumulation of heavy metals in the soil occurs due to: irrigation with water of inadequate chemical composition, application of mineral fertilizers, pesticides and protective agents based on undesirable elements. According to *Duran et al.* (2008) soil conditions are considered a potential source of accumulation of higher heavy metal content in dried fruits.

The content of mineral elements in fruits also depends on the amount of water in the soil, especially if it is known that there is a difference between mineral elements in their solubility in water. This is the reason why the content of mineral elements in fruits depends on irrigation, precipitation and soil permeability. The uptake of mineral elements is directly related to their availability in the soil, since certain elements can be fixed in clay minerals and as such are not available to plants. On the other hand, it is necessary to know their antagonism, in order to be able to interpret their content in the fruit.

However, analyzing the chemical parameters, we can conclude that we cannot observe the exact regularities, considering that the research was one-year-old and that their content cannot be observed in the context of meteorological conditions. This is especially important if it is known that environmental factors significantly influence the course of physiological and biochemical processes. Also, much more extensive and much more thorough studies are needed for more detailed analysis.

Conclusion

Based on one–year studies of the chemical composition of the fruit of autochthonous cultivars of apple from Sarajevo area, we can be made the following conclusions:
Qualitative properties of the fruit show statistically very significant to significant differences between the analyzed cultivars of apple. The content of soluble dry matter was from 12.63% (Ticiminka) to 15.82% (Staklara). The content of total acids was from 0.15% (Staklara) to 0.48% (Tičiminka). The lowest content of total sugars was in the cultivar Tičiminka (4.87%) and the highest in the cultivar Staklara (8.83%). The lowest content of invert sugars was in the cultivar Car Konstantin (3.79%), and the highest in the cultivar Staklara (5.97%). The saccharose content was from 0.88% (Tičiminka) to 2.73% (Šadićka). The lowest pH value was found in the cultivar Šadićka (3.26), and the highest in the cultivar Staklara (4.37).
The fruits of autochthonous cultivars of apple from Sarajevo area had eight mineral elements divided into three groups: macroelements (magnesium), microelements (manganese, copper, aluminum and zinc) and trace elements (lead, cadmium and arsenic).
Magnesium (Mg) was the element with the highest content in the fruit of apple, followed by, in descending order: manganese (Mn) > copper (Cu) > aluminum (Al) > Zinc (Zn) > lead (Pb) > cadmium (Cd) > arsenic (As).

Abstract

The experiment was conducted in the laboratory for post-harvest treatment and pomology of the Faculty of Agriculture, University of Banja Luka, Bosnia and Herzegovina, during 2020. There were one cultivar of gerbera (*Gerbera jamesonii* 'Olympic Gold') and one cultivar of calla (*Zantedeschia aethiopica* 'Captain Ventura') used in this research. Preservative solutions Flower care (0.2%) and sucrose (2%) were used as vase solution to increase vase life of gerbera and calla. Average temperature in cold room, during the experiment was 9°C with relative humidity 65%, without additional light. Statistical data analysis determined a significantdifference in cut flower vase life depending on the vase solution. Vase life of cut gerbera flower kept in sucrose was 28 days (in changing solution) and 21 days (in permanent solution) on average, while vase life of cut gerbera flower kept in Flower care was 24 days (in changing solution) and 16 days (in permanent solution) on average. Vase life of cut calla flower kept in Flower care was 26 days (in changing solution) and 20 days (in permanent solution) on average, while vase life of cut calla flower kept in sucrose was 24 days (in changing solution) and 22 days (in permanent solution) on average. Transpiration intensity also depended on the solution for keeping flowers. The highest transpiration intensity was determined with cut flower which had the longest vase life and vice versa. The research indicates that the application of the preparation Flower care, which contains glucose, biocides and acidifiers, affects the viability of calla flower and prolongs the vase life. Also, the application of the preparation with sucrose prolongs the vase life of gerbera flower.

Keywords: *cut flower, vase life, Gerbera jamesonii, Zantedeschia aethiopica, Flower care, sucrose.*

Introduction

Short postharvest vase life is one of the most important problems on the cut flowers. Longevity of vase life is an important factor in consumer preference (Da Silva, 2003). Maintaining good quality of cut flowers and extending the vase life, is considered important for having acceptable products for the markets. Furthermore, transportation of cut flowers over long distances has increased. These conditions are unsuitable for keeping the quality of cut flowers. Keeping quality is an important parameter for evaluation of cut flower quality, both in export and domestic markets. The major reasons for shorten vase life of cut flowers are nutrient deficiency, bacterial and fungal contaminations (Kazemi *et al.*, 2011) water stress-induced wilting and vascular blockage (Alaey *et al.*, 2011). Bacteria in the vase water can block the vessels in the surface of cut stems (Ferrante *et al.*, 2007). This can have influence on water uptake which is one of the reasons for water deficit and wilting during vase life (Knee, 2000; Van Ieperen et al., 2002).

Gerbera (*Gerbera jamesonii*) and calla (*Zantedeschia aethiopica*) are very popular cut flowers, having short vase life, and mostly are used freshly, so their vase life improvement is one the first floriculture's purposes (Elgimabi and Ahmed, 2009).
Postharvest life of cut flowers could be affected by the application of various chemicals. Different chemicals have been used in vase solution to extend vase life of cut flowers mainly by improving their water uptake and reducing transpiration, inhibiting microorganisms growth, thereby promote the vase life ((Nair *et al*., 2003; Prashanth *et al*., 2010; Lu *et al.*, 2012). Some of these chemicals include silver nitrate, 8-hydroxyquinoline sulfate and 8-hydroxyquinoline citrate, which are expensive and harmful for the environment and human health (Ichimura *et al*., 1999; Solgi *et al*., 2009; Ansari *et al.*, 2011). It is very important to use natural, safe and inexpensive compounds for the application of preservatives improving cut flower vase life (Kilic and Cetin, 2014). The application of different medicinal plants essential oils on increasing the vase life of cut flowers have been studied by many researches. Essential oils (EO) are organic, natural, safe and eco-friendly substances that have strong anti-inflammatory, antibacterial, antifungal, antioxidant and anticarcinogenic effects, and have the high levels of phenolic compounds (Bayat *et al*., 2011; Raut and Karuppayil, 2014).
Carbohydrate is the main food source to maintain the energy requirement for flowers. Sugars play important roles in keeping the quality of cut flowers as substrates for respiration and cell walls as well as osmolytes. Since the amount of sugar contained in cut flowers is limited the addition of sugars such as sucrose to vase water is effective in improving the vase life of some cut flowers (Chaudhary and Khanal, 2018). Addition of sugars to vase water not only extends the vase life of cut flowers but also promotes flower opening.
Cut flower food products provide all the nutrients needed for flowers to bloom naturally and fully. At the same time it keeps the flowers and foliage fresher and healthier longer, and extends the vase life of cut flowers. Flower food is available in gel, powder or liquid forme.
Therefore the aim of this study was to search for the preservative solutions ("Flower care" and sucrose) for extending vase life of cut gerbera and calla flowers.

Material and Methods

The experiment was conducted in the Laboratory for post-harvest treatment and pomology of the Faculty of Agriculture, University of Banja Luka, Bosnia and Herzegovina, during 2020. There were one cultivar of gerbera (*Gerbera jamesonii* 'Olympic Gold') and one cultivar of calla (*Zantedeschia aethiopica* 'Captain Ventura') used in this research. Preservative solutions "Flower care" (0.2%) and sucrose (2%) were used as solution to increase vase life of gerbera and calla. Experiment was laid out with two treatments, under completely randomized design with four replications with three flowers steams in each replicate. Flowers were kept in 750 ml glass jars, containing 300 ml of vase solution. There were two variant, with changing solution (every third day) and with permanent solution. Average temperature in cold room, during the experiment was 9°C with average relative humidity 65%, without additional light. Temperature and relative humidity were recorded in the morning and evening each day. Before setting up the experiment, stems were recut to 35 cm length. The following data were recorded: fresh weight of flowers (g); transpiration intensity of the solution (ml), and flower longevity - vase life. A digital scale, typ KERN, was used to determine fresh weight (g) of the flowers. The transpiration intensity of the solution (ml) was measured by subtracking the vase solution after a certain time from the initial vase solution:

transpiration intensity = $Vu - V_1$
Vu (ml) – initial vase solution (300 ml); V_1 (ml) – the vase solution after a certain time
Flower longevity or vase life of cut flowers was completed when the petals or stem below the flower had lost turgidity. Collected data were analyzed using a statistical program VV-Stat (Vukadinović, 2017). Fisher's LSD test was applied to judge statistical significance of differences between treatments using. Mean values were considered significantly different when $p < 0.05$.

Results and Discussion

The average values of fresh weight of cut gerbera and calla flowers in the cold room statistically depending on the applied and typ of solution.
The highest average value of fresh weight of cut gerbera flower was observed in the flower food solution (A1) in the amount of 30.49 g, in a changing solution. Also, the lowest value was observed in the flower food solution, in a permanent solution, in the amount of 26,14 g (A1). In the sucrose solution (A2), in both solution variant, value of fresh weight of cut gerbera flower was almost the same (27.74 g; 28.71 g).
The highest average value of fresh weight of cut calla flower was observed in the flower food solution (A1) in the amount of 36.23 g, in a changing solution. The lowest value was observed in sucrose solution (A2) in the amount of 28.25 g, in a permanent solution.

Table 1. Fresh weight of cut gerbera and calla flowers (FW g) (means marked with different letters ^{a,b} significantly differ at $p < 0.05$; *ns* = not significant; ** = Ftest 99%; * = Ftest 95%)

The highest transpiration intensity (ml) of cut gerbera flower, in changing solution, was observed in the flower food solution (A1) in the amount of 14.46 ml, and the lowest in the sucrose solution (A2) 11.82 ml. In permanent solution results were different, the highest transpiration intensity (ml) of cut gerbera flower, was observed in the sucrose solution (A2) in the amount of 115 ml, and the lowest in the flower food solution (A1) 75 ml. The same ration was observed in transpiration intensity of cut calla flower, where the highest transpiration intensity was observed in the flower food solution (A1) in the amount of 5.85 ml, and the lowest in the sucrose solution (A2) 3.12 ml. In permanent solution results were almost the same in both vase solution (34 ml; 35 ml) (Table 2.).

Vase life of gerbera and calla varied among the vase solutions (Table 3.). Maximum vase life of cut gerbera flowers, was found in changing sucrose solution (27.78 days) followed by 23.78 days in changing flower food solution. Minimum vase life of cut gerbera flowers was found in permanent sucrose solution with 21.33 days followed by 15.66 days in permanent flower food solution. Maximum vase life of cut calla flowers was also in changing solutions with maximum vase life of 26.33 days in the flower food solution, and minimum with 23.89 days in the sucrose solution. In permanent solutions vase life of cut calla flowers was almost the same in the flower food and in the sucrose vase solution (20.33 days; 21.67days).

According to the presented results for flower longevity or vase life is better to changing vase solution than left it constant. Maximum vase life of cut gerbera flowers was in sucrose vase solution, while maximum vase life of cut calla flowers was in the flower food solution. Flower longevity and quality of cut flowers in vase solution depend of numerous number of factors like genetical constituents, pre-harvest conditions, harvesting technique, packaging, post-harvest handling and storage. But for the post harvesting storage different chemicals influences the vase life and floral quality of cut flowers (Khan et al. 2015). The vase life of gerbera and calla mostly depending on the how upright the stem is or "bent neck". Sugar acts as the carbohydrate source and also makes the cells of the flower stem concentrated with sugars that are carried up by the phloem. The hypertonic solutions inside the cells allow water to enter the cells by osmosis and thus make them turgid. This turgidity gives the stem a rigid, upright structure (Khan et al. 2015).

The longest vase life of cut gerbera flower was found in the treatment with sugar, but the longest vase life of cut calla flowers was in the treatment with flower food, in both variant when solution is changing. Flower food has certain antimicrobial properties, which reduce the degree of vascular blockage, thus allowing for optimum solution uptake and reducing stem bending.Treatment with sucrose promoted floret opening and extended the vase life of cut flower, increased anthocyanin concentrations in petals as well as extended the vase life of several cultivars of cut Eustoma flowers and of cut hybrid Limonium (Ichimura, 1998). Longevity of many cut flowers is negatively influenced by the presence of ethylene by inducing various physiological responses like wilting of leaves and petals. Silver thiosulphate is known to suppress autocatalytic ethylene production (Da Silva, 2003). Silver ion available in the silvar thiosulphate had bactericidal property and reduced the frequency of bent necks and improved the vase life of cut roses (Torre and Fjeld, 2001). Citric acid has also been found to play a key role to extended vase life of cut gerbera. Citric acid has an ability to extend vase life of cut flowers in association with inhibition of ethylene production (Srivastava and Dwivedi, 2000).The application of the flower food preparation "Chrysal clear", which contains glucose, biocides and acidifiers, affects the viability of rose flower and prolongs the vase life (Kraljičak et al., 2012).

Conclusions

Based on the results of this study agents such as sugar and "Flower care" had a positive effect on flower vase life. Sugar (treatment A2) was the best chemical treatments for increasing the vase life of gerbera by delayed senescence, while maximum vase life of cut calla flowers was in the flower food solution (treatment A1). Flower food had very effective antimicrobial agents, which inhibited the microbial growth and prevented bacterial plugging in conducting tissues. Additional supply of sugars can increase water balance and osmotic concentration and sucrose had an important role in lengthening the vase life of cut flowers. Flower longevity and quality of cut flowers in vase solution depend of numerous factors, and this reserach showed that vase life of cut flowers also depends on the flower species. According to the presented results for vase life is better to changing vase solution than left it constant. Thus, it is recommended to use sugar or flower food as a vase solution for gerbera and calla to extent shelf life.

ENERGY FOR DYNAMIC TEARING OF GYNOPHORS OF BULGARIAN PEANUT VARIETIES

Nayden NAYDENOV*, Stoyan ISHPEKOV

Agricultural University of Plovdiv, Department of Agricultural Mechanization, Bulgaria
*Corresponding author: nanndo@abv.bg

Abstract

The aim of the research is to determine the energy for dynamic detachment of the fruits of fifteen promising Bulgarian peanut varieties. It was determined that the value and nature of the energy change differ significantly for the studied varieties, but it predetermines scattering losses during the mechanized harvesting. The results shows different dynamics of change of energy for tearing off gynophore in different varieties. In some of them, it varies widely, at the expense of a slight decrease in humidity. In others, the energy changes in a narrower range with a more intensive decrease in the pods' humidity. The strengthening of the gynophore by lowering the moisture content in the fruits is an indicator for increasing the resistance of the beans to mechanical influences during the period of field ripening until reaching technological maturity. The most suitable variety of peanuts for mechanized harvesting is 539_mother. Its energy used to detach fruits from stems decreases with decreasing humidity and mass of the fruit. It reaches a maximum of 0.075 J at an average mass of 2 g and a moisture content of 10%. The results obtained can be used to determine the varieties which give the least scattering losses of peanut fruits at mechanized harvesting as well as in the selection varieties, suitable for mechanized harvesting.

Keywords: *Peanuts, Energy, Gynophors, Bulgarian.*

Introduction

Peanuts are the fifth most important oil crop in the world (Burns, 2010). It is a valuable raw material not only because of its good taste, but also because of its high nutritional value. The seeds contain up to 32% protein and 42% to 52% oil (Putnam et al., 2013). Peanuts in Bulgaria are not the main crop and are grown mainly by small farmers with a lot of manual labor (Bencheva and Gergiev, 1997). Mechanization of peanut harvesting processes makes their cultivation more cost-effective (Bertonha et al., 2014). But with the introduction of mechanization, a significant problem arises, namely the large losses of peanuts fruits on the field (Thomas et al., 1983). Most of the losses are formed during the digging of plants from the soil. According to studies by Santos et al., (2013), these losses range from 3.1% to 47% relative to yield. Other authors report losses of 8%, which reach 40% if harvesting is carried out at a humidity below the optimum (Young et al., 1982; Lamb et al., 2004). Similar results have been achieved in studies conducted in Bulgaria with established Bulgarian peanut varieties. They indicate total losses of 9.7% to 30.6% relative to biological yield (Stamatov et al., 2020).
According to many researchers, the main factor on which the formation of losses in mechanized harvesting of peanuts depends is the retention force of the fruits to the plant (Zerbato et al., 2014; Bencheva et al., 2008). It was found that it is not affected by the diameter of the gynophore and depends most strongly on the anatomical structure of gynophores (Thomas et al., 1983,

Bogomilov et al., 2016). Experiments conducted with Bulgarian peanut varieties - Tsvetelina, Kremena, Kalina, Adata and Hybrid 11 - confirm the individual varietal characteristics in terms of strength of gynophore. The energy for tearing the fruits was studied and was found that of different varieties their values and natures of change are different (Ishpekov, et al., 2021). These results indicate that the selection of Bulgarian peanut varieties is not aimed at strengthening the gynophores so far. The assessment the dynamic strength of gynophores by the energy for their detachment creates conditions for determine the susceptibility of peanut varieties to mechanized harvesting. This energy provides valuable information for selecting peanuts varieties with increased dynamic strength of the bond between the peanuts fruit and the plant in order to minimize losses in mechanized harvesting. The aim of the study is to determine the energy for dynamic tearing of peanut fruits from Bulgarian peanut varieties.

Materials and Methods

Existing methodology and experimental tool are applied to determine the strength of the peanut pod (Ishpekov et al., 2021). The energy consumption for picking a single peanut pods is measured depending on its mass and the moisture content of the shell. The study was performed with 15 genotypes from the early generations of the selection at three levels of the mentioned factors. The mentioned energy is measured by means of an experimental system consisting of a pendulum apparatus, stem attachment tool and an electronic data acquisition system.

At the beginning of each experiment, the stem is cut from the plant with a length of 40 - 50 mm to which a gynophore with peanut beans is attached. The bean is positioned on the base of the pendulum platform so that it touches the pendulum in its equilibrium position, and the stem is fixed between two planes. The electronic system is started, the pendulum is deflected at a set angle and after the pause, it is unlocked and lowered to its equilibrium position, where it detaches the bean from the stem. The energy for tearing and moving the beans is calculated through the difference between the angle of descent and the angle of deflection of the pendulum after tearing the bean off. The measurement is repeated with the same bean to determine the energy for its movement only. The difference between the two measured energies gives that for tearing the bean from the gynophore. The measurement data is visualized using a virtual instrument developed in the environment of the LabView software package (Figure 1).

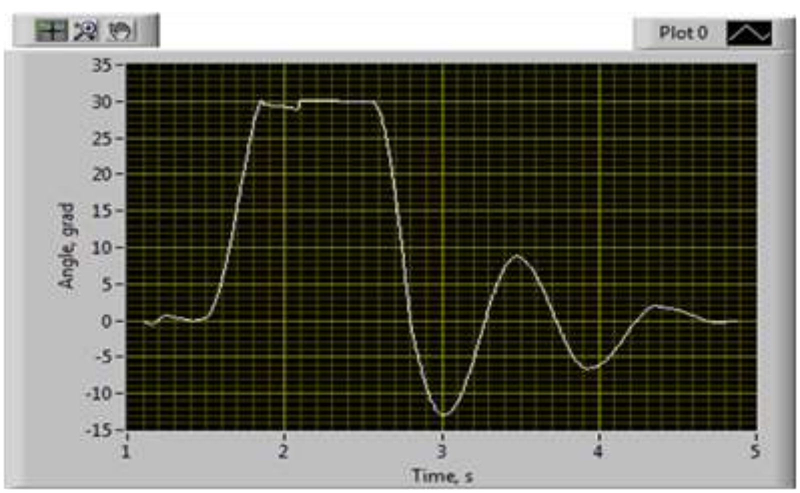

Figure 1. Graph for reading the angles of incidence and deflection of the pendulum after tearing peanuts pods off

Results and Discussion

On figures 2a and 2b are shown the influence of the average mass of bean on the energy for its detachment.

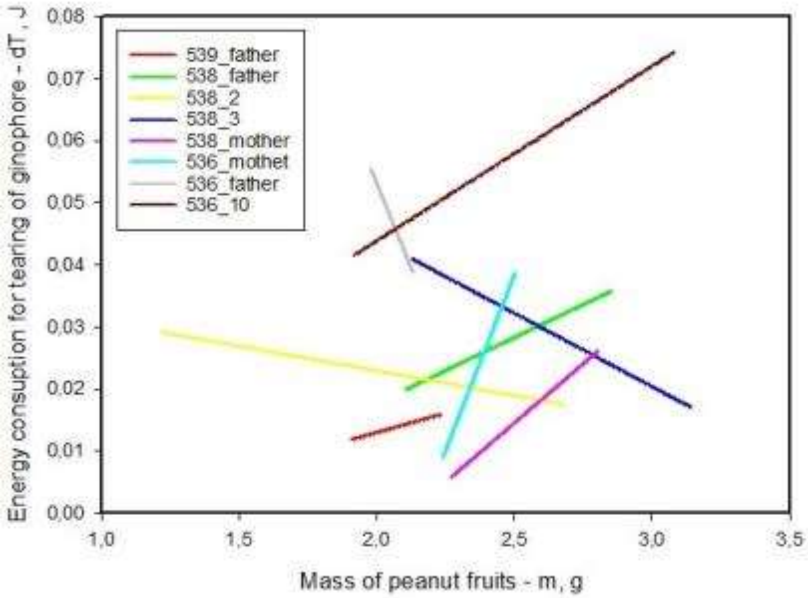

Figure 2a. Energy for tearing off peanut fruit depending on its mass

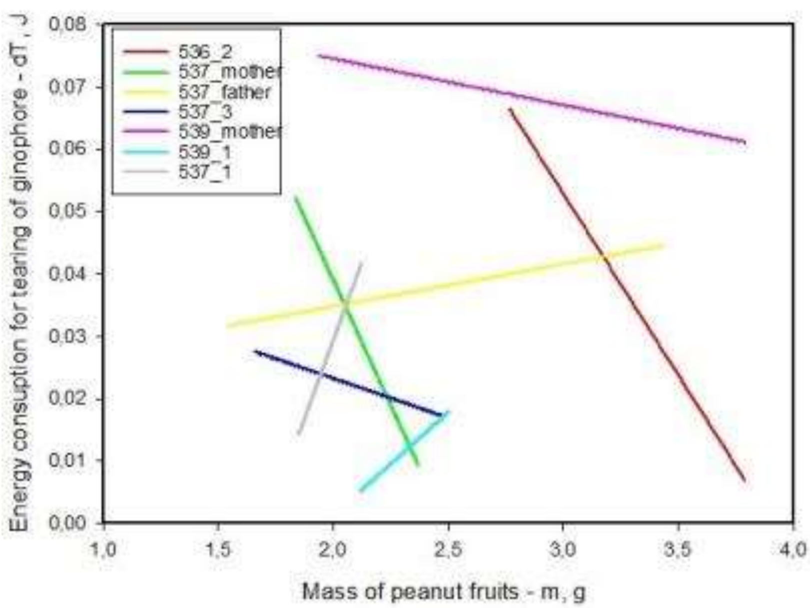

Figure 2b. Energy for tearing off peanut fruit depending on its mass

It is obviously that the nature of the change in the energy for plucking the peanut beans is different in different genotypes. Depending on this, two groups of varieties are distinguished. The first group includes those in which the energy for detachment decreases with the increasing mass of beans. This is observed in genotypes 536_2, 537_mother, 537_3, 539_mother, 538_2, 538_3, and 536_father. The second group includes varieties in which the energy for detachment increases with decreasing bean mass. These genotypes are: 537_father, 539_1, 537_1, 539_father, 538_father, 538_mother, 536_mother and 536_10.

The influence of peanut fruits moisture content on energy consumption is similar (Figure 3 a, b). It is obvious that the nature of the change in energy for dynamic tearing off strongly depends on the specific genotype. This confirms the results from studies conducted by Ishpekov, S., (2021), where the same phenomenon was observed in other varieties.

The results show different dynamics of change of energy for tearing off gynophore in different varieties. In some of them, it varies widely, at the expense of a slight decrease in humidity. This is observed at 536_10, 538_3, 537_1, 537_mother, 536_2, 538_mother and 538_3. In others, the mentioned energy changes in a narrower range with a more intensive decrease in the humidity of the pods. This applies to the varieties 538_father, 539_father, 536_mother, 537_father, 537_3, and 539_mother.

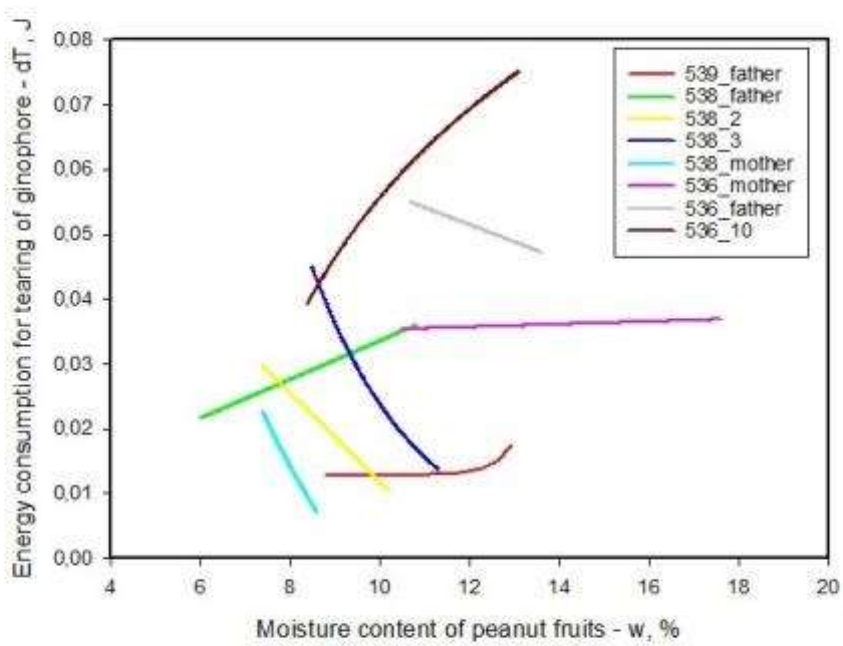

Figure 3a. Energy for tearing beans depending on its humidity

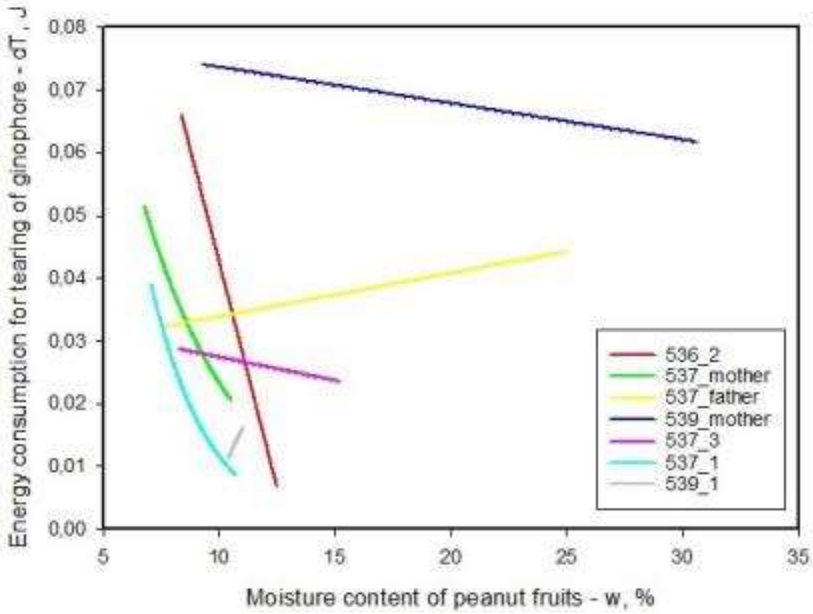

Figure 3b. Energy for tearing beans depending on its humidity

The results provide information for the dynamic strength of the gynophores of 15 Bulgarian peanut varieties. The higher energy release shows a greater dynamic strength between the bean and stem, which is decisive for the losses when digging the fruits out of the soil. The strengthening of the gynophore by lowering the moisture content in the fruits is an indicator for increasing the resistance of the beans to mechanical influences during the period of field ripening until reaching technological maturity.

Within the studied varieties, the best indicators were achieved by variety 539_mother. Its energy expended to detach the beans from the stems decreases with decreasing humidity and bean mass. It reaches its maximum of 0.075 J at an average bean weight of 2 g and shell moisture of 10% (Figure 2b and Figure 3b).

The results obtained can be used to determine the varieties that are suitable for mechanized harvesting, as well as for the selection of varieties with reinforced gynophores, which minimize scattering losses in mechanized harvesting.

Conclusions

The energy for dynamic tearing off of the gynophore, which connects the stem with the fruit of the peanuts, predetermines their resistance to rupture during their mechanized harvesting and reflects on the losses of unharvested production.

The energy for dynamic tearing off of a single bean from promising Bulgarian peanut variety lines has been experimentally determined. These are 536_2, 537_mother, 537_3, 539_mother, 538_2, 538_3, 536_father, 537_father, 539_1, 537_1, 539_father, 538_father, 538_mother, 536_mother and 536_10. The size and nature of its change depending on the mass of the bean and the moisture content of its pods have been established. The energy for tearing the peanut varies in different directions for different varieties. In some, it increases, and in others, it decreases with decreasing moisture content and mass of beans, which confirms that the dynamic strength of the gynophore is a varietal characteristic.

From the point of view of the energy for tearing off the beans, the most suitable for mechanized harvesting is variety 539_mother, followed by 536_10 and 536_2. The varieties 538_mother, 539_father, 539_1, 538_2, and 537_3 show the lowest energy for dynamic tearing off.

Abstract

Sorghum is a crop that belongs to the *Poaceae* family and is known for its high yields. A field experiment was conducted in the experimental farm of the University of Thessaly, (coordinates: latitude 39^{o}24'50.95''N, longitude 22^{o}44'0.79''E, altitude 78m ASL), to investigate the quality characteristics of six different sorghum varieties (V_1: Buffalo grain, V_2: Elite, V_3: Big Kahuna, V_4: 25K1009, V_5: 4264 and V_6: 5D61) under different nitrogen fertilization levels (N_1: 0, N_2: 80, N_3: 160 and N_4: 240 kg ha^{-1}, using urinary ammonia 40-0-0). There was used a factorial split-plot design with three replicates and twenty-four plots per replication, where the main factor was the different varieties and the sub-factor the different N-fertilization levels. The climate in the research region is typical of the Mediterranean. During summer months, the average recorded air temperature was 25.8°C and the recorded summer precipitation was just 46 mm. Protein content was not statistically significant different between the tested varieties but only between nitrogen levels with "Buffalo grain" being the variety with the higher protein content, while phosphorus and calcium content were statistically significant different between the tested varieties. Finally, ash, neutral detergent fiber and acid detergent fiber, was also statistically significant different between the tested varieties. The variety "5D61" was the one with higher ash content while the "Buffalo grain" variety lags statistically significantly behind all the others in both measured quality characteristics (neutral detergent fiber and acid detergent fiber).

Keywords: *Sorghum, protein, ash, ADF, NDF, nitrogen.*

Introduction

Agriculture's intensification and over-exploitation of land have resulted a loss of soil fertility and an increase of cultivation costs. Producers began to use more fertilizers to enhance agricultural yield. Nitrogen constitutes the most applied nutrient and nitrogen fertilizers are those with the lowest price. Nitrogen (N) is a key component of enzymes and other proteins essential to all growth functions and when N is suboptimal, growth is reduced (Kiani et al., 2016). Nitrogen is the element that helps crop growth and has been mentioned worldwide for its benefits increasing grain yields in most crops and especially in maize case (Muhammad et al., 2020). Kurai et al. (2015) reported that 90 kg N ha^{-1} is an efficient N fertilization rate for sustainable sweet sorghum cultivation.
Sorghum is a member of the *Poaceae* family and is one of the most important crops used as animal feed in semi-arid, tropical countries because of its capacity to thrive in high temperatures and dry conditions where no other crops can be cultivated (Morris, 2005; McCary et al., 2020). Sorghum is one of the most important cereal crops in the world, coming in fifth place behind

maize, wheat, rice, and barley, with annual production of 57.6 million tons in 2017 (FAO, 2017). Also, sorghum crop is characterized by a high adaptability and a high-water use efficiency (WUE), and a low nutrient requirement compared with corn (Wu et al, 2010; Zhang et al. 2016; Hasan et al., 2017). Sorghum base growing temperature is 13°C (Ferraris and Charles-Edwards, 1986) while the favor temperature growth range is 20-30°C. The above characteristics allow it to grow in a wide variety of climates.
Roby et al., (2017) reported that sorghum cultivation is recommended for silage production under drought scenarios, while there are many studies where it is reported that brown midrib sorghum silage could totally replace maize silage without affecting the milk yield of dairy cows (Oliver et al., 2004; Bernard and Tao, 2015; Cattani et al., 2017). As a result of the circumstances, sorghum output for animal feed has increased in the Mediterranean countries in the previous two decades (Miron et al., 2005).
The aim of this study was to determine which of the tested sorghum varieties could produce an animal feed with higher quality characteristics. In addition, the aim of the present study was to investigate which nitrogen fertilization level will contribute to the improvement of the quality characteristics of the selected sorghum varieties.

Materials and Methods

The experimental site is within the experimental farm of the University of Thessaly, located in the vicinity of Velestino village, Prefecture of Magnesia (coordinates: latitude 39^{o}24'50.95''N, longitude 22^{o}44'0.79''E, altitude 78m ASL).
A field experiment using a factorial split-plot design was used with three replicates (blocks) and twenty-four plots per replication in a particularly fertile (organic matter of 2.91% at a depth of 0-30 cm and 1.86% at 30-60 cm), clayey soil with an alkaline reaction (Table 1; presents the soil properties). The main factor was the different varieties (V_1: Buffalo grain, V_2: Elite, V_3: Big Kahuna, V_4: 25K1009, V_5: 4264 and V_6: 5D61, six varieties in total) and the sub-factor the different nitrogen fertilization levels (N_1: 0, N_2: 80, N_3: 160 and N_4: 240 kg ha^{-1}, using urinary ammonia 40-0-0). The occupied area of each plot was 42 m^2 (6 m wide and 7 m long).

Table 1. Soil properties of surface (0-30 cm) and sub-surface horizons (30-60 cm).

Characteristics / Depth (cm)	***Particle size distribution***			***Bulk Density***	***pH***	***CEC (cmol/kg)***	***Organic Matter (%)***	***CaCO$_3$***	***C/N***
	Sand (%)	***Silt (%)***	***Clay (%)***						
0 - 30	26,8	31,33	41,87	1,27	7,63	26,05	2,91	6,78	8,78
30 - 60	25,93	30,93	43,13	1,27	7,9	23,18	1,86	7,68	8,85

On June 5, 2019, sorghum was sown and on July 20, 2019, the surface nitrogen-fertilization was carried out. Plant distance between lines was 50 cm (for the first three varieties V: 1-3) and 75 cm (for the rest V: 4-6), while plant distance on the line was 8 cm for all types, as per recognized right procedure (and the characteristics of the varieties).
On October 25, 2019, the final harvest took place, by cutting of plants of 1 m^2 from the inner portion of each plot to reduce the boarder impact. Two representative plants were selected and

chopped for further laboratory analysis. Ash, protein, neutral detergent fiber (NDF), acid detergent fiber (ADF), calcium and phosphorus content were determined in crushed plant sub-samples of each sample by near-infrared reflectance (NIR) spectroscopy technique using the DA 7250 NIR analyzer (Perten Instruments, Hägersten, Sweden). NDF and ADF suggest plant quality characteristics that are related to the age and growth stage of the crop. NDF and ADF values estimate the feed content of lignin, cellulose, hemicelluloses, and insoluble minerals.
Complete weather data were recorded by an automated meteorological station, which was installed next to the experimental field.
Finally, the analysis of variance (ANOVA) within sample timings for all measured and derived data was conducted using the statistical package GenStat (7^{th} Edition). The $LSD_{0.05}$ was used as the test criterion for assessing differences between means (Steel and Torrie, 1982) of the main and/or interaction effects.

Results and Discussion

Climatic data

The climate in the research region is typical of the Mediterranean. During the summer months, the average recorded air temperature was 25.8°C, which is nearly identical (26.2°C) to the study area's normal air temperature. Following that, during September, the air temperature dropped by 4°C, the same as the area's normal air temperature (Fig. 1).

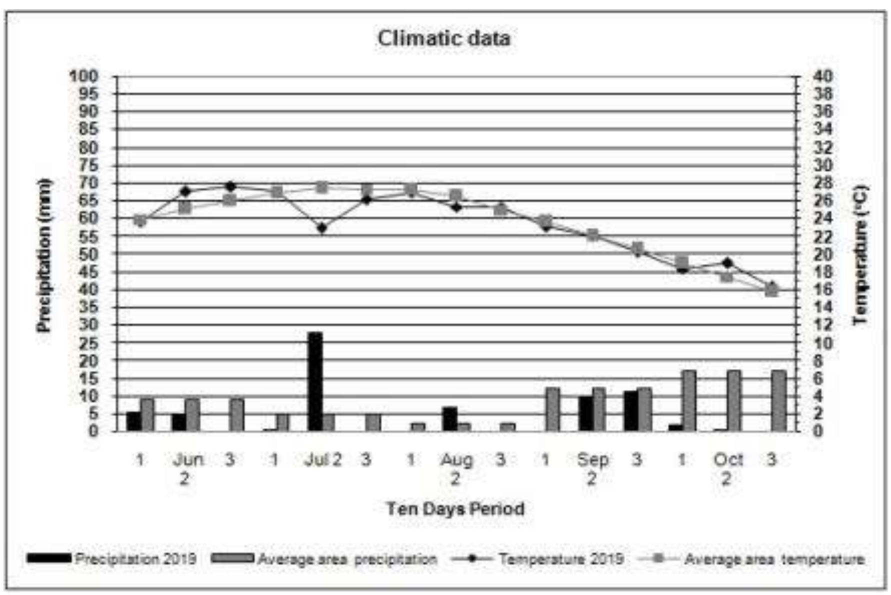

Figure 1. Average air temperature and precipitation occurred during sorghum cultivation.

Summer precipitation was just 46 mm, practically identical to the average precipitation in the study area, and only 5 mm less than the average precipitation (Fig. 1). In addition, it appears that the average precipitation of the area where the experiment is conducted was distributed more smoothly in the summer months, while during the experimental year the 60% of the precipitation occurred in the second ten days of July (Fig. 1). In September there was recorded a precipitation of 21 mm (Fig. 1), which is almost the half (43%) of the average precipitation, making the growing year very dry and adverse. Due to the significant rainfall (28 mm) that recorded in the second ten days of July, there was accompanied a significant drop in temperature.

Biomass quality characteristics

There were not found any statistically significant differences in protein content between the tested varieties (Fig. 2, a). The first three nitrogen levels differed statistically significantly, but not the fourth from the third (Fig. 2, b). It seems that in almost all varieties (except "5D61") the level of 160kg N per hectare had the highest protein content (Fig. 2 c).
In figure 2 (d, e, f) it is illustrated the phosphorus content. The varieties "Big Kahuna" and "5D61" are significantly superior to all others except "Buffalo grain", while "4264" lags significantly behind all except "25K1009" (Fig. 2, d). The different nitrogen levels had not any effect on the phosphorus content (Fig. 2, e), while in figure 2 (f) where are presented the interaction of the factors, the lowest value (0.11) was recorded by the variety "25K1009" at the control treatments and by the "4264". The highest value (0.18) was recorded by the variety "Big Kahuna" at the treatment where 240 kg N ha^{-1} were supplied and by the variety "5D61" for both treatments of 80 and 240 kg N ha^{-1} (Fig. 2, f).
In the case of calcium content, the variety "5D61" is significantly superior to all others, while "Elite" lags significantly behind all except "Buffalo grain" (Fig 2, g). Furthermore, the control treatments (0 nitrogen fertilization) lag significantly behind (Fig. 2, h). Finally, in case of interactions (Fig. 2, i), the lowest calcium content was recorded by the variety "Elite" at 0 nitrogen fertilization per hectare (0.20) and the highest by the "5D61" variety at the fertilization of 80 kg N ha^{-1} (0.33).

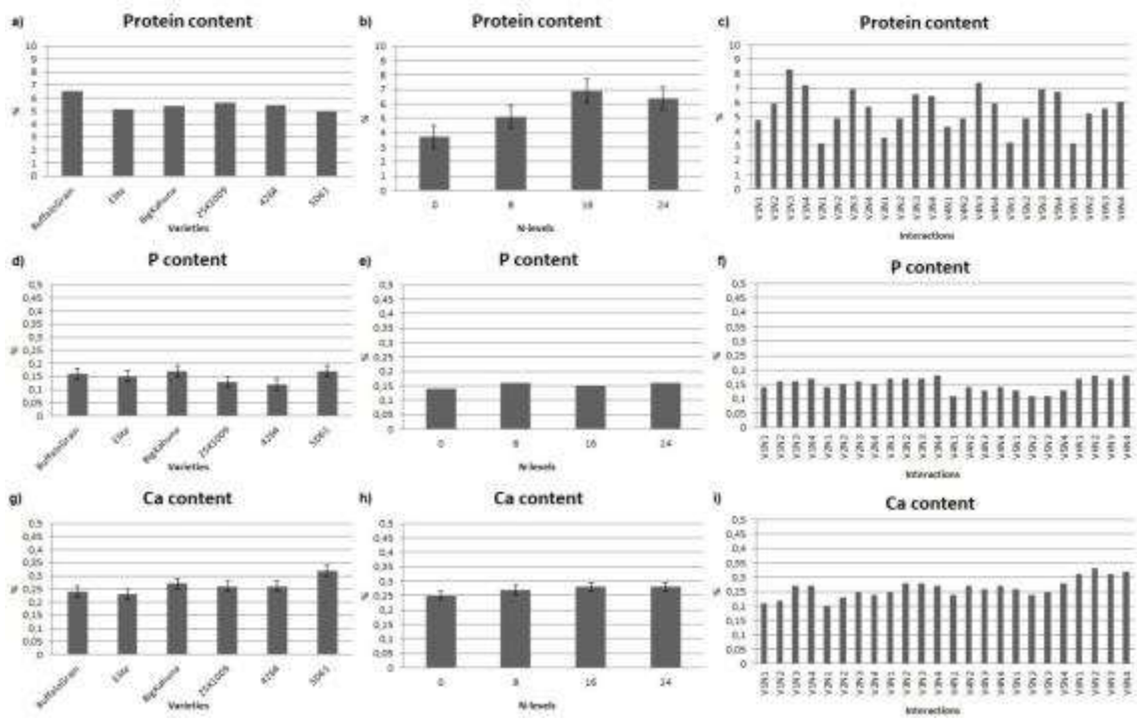

Figure 2. Protein (a, b, c), phosphorus (d, e, f) and calcium (g, h, i) content on the silage of the tested varieties as affected by the different N-fertilization levels (0, 80, 160, and 240 kg N ha^{-1}).
*V1: Buffalo Grain, V2: Elite, V3: Big Kahuna, V4: 25K1009, V5: 4264, V6: 5D61
**N1: 0, N2: 80, N3: 160, N4: 240 kg N ha^{-1}

An additional feature that needs to be measured is the ash content. In this case, the highest percentage was shown by the variety "5D61" (5.6%) followed by "Big Kahuna" (5.1%) and then

the rest with the last being "Elite" variety (4.4%; Fig. 3, a). The results for the ash content at the different nitrogen fertilization levels (Fig. 3, b) were similar as on protein content, while the lowest value was recorded by the variety "Elite" at control and the highest by the "5D61" variety at the treatment where 80 kg N per hectare were supplied.
Finally, high importance features, such as neutral detergent fiber (NDF) and acid detergent fiber (ADF), which are related to the age and growth stage of the crop measured. The NDF index recorded lower values in the first two varieties "Buffalo grain" and "Elite" (Fig. 3, d). "Buffalo grain" variety lags statistically significantly behind all the others except "Elite". "Elite" variety on the other hand, has a significantly lower value than "Big Kahuna", "4264" and "5D61". The results for the NDF content at the different nitrogen fertilization levels (Fig. 3, e) were similar as on protein content where is recorded an increase in percentage as nitrogen increases and a decrease in the fourth level (240 kg N ha^{-1}) compared to the third (240 kg N ha^{-1}). In case of interactions (Fig. 3, f), the lowest value was recorded by the variety "Buffalo grain" at the treatment where 80 kg of nitrogen per hectare were supplied (50.5 %) and the highest by the variety "5D61" at fertilization level of 160 kg N ha^{-1} (59.32 %). In case of the ADF index (Fig. 3, g, h, i), lower values were recorded again by the "Buffalo grain" and "Elite" and the statistical differences were the same as in case of NDF index. The lowest value was recorded by the variety "Buffalo grain" at control treatments (29.8 %) and the highest by the variety "5D61" at the fertilization level of 160 kg N ha^{-1} (36.4 %). ADF values are inversely related to digestion and therefore feed with low ADF concentrations is usually higher in energy.

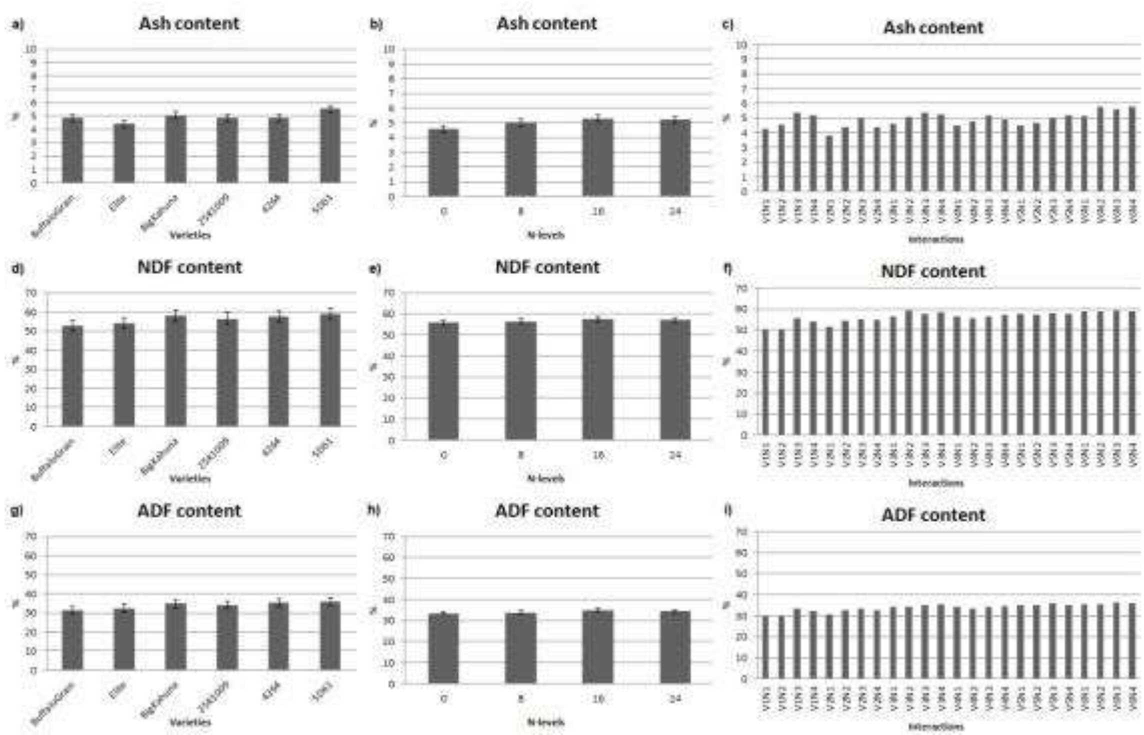

Figure 3. Ash (a, b, c), NDF (d, e, f) and ADF (g, h, i) content on the silage of the tested varieties as affected by the different N-fertilization levels (0, 80, 160, and 240 kg N ha^{-1}).
*V1: Buffalo Grain, V2: Elite, V3: Big Kahuna, V4: 25K1009, V5: 4264, V6: 5D61
**N1: 0, N2: 80, N3: 160, N4: 240 kg N ha^{-1}

However, in our study, P content was lower than the average value of 8.5% which is reported in literature (Miron et al., 2007; Samarappuli and Berti, 2018). The lower content could be explained by the maturity stage at harvest period or may be due to the different species examined since the species in the literature are forage sorghum varieties, which have higher biomass in leaves. Contrary, in case of calcium and phosphorus content the findings of the current study totally agree with the reported in literature (Da Silva Inácio et al., 2018).
The ash content observed in this study was lower than those reported by Mahmood et al. (2013), which may be explained to different soil-climatic conditions in which crops were grown and may be due to the different growing stage when harvest took place. In literature it is clearly reported that there is a decline in ash content according to plant maturity (Filya, 2004).
Finally, in literature has been reported a range in NDF and ADF of 48.3-55.4 % and 21.7 – 37.0 % (Pereira et al., 2017; Da Silva Inácio et al., 2018). The above range totally agrees with the findings of the current study, with values closer to the higher values mentioned above.

Conclusions

There were no statistically significant differences in protein content amongst the examined sorghum varieties, although there were statistically significant differences in phosphate and calcium content. Only the nitrogen levels were shown to have statistically significant differences in protein content. Furthermore, there were found statistically significant differences in ash, neutral detergent fiber, and acid detergent fiber between the studied varieties. Finally, the variety "5D61" has the highest ash content, while the "Buffalo grain" variety lags statistically significantly behind the others in both quality measures (neutral detergent fiber and acid detergent fiber).

Abstract

Beans (*Vicia faba*) are a protein-rich food and can be sown in early winter as well as in spring, providing flexibility depending on climatic conditions, soil type and cultivation systems. The micro-sperm bean which is usually used as animal feed is an important legume crop. It was decided to investigate the effect of phosphate fertilization on both seed yield and protein content because the plant performed well even in barren or depleted lands. For the purposes of the study, a field experiment was conducted in the experimental farm of the University of Thessaly (latitude 39°24'50.95''N, longitude 22°44'0.79''E, altitude 78m ASL), using a complete randomized block experimental design with four treatments (F1: control, F2: 30, F3: 60 and F4:90 kg ha^{-1} P_2O_5) and four replications. The soil in the experimental field was clayey and fertile, with 2.91 percent organic matter at a depth of 0 - 30 cm and 1.86 percent at a depth of 30 - 60 cm. Even in such a high-organic-matter soil, it was found that adding phosphorus enhanced seed yield, at the treatment of 90 kg ha^{-1} P_2O_5 having a statistically significant superiority, suggesting the need to add this macronutrient to micro-sperm beans growth. There was no difference in the protein content of the bean seeds across the different phosphate fertilization levels, while the protein content was found to be around 26% in all cases.

Introduction

The *Fabaceae* family is one of the largest and most diverse families. Soybeans, beans and lentils are examples of legumes that are commonly consumed by humans and used as animal feed. The fava bean (*Vicia faba*), commonly known as field bean, is one of the oldest and most popular cultivated plants on the planet. It has the highest yielding potential of all *Fabaceae* crops, and it is a particularly ideal high-protein component for the preparation of concentrates, as it contains around 28–30% total protein of high biological value in its seeds (Mekky et al., 2020) and traditionally used as a main source of protein for human and animal nutrition (Vioque et al., 2012; Multari et al., 2015). It can resist bending and hence receives mechanical assistance at all stages of development.

The proportion of fertile land on which grain legumes are cultivated has decreased to 1.5 percent over the last 50 years because of agricultural intensification, primarily for economic reasons (Watson et al., 2017). Of course, due to the environmental and long-term economic benefits of integrating legumes into European cultivation systems, it is now advocated that they be reintroduced into cultivation systems (Reckling et al., 2016), particularly in a decreased influx regime (Nemecek et al., 2008).

Vicia faba can be grown after sorghum and maize crops, taking advantage of the available water remaining in areas where water is not a problem, or precede dry crops (eg. wheat) when water is not available. They can be sown early in winter but also in spring, providing flexibility depending on climatic conditions, soil type and cultivation systems in which they are included (Jensen *et al*., 2010).
They are frequently sown in the winter in locations with mild winter temperatures and heavy clay soils that are difficult to cultivate in the spring, while they can be sown in the early spring in areas with light soils and considerable rainfall. Varieties that are sown in the fall mature faster than those that are sown in the winter.
Creating a healthy symbiotic relationship between bean plants and soil root bacteria is difficult to predict because it is dependent on a variety of environmental factors and growing strategies (Jensen *et al*., 2010). Bean crops bind 290,000 t N of atmospheric nitrogen each year, compared to 22 million t N binded by all other legumes, including soybeans (Herridge *et al*., 2008).
Phosphorous (P) is essential for nodulation, biological nitrogen fixation, photosynthesis, and the nutritional value of legumes like the faba bean (Haling et al., 2016, Makoudi et al., 2018). In P-limited soils, P fertilizer often results in enhanced yield and biomass of faba beans, indicating that P fertilizer is necessary for grain production in faba beans (Nebiyu et al., 2016).
As it has been already mentioned, faba bean is an important source of plant protein for human and animal consumption and can be harvested as dried seeds (Crépon et al., 2010, Singh et al., 2013). It's been suggested that in order to get a bigger seed production, you'll need more biomass accumulation. (Mortimer et al., 2012), while Kubure et al. (2016) reported that faba bean has a strong positive association between seed yield and biomass production. However, because the faba bean is a cool-season grain legume that is susceptible to high temperatures, poor moisture availability, and days to blooming (L'opez-Bellido et al., 2005), earlier maturity may be advantageous for providing the best yield. Seed yields range significantly because to significant variability in faba bean seed size (Etemadi et al., 2017) and a lack of acceptable population density.
Therefore, the aim of the current study was to test the effect of different P-fertilization to the seed yield and its seed protein content in a clayey and fertile soil.

Materials and Methods

The experimental site is within the experimental farm of the University of Thessaly, located in the vicinity of Velestino village, Prefecture of Magnesia (coordinates: latitude 39^{o}24'50.95''N, longitude 22^{o}44'0.79''E, altitude 78m ASL).
A field experiment using a complete randomized design (RCB) with four P-levels in four repetitions (a total of 16 plots) was used. The treatments used were various amounts of phosphate fertilization, with F1 being a control by no fertilization, F2 being phosphate fertilization of 30 kg ha^{-1} P_5O_2, and F3, F4 being 60 and 90 kg ha^{-1} P_2O_5, respectively.
The phosphate fertilizer was manually scattered in the separate treatments after excavating the experimental field, followed by the application of the stomp herbicide and their integration by a rotary cultivator. A quantity of 140 kg ha^{-1} seeds of the "Polykarpi" variety was used. A grain sowing machine was used to sow the seeds on November 21, 2018.
The soil of the experimental area is characterized as a clayey soil with an alkaline reaction. It is particularly fertile with a percentage of organic matter of 2.91% at a depth of 0-30 cm and 1.86% at 30-60 cm. This is initially an indication of mineralization of a higher percentage of organic nitrogen compared to the average of Greek soils.

Seed protein content was determined in crushed plant sub-samples of each sample by near-infrared reflectance (NIR) spectroscopy technique using the DA 7250 NIR analyzer (Perten Instruments, Hägersten, Sweden).
Complete weather data were recorded by an automated meteorological station, which was installed next to the experimental field.
Finally, the analysis of variance (ANOVA) within sample timings for all measured and derived data was conducted using the statistical package GenStat (7th Edition). The $LSD_{0.05}$ was used as the test criterion for assessing differences between means (Steel and Torrie, 1982) of the main and/or interaction effects.

Results and Discussion

Climatic data

Low temperatures have prevailed for the season since the sowing (9/21/2018), causing germination to be delayed (Fig. 1). Normal temperatures with few changes occurred for the region from the end of January 2019 onwards.
In terms of precipitation, a deficit of roughly 50 mm was recorded from sowing to April 2019, compared to the usual climate of the larger area, with 30 mm in March, which is the season of intense plant growth. As a result, their growth was seen to be slowed. Fortunately, the rains that fell in the first few days of April helped to make up for the shortfall and boosted plant growth.

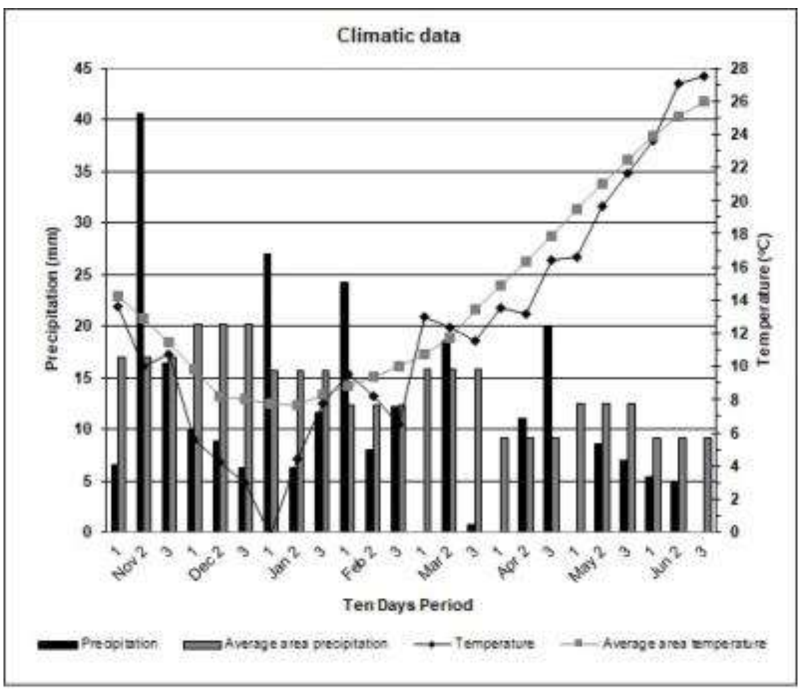

Figure 1. Average air temperature and precipitation occurred during *Vicia faba* cultivation.

Seed yield and quality characteristics

The addition of phosphorus to the field beans appears to have enhanced seed output. Although the addition of 30 and 60 kg P_2O_5 per ha resulted in simply a numerical benefit in yield, the addition of 90 kg P_2O_5 per hectare resulted in a statistically significant advantage, illustrating the

importance of include this macronutrient in legume agriculture (Table 1). Specifically, the yield achieved in control treatments was 2790 kg ha^{-1} which is almost 800 kg ha^{-1} lower compared to the recorded yield in the high p-fertilization treatments (3580 kg ha^{-1}, Table 1).
The reached seed yield is in line with that reported in literature which ranges from 3000 kg ha^{-1} to 5000 kg ha^{-1} under favorable conditions (Kowalczyk et al., 2021) and extremely lower than the recorded yields in Poland (Łabuda, 2012). The average dry yield faba bean var. minor varieties in 2016 was 0.9 t ha^{-1} (FAOSTAT 2016). Faba bean seed yields are highly variable between countries due to many factors (climate, soil, etc.). Narits (2018) reported that the highest seed yield is obtained with varieties which had the longest growing period, while late varieties did not mature and there is a high yield loss due to the small immature seeds.
Maybe higher precipitation concomitant with lower temperatures during the growing season could elevate the harvested yield because faba bean is regarded as a drought-sensitive crop, where water stress decreases the final leaf area and the light use efficiency (Ghassemi-Golezani et al., 2009) and N_2 fixation (Neugschwandtner et al., 2015).

Table 1. Seed yield (kg ha^{-1}) protein content (%).

Treatments \ Measures		Seed Yield (kg ha^{-1})	Protein Content (%)
P_2O_5 (kg ha^{-1})	**0**	2790	26,1
	30	3210	25,7
	60	3250	26,2
	90	3580	25,7
$LSD_{.05}$		596	ns
CV (%)		11,6	1,7

In terms of protein content, there was no difference between the different amounts of phosphate fertilization in terms of seed content, which was around 26% in all cases. The concentration found above is lower than the protein level described in the literature, which is higher than 28% (Iqbal et al., 2006; Rempel et al., 2019; Kowalczyk et al., 2021; Sharan et al., 2021). Furthermore, Vioque et al., (2012) reported that protein content of faba bean ranges from 27% to 34% of dry weight (depending on the variety and growing conditions).

Conclusions

The *Vicia fava* var minor (fodder bean) cultivation seems to lead to satisfactory seed yields. The addition of ninety kg of phosphorus (P_2O_5) increased seed yield by a statistically significant amount without changing seed protein content.

Abstract

Peanuts are grown commercially in several Greek regions such as Messinia and Serres. The total cropping area in Greece is around 4500 hectares. However, many farmers have started to grow peanuts at the region of Thessaly and especially at the area of Trikala where the soil texture is medium. Because of the high farmers' interest in growing peanuts in Greece, an experiment carried out at the research farm of the University of Thessaly in Larissa to study peanut response to planting patterns and row spacing. The experiment included four different treatments of planting patterns and row spacing and three replicates of each treatment. Specifically, at the first treatment (control), peanuts were planted 75 cm apart along the rows. At the second treatment, there were twin rows 10 cm apart and the planting spacing was 75 cm along the rows. At the third treatment, there were four rows 50 cm apart and the planting spacing was 75 cm along the rows while at the fourth treatment, peanuts were planted on beds with planting spacing 75 cm along the beds. Peanuts grew in experimental plots of 5 m long, 3 m wide and 1 m apart. The results showed that the yields of the second and fourth treatment were significantly higher by 41.8% and 37% respectively than the yield of the controller. The yield of the third treatment was also higher (no significantly) by 11.2% than the controller. All the above indicate that the use of twin rows of peanuts increases peanut yield because of the use of the double number of seeds compared to the control treatment. However, planting peanuts on beds seems to be an inexpensive solution considering the loamy sand soil type of the peanut plots.

Keywords: beds, twin rows, yield, soil properties, evapotranspiration, fertilizers.

Introduction

Peanut (*Arachis hypogaea* L.) is an important oil seed crop and grown in light, sandy loam soil with a pH of 5.9-7. There are numerous advantages to crop rotation, including weed control, improved soil fertility as well as yield increase. For example, peanuts in a three-year rotation with corn, yielded 50% higher than no rotated peanuts (Baughman et al., 2005). Peanuts can be produced at areas where the annual rainfall varies from 500 mm to 1200 mm and daily average temperature is higher than 20 ^{o}C. (Arioglu et al., 2013; Arioglu, 2014).
Planting density and row pattern play an important role on peanut growth, yield and quality. Thus, the response of peanut to plant density and planting patterns has investigated several years ago. Almost sixty years ago, some experiments resulted that maximum yield could be achieved if plants produce enough leaf area to provide maximum light reception during reproductive growth (Shibles et al., 1966; Tanner and Hume, 1978). Pendleton and Hartwing (1973) resulted that space between plants could affect interplant competition. Duke and Alexander (1964) reported

pod yield that was 14% higher in narrow row plantings compared with traditional wider rows. Norden and Lipscomb (1974) concluded that pod yield was 16% higher when peanut was seeded in rows spaced 46 cm apart compared with 91cm. These results confirmed Perham (1942) who demonstrated that peanuts planted in 46 cm rows yielded higher than those planted in rows spaced 61, 76, 91 or 107 cm apart. On the other hand, Kaushik and Chaubey (2000), noticed that pod yield of 30 cm inter-row spacing was significantly higher than the yield of 45 cm inter-row spacing. Wright and Bell (1992) reported that the ideal peanut plant density was 11-14 plants m^2. Baldwin et al. (1999) demonstrated that peanuts planted in twin-row spacing could produce 381 kg ha^{-1} more than the peanuts in conventional row pattern.
Planting peanuts in twin rows or in beds is a new practice in Greece while the literature does not provide much information on this topic. The objective of this study was to demonstrate the peanut response to different planting patterns and row spacing.

Materials and Methods

This study was conducted at the University of Thessaly research farm in 2019 in Larissa, Greece (Latitude: 39.6246^o, Longitude: 22.380). Peanuts were planted on 18th of May 2019 in plots in plant density of 50 kg/ha. The size of the plots was 5 m long and 3 m wide and the plots were separated with alleys of 1 m wide (Figure 1). Soil analysis showed that the soil type of the plots at the peanut root zone was sandy loam (SL) and sandy clay loam (SCL). More information for the soil profile characteristics is provided at table 1.

Figure 1. Peanut plots at the University of Thessaly research farm

Table 1. Soil texture, pH, $CaCO_3$ and organic material for different depths to understand better the characteristics of the soil profile.

Depth (cm)	Sand (%)	Silt (%)	Clay (%)	Soil Type*	pH (H2O 1:1)	CaCO3 (BERNARD) (%)	Organic Material (%)

*LS: Loamy Sand, SL: Sandy Loam, SCL: Sandy Clay Loam

The experiment included four different treatments of planting patterns and row spacing and three replicates of each treatment. Specifically, at the first treatment (control), peanuts were planted 75 cm apart along the rows. At the second treatment, there were twin rows 10 cm apart and the planting spacing was 75 cm along the rows. At the third treatment, there were four rows 50 cm apart and the planting spacing was 75 cm along the rows while at the fourth treatment, peanuts were planted on beds with planting spacing 75 cm along the beds.

Irrigation scheduling

Overhead sprinklers utilized to irrigate each plot. The irrigation scheduling method was based on the crop evapotranspiration (ETc). ETc is calculated with Equation 1 (Allen et al., 1998).

ETc = ETo * Kc (Eq. 1)

Where: ETo is reference evapotranspiration

Kc is crop coefficient

A meteorological station was installed next to the plots to acquire accurate ETo data. Kc data were obtained from other experiments that conducted in the same region in the past. Kc values for peanuts are presented at table 2.

Table 2. Duration (in days) and crop evapotranspiration for each growth stage of peanuts (Allen et al., 1998). The total amount of irrigation used in 2019 growing season was 527.97 mm while precipitation was 73.6 mm.

Growth Stage	1	2	3	4	Total
Duration of each stage (days)	20	35	51	30	136
ET_c (mm)	36,14	233,30	287,55	44,00	601,57

Fertilizer scheduling

Fertilizers were applied by hand uniformly at each plot during the growing season. The first fertilizer application took place on 14th of May 2019 when fertilizers (12-11-18) applied at a rate of 300 kg ha^{-1}. At the second application that occurred on 19th of June 2019 nitrogen (46-0-0) was applied at the rate of 108.6 kg ha^{-1}. Finally, nitrogen (15.5-0-0) applied at the rate of 55 kg ha^{-1} on 7th of August 2019.

Harvest of peanuts

Peanuts were harvested on 30th of September 2019 and the total yield of each plot was weighted manually using a digital scale and big bags.

Results and Discussion

Yield results showed that every treatment gave higher yield than the average peanut yield in the region of Thessaly (~3000 kg ha^{-1}). However, statistical analysis of yield data proved that there were significant differences in yield among the treatments. Specifically, the yield of the control treatment was 2940 kg ha^{-1} and it was significantly lower than the yields of the other treatments. The maximum yield (5047 kg ha^{-1}) was recorded at the treatment with the twin rows of planting pattern. This yield was 41.8% higher the yield of the control. This is similar to (Shibles et al., 1966; Tanner and Hume, 1978) findings who found that the more canopy the higher light perception and consequently the higher peanut yield. The second higher yield (4657 kg ha^{-1}) was achieved at the treatment where peanuts planted on beds and it was 37% higher than the control. Finally, the treatment with four rows as planting pattern gave 3310 kg ha^{-1} and it was 11.2% higher than the yield of the control (Figure 3). The ability of peanuts to adapt to different situations, wide or narrow planting patterns and high seeding rates may be one of the factors that peanuts become famous in Greece.

Even if the current experiment lasted only one growing season, the planting pattern of peanuts and the row spacing played an important role in the productivity of peanuts. However, more experiments should be conducted to confirm the results. Thus, the future plan is to continue the experiment in big commercial peanut fields and record more details such as harvest quality (how many pods stays in the ground after harvest) and soil apparent electrical conductivity.

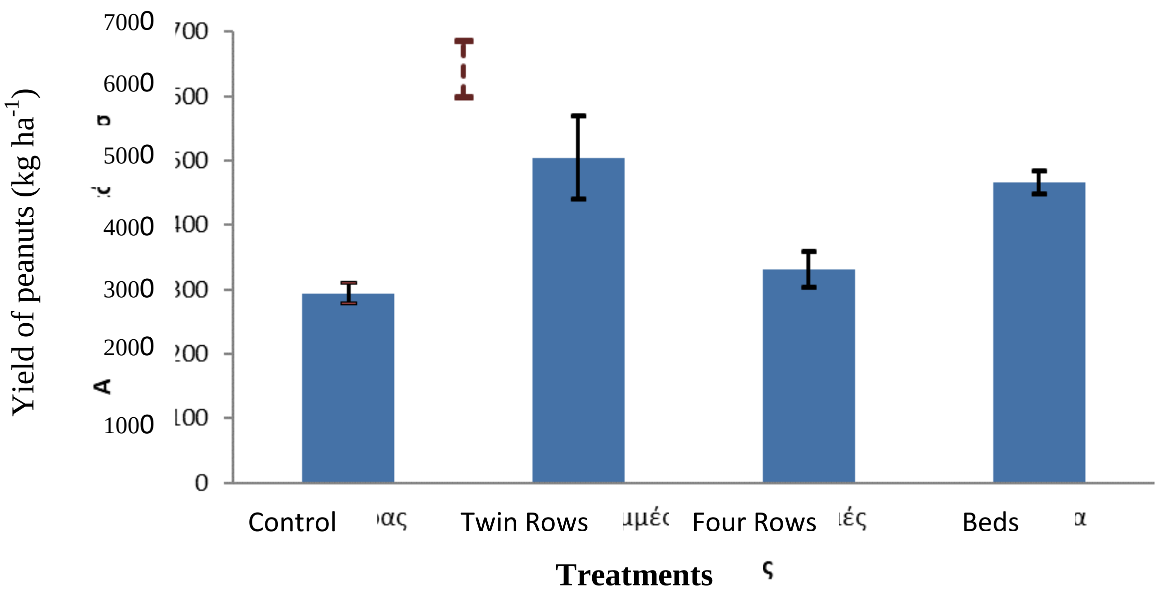

Figure 2. Statistical analysis of yield for each treatment. It is obvious that the control treatment had the significant lowest yield compared to the other treatments of the experiment. On the other hand, the twin rows planting pattern gave the highest peanut yield.

Conclusions

At the current experiment, peanuts were planted in plots. Inputs such as irrigation and fertilizers applied uniformly in every plot. The only difference among the plots is that peanuts were planted in different planting patterns and row spacing to study the peanut response. The results showed that there were significant differences in yield among the different planting patterns and the highest yield was recorded at the treatment where peanut planted in twin rows. Besides the fact that this is one-year study, these results are very valuable for peanut farmer because they can increase yield by changing only the planting pattern.

Abstract

Since the global approach to the production of medicinal plants is effective in improving the quantity and quality of the material, it seems that the nutrition of these plants through the use of biological fertilizers in different environmental conditions is most in line with the production goals of medicinal plants. Therefore, in order to investigate the effect of biofertilizers and non-biofertilizers on biological yield, flowering branches and thyme essential oil (*Thymus vulgaris* L.), an experiment in a randomized complete block design with 4 replications in a farm in central Yazd, Iran in the crop year 2019 was done. Biofertilizers and non-biofertilizers in five levels including: Control (without fertilizer application), Endomycorrhiza fungi of the genus Glomus (*Glomus mosseae*, *G. intraradics*, *G. etunicatum*), *Azospirillum brasilense*, *Pseudomonas fluorescens* and NPK , were considered as experimental factors. The results of analysis of variance showed that fertilizer treatment had a significant effect on biological yield, flowering branches and thyme essential oil. Mycorrhiza had the greatest effect on biological yield (163%), yield of flowering branches (105%) and essential oil yield (87%) compared to the control. Therefore, the use of biofertilizers, especially mycorrhiza fertilizer, which can greatly increase the yield and amount of active ingredient, is recommended in this plant.

Keywords: *Mycorrhiza, Yield, Essential oil, Thyme.*

Introduction

Thyme (*Thymus vulgaris* L.) is an aromatic and medicinal plant of the Lamiaceae family that has strong antimicrobial, antifungal and antioxidant effects in different parts of the world as a drink, food flavoring and herbal medicine. It has many uses and is very popular due to its high efficiency of essential oil (Safaei-Ghomi et al.,2009).This plant has small flowers, purple color and small seeds with different color variation.The color of the seeds is mostly dark brown (Omidbaigi,2005). Thyme contains 0.8 to 2.6% of essential oil (Imelouane et 2009; Golparvar & Bahari, 2011). Biofertilizers are widely used nowadays to increase crop yields and have largely replaced chemical fertilizers (Afzal & Bano, 2008). These fertilizers not only provide the necessary elements for the plant, but also improve the soil conditions and create a favorable microbial population in the soil (Yadegari, *et al.*, 2010). In order to understand the concepts of sustainable agriculture and create a safe production, as well as a new approach in the use of medicinal plants and fortunately the promotion of biofertilizers on the other hand, it is necessary to combine the two and introduce the best fertilizer composition to help farmers increase production.

Materials and Methods

Time, geographical location and location of the test

This experiment was performed in the 2019 crop year on a farm in the central part of Yazd city, Iran (Longitude 51° 17', Latitude 31° 53', Height 1230.2 m).

Soil characteristics of the test site

Before performing the experiment and preparing the ground to determine the texture as well as some physical and chemical properties of the soil, samples were taken from a depth of 0 to 30 cm and sent to the laboratory for analysis. The typical soil of the area was sandy- loam, which is very good soil for planting thyme.

Table 1. Analysis of soil texture and physical and chemicals characteristics of sample soil**.**

Soil Texture	EC ($dS.m^{-1}$)	(pH)	Sand (%)	Clay (%)	Loam (%)	OC (%)	K (ppm)	P (ppm)	N (%)
Sandy loam	2.05	7.66	75	10	15	0.339	19.08	14.8	0.029

Experimental design specifications and test factors

This experiment was performed as a randomized complete block design with three replications. Experimental factor includes biological and non-biological fertilizers as B_1 = control (without fertilizer application), B_2 = endo-mycorrhizal fungi of three species of the genus Glomus (Glomus mosseae, G.intraradices, G.etunicatum) (in the form of sand inoculum which contained at least 100 active organs fungi, 150 g per plant (used according to the manufacturer's recommendation), B_3 =Azospirillum (Azospirillum brasilense), B_4= Pseudomonas (fluorscens Pseudomonas) (Pseudomonas and Azospirillum were used to immerse the plant roots in them, so that according to the manufacturer's recommendation, 200 g of each The bacteria were dissolved in 10 liters of water and then the roots were immersed in the solution for 15 minutes, then cultured) and B5 = chemical fertilizer NPK (20, 20, 20) (which was 20% of each element(Nitrogen, phosphorus, potassium) in this fertilizer and was used as a granule at a rate of 200 kg per hectare).

Planting and fertilizing

At first, the plant was prepared as a seedling in the greenhouse. After preparing the suitable substrate, blocking and preparing the plots and in the 11-leaves stage, the seedlings were transferred to the field. The subplots had dimensions of 4 meters in length and 3.5 meters in width. Each experimental unit consisted of 4 planting rows with a spacing of 70 cm between rows and 50 cm on the row. After transplanting, the first irrigation in the field was done by flood. Due to the fact that the area had a hot and dry climate, but when the plants were fully established (14-15 leaves), drip irrigation was done once a week with the same volume of irrigation water for all treatments (the same volume of water was used with the contractor). so that the humidity and the amount of water is the same for all treatments. At the flowering stage, the plants were harvested.

Sampling to measure biological yield and flowering branches yield
Sampling was done at the time of full flowering. The plants were harvested and after drying in an oven at 72 ° C for 48 hours, the dry weight of each sample was measured. Flowering branches were also separated from the plants and after drying, they were weighed with an accurate balance and finally the obtained values were calculated in terms of grams per plant.

Essential oil yield measurement
The essential oil was taken from the flowering branches of the plant. In this way, after harvesting and drying the flowering branches, first the mill and then the weight and finally the essential oil extraction operation was done. Essential oil extraction was performed in the laboratory using water distillation by an essential oil extractor (Clevenger). Water distillation is used to separate water-insoluble substances (such as essential oils). Using this method, it is easy to extract essential oils from the desired plants. Finally, the extracted essential oil was poured into small glass containers (previously weighed and the empty weight of the glass was noted and had a strong plastic lid) and weighed with an electric scale. The weight of essential oil was recorded in grams and calculated as a percentage. Finally, the yield of essential oil was obtained by multiplying the yield of flowering branches by the percentage of essential oil.

Data analysis
Finally, the obtained data were statistically analyzed using SAS statistical software (V9.4) and combined analysis of experimental years was performed. Excel¬ software was used to draw the graphs. The means were compared using LSD test at 5% probability level.

Results and Discussion

Biological yield

The results of analysis of variance show a significant effect of fertilizer treatment on biological yield (P <0.01) (Table 2).

Table 2. Analysis of variance of biological and flowering branches yield and essential oil yield in treated Thymus plant with bio and non-bio fertilizers.

		Mean Square		
Source of Variance	df	Biological yield	Flowering Branches yield	Essential oil yield
Repetition(R)	2	297.65 ^{ns}	2.57 ^{ns}	0.39 ^{ns}
Fertilizers (B)	4	49824.39**	138.90 **	9.86 **
Error	8	276.12	2.13	0.14
C.V. (%)		4.85	5.54	5.49

ns, *, **: non-significantly difference and significantly differences at 5 and 1% of probability levels, respectively.

The comparison chart of the mean data showed that mycorrhiza was 163% more effective compared with the control. The highest biological yield (466.83 g /plant) was observed in mycorrhiza (Glomus) and the lowest in control (Figure 1). Regarding the positive effect of application of fungal treatments on biological yield, it can be stated that mycorrhizal fungus through hyphae expansion and root system development, provides more water uptake for the plant and after absorbing more water, more nutrients are absorbed. They lead to the production and accumulation of more dry matter in the plant (Auge, 2001; Casson and Lindsey, 2003). The positive effect of mycorrhiza fungi on increasing the biological performance of various plants including flax, wheat and sorghum has been reported by many researchers (Ansari et al., 2014; Hagh Bahari and Seyed Sharifi, 2014; Hamzei and Sadeghi Meabadi, 2014).

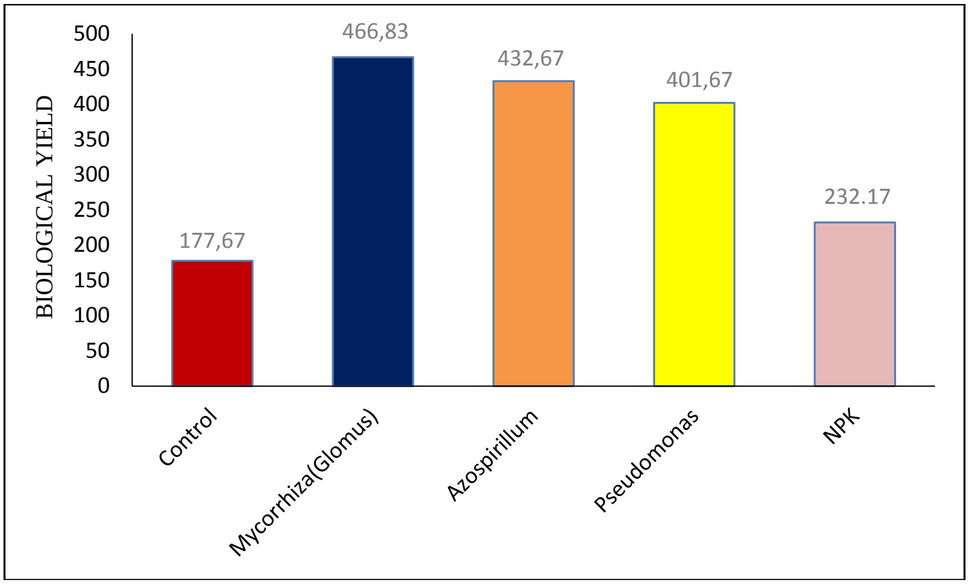

Figure1.The change of biological yield in treated Thymus plant with bio and non-bio fertilizers (Columns with at least one common letter have no statistically significant difference based on LSD test at 5% probability level).

Flowering branches yield

The results of analysis of variance showed that the effect of fertilizer on the flowering branches yield was significant ($P < 0.01$) (Table 2). Comparison of the mean effect of fertilizer on the yield of flowering branches showed that mycorrhiza fertilizer was 105% more effective than the control. The highest yield of flowering branches (36.53 g / plant) was observed in mycorrhiza (Glomus) and the lowest in control (Figure 2). Bacteria in biofertilizers in addition to absorbing the main elements of high consumption and low consumption required by the plant by making and secreting plant growth stimulants as well as the secretion of various amino acids and antibiotics cause root growth and development, aerial destruction and flowering branches (Han and Lee, 2006; Gutierrez-Manero et al., 2001). Khorramdel et al (2008), Observed that the application of mycorrhiza inoculum increased the accumulation of dry matter and flowering branches of black seed compared to the control.

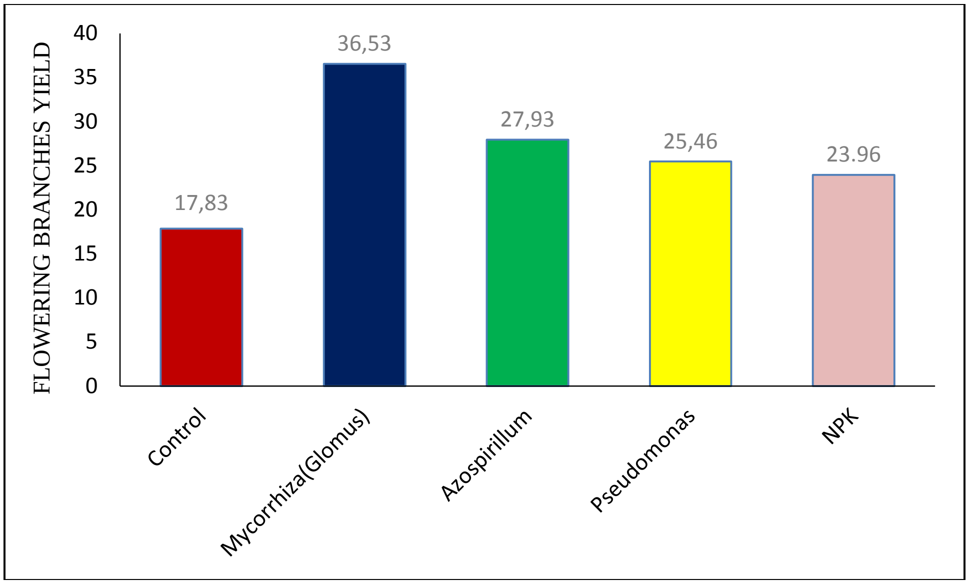

Figure2.The change of flowering branches yield in treated Thymus plant with bio and non-bio fertilizers (Columns with at least one common letter have no statistically significant difference based on LSD test at 5% probability level).

Essential oil yield

The results of analysis of variance showed that fertilizer treatment had a significant effect on essential oil yield (P <0.01) (Table 2). Comparison of mean data showed that mycorrhiza fertilizer was 87% more effective on essential oil yield than the control. The highest yield of essential oil (9.22 g / plant) was observed in mycorrhiza (Glomus) and the lowest in the control treatment (Figure 3).

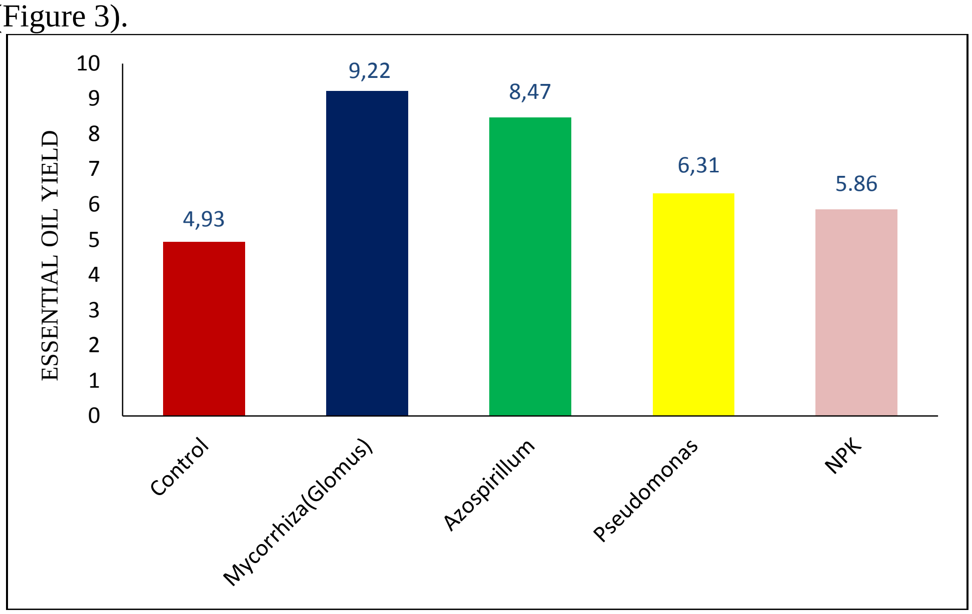

Figure3. The change of essential oil yield in treated Thymus plant with bio and non-bio fertilizers (Columns with at least one common letter have no statistically significant difference based on LSD test at 5% probability level).

Conclusions

Since the ultimate goal of cultivating medicinal plants is to use the essential oils and active ingredients in the essential oils of these plants, and certainly the higher the amount of these effective substances per unit weight of the plant, the greater the economic benefit, Therefore, studying and obtaining the best conditions of the culture environment that can lead to plant production with the highest essential oil yield is one of the most important goals in research related to the cultivation of medicinal plants. According to the results of this study, it is concluded that mycorrhiza biofertilizer has had the greatest impact on biological performance and flowering branches and essential oils of thyme. Therefore, this bioferilizer is recommended to increase the biological yield and essential oil and active ingredient of thyme.

Abstract

The objective of this study was to apply the three-dimensional plots of stress selection indices to screen tolerant genotypes of durum wheat. Fourteen genotypes were grown under both drought stress and potential conditions using a randomized complete block design with four replicates. Eight drought tolerance indices were used as well as yield performance under potential (YP) and stress (YS) conditions for drawing three-dimensional plots. Genotypes G1, G4, G5, G6, and G13 were found the most favorable genotypes according to YP, YS and SSI, while genotypes G3 and G8 displayed the highest performance based on STI. Using modified STI indices, K_1STI and K_2STI did not alter pervious results and produced similar findings. The three-dimensional plots based on average statistics (MP, GMP and HM) as well as YP and YS identified G3 and G8 as the best genotypes, while according to TOL, genotypes G3 and G4 were selected as the most favorable genotypes. Although genotypes performed differently in potential (YP) and stress (YS) conditions, which justifies screening them for both conditions simultaneously, we could find some genotypes which responded good in both conditions like genotypes G3 and G4. Therefore, most of studied indices could discriminate drought tolerant genotypes with high yield using the three-dimensional plots.

Keywords: *the three-dimensional plots, graphic analysis, tolerance indices.*

Introduction

Drought stress may lead to a loss in yield; particularly severe deficit at anthesis stage has serious effects on durum wheat yield, which is the main concern of durum wheat breeders and they emphasize on yield performance under drought stress conditions. Breeding for tolerance to drought stress is complicated by the lack of proper screening methods and the inability to create repeatable water drought conditions where large populations can be evaluated efficiently. To differentiate tolerant genotypes, several indices have been suggested on the basis of a relationship between non-stress and stress conditions which are providing a measure of drought based on loss of yield under drought stress conditions in comparison to non-stress conditions. Fischer and Maurer (1978) proposed the stress susceptibility index, and Rosielle and Hamblin (1981) defined stress tolerance and mean productivity for evaluation of genotypes for drought tolerance. Fernandez (1992) also has been suggested stress tolerance index, geometric mean productivity and harmonic mean for screening breeding materials for stress.

The best index must detect genotypes perform uniform superiority in both stress and non-stress conditions from the genotypes that are favorable only in one condition. Among the different stress tolerance indices, selection based on stress susceptibility index and stress tolerance criteria favors genotypes with low yield potential under non-stress condition and high yield under stress condition and selection based on these indices will be resulted in genotypes with higher stress tolerance and yield potential will be selected. The objectives of this study were to identify tolerant genotype as well as determine the efficiency of screening indices to grouping genotypes into tolerant versus sensitive genotypes.

Materials and methods

14 durum wheat genotypes were studied under dry-land condition in growing season 2012-2013. The experiments were conducted a randomized complete block design with four replicates under non-stress and stress conditions. Each plot was 5 × 6 m, rows with a 20 cm row space and total plot size was 6 m^2 and Plants were fertilized with nitrogen at the rate of 50 kg ha^{-1} urea and phosphorus at the rate of 120 kg ha^{-1} ammonium phosphate and proper agronomic management practices were adopted throughout the growing season to ensure good crop growth. Various drought tolerance indices were calculated as; the stress susceptibility index (SSI) of Fischer and Maurer (1978); the mean productivity (MP) and tolerance (TOL) of Rosielle and Hamblin (1981); the stress tolerance index (STI), geometric mean productivity (GMP) and harmonic mean (HM) of Fernandez (1992); the STI-based indices consist on K_1STI and K_2STI (Naderi *et al*., 1999).

Results and discussion

According to the three-dimensional plot SSI (Fig. 1), four zones, A, B, C and D were identified as A, genotypes with high yield performance in both potential (YP) and stress (YS) conditions; B, genotypes with high yield performance in potential (YP) condition and low yield performance in stress (YS) condition; C, genotypes with low yield performance in potential (YP) condition and high yield performance in stress (YS) condition; and D, genotypes with low yield performance in both potential (YP) and stress (YS) conditions. In each of these conditions, the high values of SSI greater than average can be favorable and thus, genotypes G3 and G8 had the best performance following to G1, G6, G13 and G14. However, genotype G10 was located in this zone with low SSI values and this index could not detect these genotypes as most favorable ones. Genotypes G4, G9 and G12 were located in zone B while only G4 had high SSI values and was identified as the most favorable genotype based on SSI. There is not ant genotype in zone C, and so none of the studied genotypes show high performance only in stress condition. Genotypes G2, G5 and G7 were located in zone D and none of them had high SSI values and was identified as the as worst genotypes.

The pattern of response in STI, K_1STI and K_2STI was similar (Fig. 1), and introduced genotypes G3 and G8 as the most favorable genotypes in zone A. Mevlut and Sait (2011) showed that genotypes with high STI values usually have high difference in yield in two different humidity conditions and also, Ilker *et al*. (2011) and Sabaghnia and Janmohammadi (2014) reported that STI-related indices (K_1STI and K_2STI) are convenient parameters for selecting high yielding genotypes in both stress and non-stress environments whereas relative decrease is observed in yield performance.

The four zones in the three-dimensional plot baes on central tendency indices, MP, GMP and HM as well as TOL were relativity similar and detected introduced genotypes G3 and G8 as the

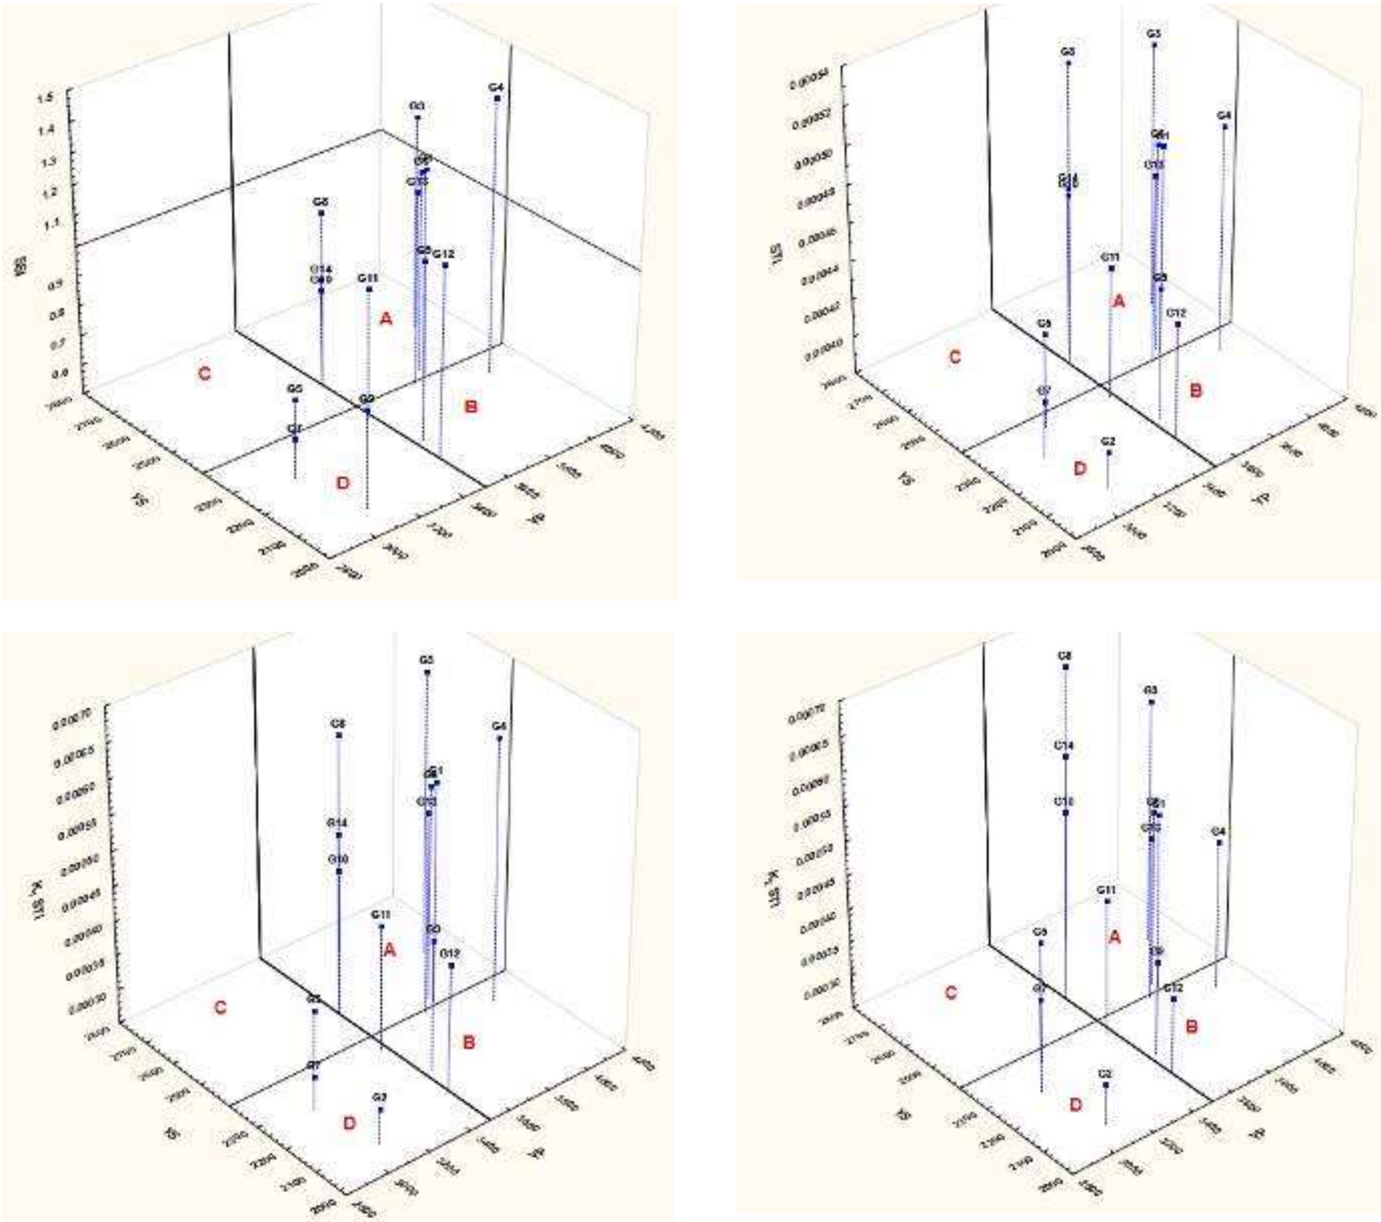

Fig. 1. The three-dimensional plots of YP, YS and drought selection indices (up-left) SSI, (up-right) STI, (down-left) K1STI and (down-right) K2STI.

most favorable genotypes in zone A and these results were in agreement with SSI, STI, K_1STI and K_2STI results which indicates high associations among them.

Similar interrelationships among MP, and GMP indices (Toorchi *et al*., 2012) and among GMP, MP and STI indices (Dehghani *et al*., 2009) were reported. Also, positive correlation of STI, GMP and HM were reported by Sabaghnia and Janmohammadi (2014). In general, the observed relationships in our dataset were consistent with those reported by Khalili *et al*. (2012). Some studies showed that GMP and STI indices are preferred in late drought condition for selecting the most favorable genotypes (Akcura *et al*., 2011) while some other investigation indicated that MP are preferred for selecting the most tolerant genotypes (Sio-Se Mardeh *et al*., 2006; Khalili *et al*., 2012). Relatively, such similar conclusion is reported by Fernandez (1992), and Sabaghnia and

Janmohammadi (2014), which mentioned that priority of STI and K_2STI parameters under level of high to moderate stress. Akcura *et al*. (2011) reported STI was able to differentiate genotypes belong to genotypes with high yield performance in both conditions, from the others. The genotypes G3 and G8 were found to be the best genotypes and advised for future cultivation in semi-arid regions.

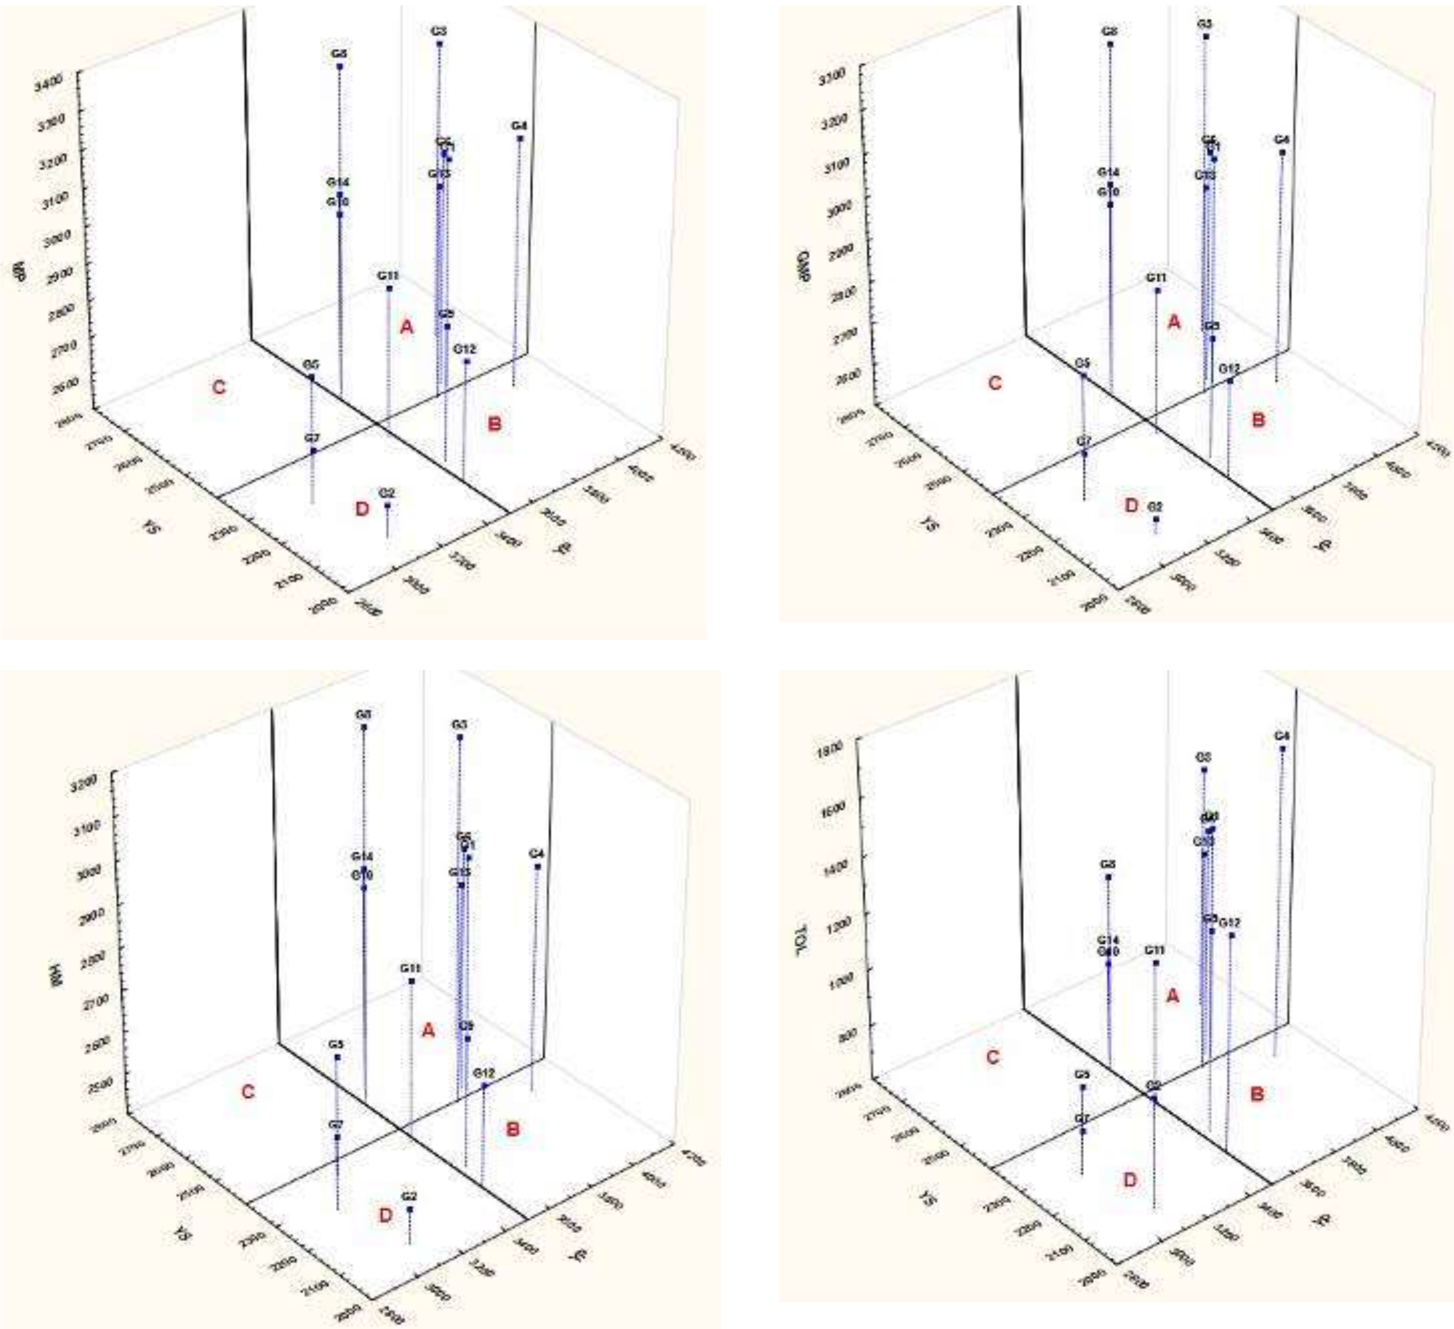

Fig. 2. The three-dimensional plots of YP, YS and drought selection indices (up-left) MP, (up-right) GMP, (down-left) HM and (down-right) TOL.

Conclusion

The GMP and STI indices are found to be best tools in drought condition for selecting the most favorable genotypes and the genotypes G3 and G8 were found to be the best tolerant genotypes in semi-arid conditions.

Abstract

Plums have been known as one of the most diverse fruits in temperate regions, although their variation and diversity also cause differences in the physicochemical features of the fruit. Therefore, the aim of this study is to introduce and investigate the physicochemical and pomological traits of these cultivars. The present study was conducted to investigate the physicochemical properties of 7 Iranian plum. Plum cultivars with the usual names included: 'Ghatretala', 'Pivehzhan', 'Rotaby', 'Ghandy', 'Beygom', 'Torghabeh Sabz' and 'Bokhara'. Analysis of variance demonstrated that all cultivars had significant differences ($p \leq 0.01$) for all measurement parameters of chemical and physical features. The results also showed that in most of the chemical features studied, cultivars 'Beygom' and 'Torghabeh Sabz' were superior to other cultivars and had the highest amount of chemical compounds. The results also showed that there was a high amount of compounds such as antioxidants, flavonoids and vitamin C in the cultivars. Therefore, it can be said that some of the cultivars investigated in this study were rich in bioactive compounds and had high nutritive values.

Keywords: *Antioxidant Capacity, flavonoids, Vitamin C, Physical properties.*

Introduction

Plums belong to the family Rosaceae, subfamily Prunoideae and genus Prunus. Plum is one of the most diverse fruits that grows in a wide range of climatic and geographical conditions. This product is native to Europe and Asia (Karimifar et al., 2012). Some plum cultivars such as Ghandy', 'Black', 'Bokhara', 'Shams' and 'Ghatretala' are native species from Prunus domestica L. The highest provinces of plum production were Khorasan Razavi, Alborz, Golestan and Azarbayejan Gharbi in Iran, respectively (Falati et al., 2018). Plums contain carbohydrates (sucrose, glucose, fructose), organic acids (citric and malic acid), fibers, tannins and aromatic compounds that determine the nutritional value and taste of plums (Arion et al., 2014). It is also a good source of carotene, anthocyanins and natural antioxidants (Kim et al., 2003). Jalili et al. (2011) conducted an experiment on 38 genotypes of Iranian plums and reported that the soluble solids content in plum genotypes was in the range of 16 to 31 ° Brix. The amount of titratable acids in different plum genotypes varied from 0.4 to 0.94. According to Vangdal (1980) studies, the acceptance of plums with a soluble solids content of less than 12 ° Brix is very low for most consumers. The better taste of plum fruit and its greater acceptance depend on less titratable acidity and higher soluble solids content (more than 12%) of the fruit. The quality of fruit plums is also related to external characteristics, such as the size and color of the pulp and skin, which are associated with chemical composition (Yousefi and Emam-Djomeh, 2015).

Material and Methods

Plant material

This research was conducted in Ferdowsi University of Mashhad (Iran) in 2019. Seven important plum cultivars from one of the commercial orchard of Neishabour city in Khorasan Razavi province were picked at full maturity stage and transferred to the laboratory. The experimental design was a randomized complete block design (RCBD) with seven treatments (plum cultivars) and five trees as replications. Due to the fact that the maturity of different cultivars was happened on different days, the cultivars were collected over a period of four months (from June to September).

Physical properties

The weight of the fresh fruit and its stone were determined using a digital laboratory balance (accuracy: 0.001 g). The two linear dimensions of length and width were measured with a digital caliper (accuracy: 0.01 mm). The firmness of fruit texture was determined by penetrometer (8 *mm* Tip) and recorded in N/cm^2 (Davarinejad et al., 2010).

Biochemical properties

The soluble solid content (SSC) of fruit juice was immediately measured using a digital refractometer. The titratable acidity (TA) was determined based on mg of malic acid (major organic acid) in 100 g of fruit tissue by titration of 10 ml of fruit extract with 0.1 N sodium hydroxide solution to reach pH = 8.3 (Najafzadeh et al., 2012). Finally, the SSC/TA ratio was calculated (Davarinejad et al., 2010). The ascorbic acid was measured by titration method and expressed as mg in 100 ml of fruit juice (AOAC, 2005). The antioxidant capacity of plum fruits was determined by the free radical scavenging properties of DPPH (2,2-diphenyl-1-picryl-hydrazyl-hydrate). Finally, the antioxidant capacity of fruit juices was reported as a percentage of inhibition (DPPHsc %). Total flavonoids of fruits were measured according to Gil et al. (2002) at 506 nm.

Statistical analysis

Statistical analysis was performed using JMP 9 statistical software (SAS, Institute, and Cary, NC, USA). The standard error in the tables was also shown as (mean ±SE).

Results and discussion

The results of analysis of variance showed a significant difference between the plum cultivars in terms of physical characteristics including fruit and stone dimensions ($p \leq 0.01$). The results also showed that plum cultivars have significant effects on the soluble solid content, titratable acidity, flavor index, vitamin C, antioxidant capacity and flavonoids.

According to the results of fruit dimensions (Table 1), 'Pivehzhan' cultivar had the highest values of fruit length (36.55 mm) and width (34.71 mm). While 'Ghandy' and 'Beygum' cultivars had the lowest length (30.78 mm) and width (29.30 mm) of fruit, respectively. The maximum and minimum firmness of fruit tissue with values of 2.19 and 1.21 N/cm2 were observed in 'Beygum' and 'Bokhara' cultivars, respectively. Previously, the average firmness in four plum cultivars has been reported by Yousefi and Emam-Djomeh (2015) as 1.87 N/cm^2. Calisir et al., (2005) also studied the physical properties of some wild plums and determined the firmness values of fruit tissue between 0.625-0.499 N/cm^2.

Table 1. Physical properties of plum cultivars.

Cultivar	Fruit length (mm)	Fruit width (mm)	Fruit weight (g)	stone weight (g)	Firmness (N/cm^2)
Ghatretala	34.19±0.3 b	34.59±0.3 a	24.52±0.6 b	1.35±0.1b	1.67±0.06 c
Pivehzhan	36.55±0.2 a	34.71±0.3 a	26.24±0.4 a	1.54±0.3a	1.30±0.10 d
Rotaby	35.08±0.3 ab	30.36±0.2 c	21.27±0.4d	0.55±0.1d	1.40±0.02 d
Ghandy	30.78±0.2 d	34.24±0.2 a	25.86±0.3ab	1.27±0.2 c	1.24±0.04 e
Beygom	34.11±0.2 b	29.30±0.2 d	21.37±0.3d	1.29±0.1c	2.19±0.04 a
Torghabeh Sabz	32.68±0.4 c	32.25±0.4 b	22.70±0.8 c	1.40±0.2 b	2.02±0.04 b
Bokhara	34.02±0.3 b	30.03±0.4 cd	21.25±0.8 d	1.32±0.1 bc	1.21±0.03 e

The changes in the TSS/TA ratio of the studied plum fruits ranged from 20.51 ('Ghatretala') to 41.21 ('Ghandy').The highest value of TSS/TA ratio was recorded in 'Torqhabeh Sabz' and 'Ghandy' cultivars. No significant difference was observed between other cultivars.

Vitamin C (ascorbic acid) content in the evaluated cultivars ranged from 2.53 to 9.24 mg per 100 g of fresh weight. This is lower than the amount of ascorbic acid reported by the USDA (2012) for plums at about 9.5 mg per 100 g fresh weight of fruit. Falati et al. (2017) also reported the range of vitamin C changes in plum cultivars and genotypes about 7.04 – 18.5 mg per 100 g of fresh weight. On the other hand, Hajilou et al. (2013) measured lower levels of ascorbic acid for the plum cultivars (4.33 – 4.17 mg per 100 g).

The range of antioxidant activity in the cultivars evaluated in this study was 14.97 to 73.36 %. 'Ghatretala', 'Pivezhan' and 'Rotaby' cultivars had the lowest level of antioxidant activity with significant differences from other cultivars. Previously, the percentage of antioxidant activity of plum cultivars has been reported between 96.3 – 11% (Falati et al., 2017) and 82.8% (Hajilou et al., 2013).

Total flavonoids content was between 452 and 967 mg quercetin per 100 g fresh weight, although there was no significant difference between the cultivars in this experiment. Also, the concentration of total flavonoids in plum cultivars has been reported to be around 118 to 237 (mg/100 g of fresh fruit) (Donovan et al., 1998), which is much lower than values obtained in the cultivars evaluated in this study.

Table 2- Biochemical properties of plum cultivars.

Cultivars	TSS/TA	Ascorbic acid (mg/100 g)	Antioxidant activity (%)	Flavonoid (mg/100 g)
Ghatretala	20.51±0.4d	2.53±0.1e	14.97±2.8e	452.20±8.7d
Pivezhan	27.52±1.9c	9.24±0.5a	23.51±0.d	674.80±15.2c
Rotaby	23.13±0.5cd	4.51±0.5cd	30.97±6.7d	477.80±7.7d
Ghandy	41.21±1.0a	5.94±0.4c	65.23±1.3b	904.80±7.4ab
Beygom	34.97±0.9b	7.15±1.3b	73.36±1.2a	967.00±8.9a
Torghabeh Sabz	41.15±1.1a	8.69±0.1ab	69.78±1.2ab	964.80±14.8a
Bokhara	36.57±1.1b	4.84±0.3d	51.55±3.7c	881.60±24.0b

Conclusion

The high diversity of cultivars studied in this experiment in terms of physical and biochemical properties was one of the most important results that can be used in the introduction, reproduction and breeding projects.

Abstract

Aromatic plants, in addition to the primary metabolites, fundamental in the life cycle of the plant, produce high levels of secondary metabolites, biologically active compounds that can confer a range of properties such as aromas, fragrances, antioxidant and antimicrobial effects, as well as therapeutic and pharmacological properties. Conditions of stress and alteration of the balance within the plant organism stimulate the production of secondary metabolites, since these substances actively participate in the restoration of normal conditions and the survival of the plant. *Lamiaceae* are characterized by high adaptability and resistance in the most disadvantaged environments, having Mediterranean origin and able to withstand the most diverse climatic conditions; moreover, they are known for high content in active ingredients and essential oils to be used, in addition to the food sector, also for therapeutic uses and the preparation of cosmetics, drugs and pesticides. One of the main aspects distinguishing the quality of officinal species is the content and composition of essential oils, parameters influenced by numerous endogenous and exogenous factors. The aim of this review was to investigate the influence that some cultivation techniques, such as planting density, irrigation regime, fertilization, harvest time, had on the commercial yield, on the percentage content and on the composition of the essential oil extracted from *Origanum. vulgare* L., *Rosmarinus officinalis* L., *Salvia officinalis* L., *Thymus vulgaris* L., four species belonging to the Lamiaceae family widespread in the Mediterranean area.

Keywords: *Aromatic plants, essential oils, yield, agro techniques.*

Introduction

In recent years, modern society, in addition to requiring food products without any limitation, increasingly feels the need to have "healthy" and "clean" products obtained without the use of chemicals products and with "natural" methods. In this regard, there is an increasing demand for products derived from plants that are proposed, not just as food in the strict sense, but as functional foods capable of providing mineral salts, vitamins and phytocomplexes that can have a beneficial effect on health. (Lucera et al., 2012). In other words, it refers to a serier of compounds that the plant biosynthesizes as part of the so-called secondary metabolism such as aromas, tannins, dyes, etc. (Pichersky et al., 2006).

A group of plants of great interest and able to supply the sector of natural substances with high quality raw materials is represented by medicinal plants. Since ancient times, man has exploited these plants both as food and as a curative product. In addition to the primary metabolites, as highlighted above, which are fundamental in the biological cycle of plants, they also produce high levels of secondary metabolites, biologically active compounds that can confer a range of properties such as aromas, fragrances, antioxidant and antimicrobial effects, and also therapeutic and pharmacological properties. These characteristics allow their use in the food, pharmaceutical, cosmetics and even pesticides sectors, both in pure and mixed form (Piccolella et al., 2018). One of the main aspects that distinguishes the quality of officinal species is the content and the composition of essential oils which are influenced by numerous factors, depend on the plant (endogenous or genetic factors), others depend on the environment in which the plant grows (exogenous or environmental factors and biotic factors), others concern the collection, preparation and conservation of the plant or processed products (Trivellini et al., 2016; Marzi & De Mastro, 2008). Among the medicinal plants, within the Sicilian territory, some species such as *Origanum vulgare* L., *Rosmarinus officinalis* L., *Salvia officinalis* L., *Thymus vulgaris* L., belonging to the *Lamiaceae* family (ex *Labiatae*), known for their high content in active ingredients and essential oils, to be used, in addition to the food sector, also for therapeutic uses, for the preparation of cosmetics, drugs and pesticides (Lubbe & Verpoorte, 2011). The main purpose of this work, focused on the analysis of the scientific publications of the last twenty years concerning the medicinal plant sector, was to analyze the results obtained by the various authors, in different environmental conditions, in order to establish what the influence that some factors of the agronomic technique, such as planting density, irrigation, fertilization and the time of harvest, exert on the commercial yield, on the percentage content and on the composition of the essential oil extracted from the main medicinal species cultivated in Sicily.

Materials and methods

The activity carried out as part of this work was a thorough bibliographic research on the influence of agronomic techniques (planting density, fertilization, irrigation, harvest time) on the production of essential oils of the four species object of the work. The databases used were the Google Scholar platform, the Discovery Service of the University of Palermo, the Scopus scientific database, and the editorial portal https://www.mdpi.com/. The research took into consideration only the publications of the period 2000 - 2021, using as keywords "aromatic plants", "essential oil", "variability", "influence", "fertilization", "irrigation", "water use", "Plant density", "spacing", "harvesting time", as well as the scientific names of the individual species, *Origanum vulgare* L., *Salvia officinalis* L., *Rosmarinus officinalis* L., *Thymus vulgare* L..
From each publication, data and results regarding the effective influence of agronomic techniques on the qualitative and quantitative production of essential oils have been extrapolated. In the data summarized in the results are highlighted the effects on the yield and content of the main components of the essential oils extracted from each species were highlighted, due to the different plant densities, irrigation strategies, different types of treatments and fertilization, at the different times of harvest.

Results and discussion

The qualitative and quantitative parameters relating to essential oils are fundamental to define the quality and commercial value of a medicinal plant. It is therefore necessary to define the techniques and treatments to be applied to obtain the best results and optimize the cultivation of aromatic and medicinal species. The officinal species accumulate active principles during the entire biological cycle, but it cannot be excluded that, in some cases, temporary stress conditions may cause an increase in the content and yield of active ingredients within the plant species, by appropriately choosing treatments and durations (Trivellini et al., 2016; Kulak et al., 2020).

Influence of plant density

The choice of the planting density is a fundamental aspect to take into consideration to maximize the yields and the quality of the cultivated plants.

A high planting density and, consequently, a high competition between plants, allows to obtain better yields and higher percentages of essential oil in oregano plants (De Falco et al., 2013; Tuttolomondo et al., 2016) and sage (Abu Darwish et al., 2011); also for *Rosmarinus officinalis* L. (Leto et al., 2004) the yield in essential oil increases in conditions of high planting density but it is necessary to deepen the experimentation, since the publications analyzed are a small number and with disagreeing results.

For thyme plants, with low planting densities, were obtained the highest percentages in essential oil, but, in some cases, the higher oil yield per unit area was obtained with a higher planting density, thanks to the increase in the quantity of biomass produced per unit of surface (Badi et al., 2004; Abu-Darwish et al. 2012).

The competition for light, water and nutrients, due to the distances between plants, can play a very important role in increasing or decreasing the synthesis and accumulation of essential oils in the plant organs of medicinal species. It is necessary to optimize plant density to maximize biomass production and essential oil yield, especially when water is a limiting factor, as competition increases and water availability per plant is reduced (Khazaie et al., 2008).

Influence of the irrigation regime

Water is an important resource for plant growth and production. Efficient use of water is important to ensure acceptable production, especially in conditions of scarce availability or in semi-arid areas, where water is not sufficient to meet crop requirements (Bernstein et al., 2009).

Subject to controlled and moderate water stress conditions *Origanum vulgare* L. (Azizi et al., 2009; Morshedloo et al. 2017), *Rosmarinus officinalis* L. (La Bella et al. 2020, Raffo et al. 2020, Pirzad & Mohammadzadeh 2018), *Salvia officinalis* L. (Mohammadi et al. 2020, Vosoughi et al. 2018, Rioba et al. 2015, Govahi et al. 2015) and *Thymus vulgaris* L. (García-Caparrós et al. 2019; Mohasseli & Sadeghi 2019; Arpanahi & Feizian 2019; Mohammadi et al., 2019; Pirzad & Mohammadzadeh 2018; Askary et al. 2018; Alavi-Samani et al. 2015; Pirbalouti et al. 2014; Khazaie et al. 2008) guarantees an increase in yield and content percentage of essential oil extracted.

In thyme plants, severe water stress, accompanied by foliar treatments based on hormones and stimulants, guarantee a significant increase in the yield, percentage content and quantity of thymol (Abd Elbar et al., 2019; Khalil et al., 2018).

The use of wastewater in oregano (Virga et al., 2020; Bernstein et al., 2009) and rosemary (Bernstein et al., 2009) did not cause differences in the quantity and quality of the extracted oils, compared to plants irrigated with fresh water.

Irrigation with waters characterized by a modest content of salts causes an increase in the percentage of oil and carvacrol in oregano plants (Hancioglu et al., 2019); in sage plants, the same treatment causes an increase in the values of camphor, 1.8 cineole, α-thujone and β-thujone (Kulak et al., 2020).

Water stresses greatly influence the growth and productivity of medicinal plants; careful choice of irrigation doses and intervals can cause a significant increase in biomass yield and essential oil production (Virga et al., 2020).

Influence of treatments and fertilization

Nutrition plays a key role in the growth and development of all cultivated plants; in the case of officinal and medicinal herbs that synthesize essential oils, the availability of micro and macro-elements, as essential to produce both primary and secondary metabolites, can influence and effectively increase the yield and quality of essential oils (NurzyĚska-Wierdak, 2013).

Increases in quantitative and qualitative parameters were found by organic fertilization in oregano (Matłok et al. 2020, Bolechowski et al. 2011), sage (El-Haddad et al., 2020), rosemary (Singh and Guleria, 2013) and thyme (Askary et al., 2018; Noroozisharaf and Kaviani, 2018).

Inorganic fertilizations have caused an increase in the oil yield and the percentage of carvacrol in thyme (Abbaszadeh and Layegh Haghighi 2013), an increase in the values of the main constituents of the essential oil in sage (Rioba et al., 2015), an increase in percentages of α-pinene and 1.8 cineole in rosemary essence (Anuradha et al., 2009).

Nitrogen fertilization caused an increase in yield and carvacrol content in oregano plants (Król et al., 2020; Sotiropoulou & Karamanos, 2010; Azizi et al., 2009) and an increase in yield in thyme plants (Baranauskiene et al. 2003), but a decrease in the percentage of essence content in both cases.

Treatments based on phosphorus and potassium on thymus caused an increase in all the parameters considered except for the value of thymol which decreased with the treatment carried out exclusively with potassium (Kılıccedil et al., 2012).

Inoculation with AMF (arbuscular mycorrhizal fungi) and with PGPR (plant growth promoting rhizobacteria) has always caused an increase in quantitative and qualitative parameters in oregano (Kutlu et al. 2020), rosemary (Bidgoli et al., 2019) and sage (Govahi et al., 2015; Geneva et al., 2009), also in combination with organic and inorganic fertilizers.

The administration of hormones and stimulants via foliar treatments resulted in an increase in qualitative and quantitative parameters in oregano (Wahab & Alobady, 2019), rosemary (Nia et al., 2016) and sage (Es‐ sbihi et al., 2020; Vosoughi et al., 2018); also for thyme plants, increases in yield and oil content were obtained with various types of stimulants (Mohammadi et al. 2019, Pavela et al. 2018, Khalil et al. 2018, Pirbalouti et al. 2014), for example exclusion of the treatment with jasmonic acid which caused an increase in the percentages of thymol and carvacrol but a decrease in the yield and content of essential oil (Alavi-Samani et al., 2015).

In addition to the influence of water availability and water stress, the effect linked to the administration of different types of organic and inorganic fertilizers, stimulants, probiotic microorganisms, and mixtures of various fertilizers, is certainly one of the aspects concerning agrotechnics. of medicinal plants which has been most investigated by researchers in the last 20 years.

Influence of the harvest time

The choice of harvest time corresponding to a specific phenological phase is certainly one of the factors that most influences the yield, content and composition of essential oils in all medicinal species (Singh and Guleria, 2013).

The differences in the yield in essential oil, determined by the choice of the different moments of collection, are mainly linked to the structures that secrete essential oils, the glandular trichomes, which, in correspondence with the different phenological stages, have variable densities and dimensions, also in relation at temperature and photoperiod (Miguel et al., 2007).

The optimal harvest time to obtain the best quantitative and qualitative parameters of essential oils from oregano plants seems to be full flowering (Morshedloo et al. 2017, Baranauskienė et al. 2013, De Falco et al. 2013; Napoli et al., 2020).

To obtain the highest yield and oil content, the optimal time to harvest rosemary plants seems to correspond with the initial flowering phase (Yosr et al. 2013); other authors have found an increase in yield at the ripening stage of the seeds but at the same time also a decrease in the percentage content of essential oil (Alipour and Saharkhiz, 2016; Singh and Guleria, 2013).
In the research carried out on sage plants, the authors obtained different results; some authors have obtained the maximum oil content and the highest yield by harvesting at full bloom (Farhat et al. 2016), Nguyen et al. (2019) with harvest taken at the beginning of flowering, and Verma et al. (2015) by harvesting at the last stage of flowering.
Disagreeing results are also found for the thymus. Safaii et al. (2014) found an increase in the content and yield of essential oil by carrying out the harvest in the last phase of flowering and in correspondence with the ripening of the seeds; some authors (Abu-Darwish et al., 2011; Jordàn et al., 2006; Badi et al., 2004), harvesting in correspondence with the vegetative phase and at the beginning of flowering, found only an increase in oil yield.

Conclusions

The quantitative and qualitative parameters of essential oils can be significantly influenced both by exogenous factors such as climate, soil type, altitude, latitude, agronomic technique, post-harvest and extraction treatments, but also by endogenous factors, such as the age of the plant, stage of development, genetic characters.
The synthesis of essential oils can also be stimulated by non-optimal conditions or momentary stress for the plant; to increase the accumulation of secondary metabolites, the so-called crop manipulation or deliberate elicitation is increasingly recognized, a management strategy that consists in provoking, during the crop cycle, temporary conditions of stress for the plant organism.
From the analysis of the literature of the last 20 years, it is noted that the information available for the cultivation techniques analyzed are often conflicting and that it is therefore necessary to develop further research for a better understanding of the mechanisms that regulate the production and quality of essential oils and their interaction with genetic and environmental factors.

Abstract

The caper is widespread in the Mediterranean basin both spontaneously and in specialized cultivation, showing considerable genetic and phenotypic variations. Although this plant represents a good opportunity for growers in subtropical areas, it still needs innovation in agrotechnical techniques. The aim of the study was to evaluate the morphological and productive behavior of seven accessions of *C. spinosa* L. subsp. *rupestris*, identified on the island of Linosa, in the two-year period 2007-2008. The experimental protocol involved a randomized block design. Not only the main morphological and production parameters were determined but also the phenological phases. In order to broaden the qualitative parameters of the flower buds, in addition to the evaluation of the diameter, the consistency was evaluated using a penetrometer. The results obtained showed variability between accessions and higher levels of production in the second year. Although for most of the parameters examined the best results were provided by the SCP2 access, it is also worth noting that the results for the SCP1 and SCP5 biotypes were also satisfactory. Our results have allowed us to identify accessions of interest for the introduction of new caper fields. Further research is needed to characterize caper biotypes in terms of the chemical composition of flower buds and fruit.

Keywords: *caper plant, island of Linosa, morphological and productive characteristics, growing.*

Introduction

The caper plant belongs to the Capparaceae family, which includes about 40-60 tropical, subtropical and temperate genera, of which 700-900 species belonging to arboreal, shrubby and herbaceous plants (Hall *et al.,* 2002). The genus *Capparis* L. includes about 250 species distributed in tropical and subtropical regions (Fici, 2001).
In Sicily (Italy) and the surrounding islands, *C. spinosa*, with the two intraspecific taxa, subsp. *spinosa* and subsp. *rupestris*, is widespread both spontaneously in natural habitats and as a specialized crop (Gristina *et al.*, 2014).
Caper sprouts, collected from wild and cultivated plants, are mainly used for food and medicinal purposes (Rivera *et al.,* 2005). The immature flower buds, called "capers", the fruits, called "cucunci" or "caperone" and the tender leaves, preserved in salt or vinegar, are widespread in the kitchen, enjoying good levels of world trade (Saadaoui *et al.,* 2014; Chedraoui *et al.,* 2017; Legua *et al.,* 2013; Romeo *et al.,* 2007). Furthermore, different pharmacological properties are attributed to the extracts of leaves, stems, flowers, fruits and roots (Ali *et al.,* 2007; Gadgoli and

Mishra, 1999; Kazemian *et al.,* 2015; Mollica *et al.,* 2017; Trombetta *et al.,* 2005; Zhou *et al.,* 2010).

Among the most abundant phenolic compounds, in fresh bud, rutin is included, while quercetin, now attentive to the possible interference against the replication of the SARS-COV-2 virus, is the most abundant phenolic compound in fermented bud (Francesca *et al.,* 2016; Haslberger *et al.,* 2020).

In addition to its food and medicinal uses, the aesthetic properties of *Capparis spinosa* also make it popular as an ornamental plant for gardens, walls and terraces (Faran, 2014). Furthermore, due to its xerophilic nature, very extensive root system, extremely high root / stem ratio and moderate water consumption (Zuo *et al.,* 2012; Gan *et al.,* 2013), the caper is very suitable as a crop in regions with harsh climatic conditions, such as those of the Mediterranean area.

However, while it contributes to a thriving market, innovation in caper cultivation is low. The specialization of caper cultivation is limited by the absence of improved cultivars and by the lack of studies on the characterization and enhancement of the Sicilian caper germplasm. In Italy this species is of particular interest in the smaller islands of Sicily, in particular in Pantelleria and Salina and recently also in Linosa (La Bella *et al.,* 2021).

The aim of the study was to evaluate the agronomic and productive behavior of seven biotypes of *Capparis spinosa* L. subsp. *rupestris*, identified on the island of Linosa (Italy), in a two-year trial period and to identify the most promising biotypes for cultivation.

Material and Methods

The study was carried out in 2007-2008, on the island of Linosa, Sicily, Italy, (35 ° 51′43″ N 12 ° 52′37″ E: Google Earth) at a local farm, 32 m above sea level. The test site is located on undulating terrain facing north-west. The soil is typical xerorthents; volcanic, shallow, loose and with little organic matter (Fierotti, 1997). Before sowing, the biotypes identified in a previous study (Tuttolomondo *et al.,* 2009), classified as *Capparis spinosa* L. subsp. *rupestris* and marked with the abbreviation SCP1-7. The experimental plot envisaged a randomized block design with three replicates using the plants of the 7 biotypes being evaluated, with a planting spacing of 2.50 × 2.50 m (Figure 1).

In the two-year period (2007-2008), weekly measurements of the main phenological stages were carried out: start of plant growth, flower bud formation, flowering, fruit formation and plant dormancy. Each phenological phase was identified when each parcel presented 70-80% of the plants in the phase considered. The following parameters were also determined for each caper biotype: fresh weight of the flower bud (FW); dry weight of the bud (DW); weight of 100 flower buds; percentage of dry matter of the flower buds; flower bud diameter; texture of the bud; average length of primary branches; number of nodes for cm on the primary branch; number of secondary branches on the primary branch; number of flower buds for primary branch; number of flower buds for secondary branch. The data of all parameters showed a normal distribution. A penetrometric test (FT02, 0–1 kg) with a 2 mm ferrule was used to determine the consistency of the gems; the values are expressed in grams.

All biometric data and production parameters were subjected to variance analysis. The difference between the means was made using the Tukey test. Data analysis was performed using Minitab 19 software for Windows.

Figure 1. A view of the experimental field.

Results and Discussion

The increased demand for caper buds and fruit has prompted farmers to switch from harvesting wild plants to specialized caper plant crops (Tuttolomondo *et al.*, 2009). Of fundamental importance for the creation of new caper plants is undoubtedly the genetic material used for propagation purposes (Gianguzzi *et al.*, 2019; Germanà *et al.*, 2020). Therefore, the identification of biotypes in nature and characterized by high agronomic performances, which can be recommended to breeders or included in genetic improvement programs, is considered an excellent strategy (Tuttolomondo *et al.*, 2020; Perrino *et al.*, 2020; Landucci *et al.*, 2014).
The trend of precipitation and air temperature during the test period is shown in the Figure 2.

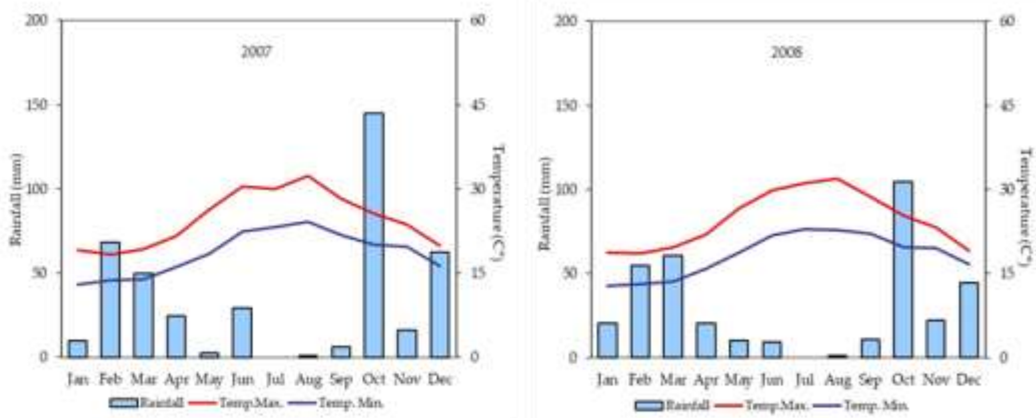

Figure 2. Rainfall and air temperature trends during the test period in the experimental area. The graph on the left refers to the year 2007, the graph on the right to the year 2008.

The levels of precipitation during the 2 years of the experimental test were not always typical of the environment under examination. In 2007, when phenological and production measurements began, rainfall was approximately 100 mm higher than that typical of the test environment (414.40 mm). In 2008, rainfall was consistent with the test environment (359.00 mm). Rainy events have always been concentrated mostly in January and in the months between September and December.
Previous studies (La Bella *et al.*, 2021) have led to the identification of specific characteristics considered of interest for the development of crops; for example, high productivity, long stems, short internodes and high fertility of the nodes, dark green spherical buds with close bracts, non-pubescent and late opening, oval fruits with light green pericarp and few seeds, absence of stipulating thorns, easy separation of the stems to simplify the harvesting and post-harvest operations, suitability for agamic reproduction and resistance to biotic and abiotic stresses.

Means followed by the same letter in the same column are not significantly different according to Tukey's test ($p \leq 0.05$). * significant at $p \leq 0.05$; ** significant at $p \leq 0.01$.

Taking into consideration the biotype factor (Table 1), the highest mean fresh and dry weight values of the bud were found, in SCP2, SCP3, SCP4, SCP5 and SCP1 accessions (FW: 1167.61-1031.89 g; DW: 220, 83–160.70 g), while the lowest averages were recorded in SCP7 (FW: 745.17 g; DW: 147.97 g) which were also distinguished by the maximum weight of 100 flower buds. The dry weight percentage of the gems ranged from 19.84% (SCP7) to 14.23% (SCP4). Among the most sought after features is the diameter. The Official State Gazette distinguishes seven classes of increasing diameter, from the smallest of 7 mm to the largest of 13 mm, highlighting the fact that those most appreciated by consumers are actually less than 7 mm. The diameter of the largest bud (8mm) was recorded in SCP5, SCP2 and SCP4, while that of the smallest bud (7mm) was observed in SCP1, SCP7, SCP6 and SCP3 (Figure 3).

Figure 3. Determination of flower bud diameter.

The consistency of the gems is, without doubt, extremely important in defining the qualitative parameters. In our study, the highest bud consistency (957.47g) was determined in SCP1, while the lowest (842.16g) in SCP4 (Figure 4).

Figure 4. Determination of flower bud consistency using a penetrometer.

Regarding the biometric parameters of the caper accessions in the study, the maximum mean length of the primary branch, the greatest number of nodes / cm of primary branch and the greatest number of flower buds / primary branch were observed in SCP2. According to previous studies (Sozzi e Vicente, 2006; Aytaç *et al.,* 2009) which had found that a longer primary branch determined a greater number of nodes, allowing greater differentiation of flower buds and, therefore, greater productivity. SCP3, SCP5 and SCP4 had the highest number of secondary branches / ratio of primary branches while SCP7, along with the accessions of SCP1 and SCP5, showed the lowest. The highest number of flower buds / secondary branch ratio (47,10) was recorded in SCP3 while the lowest in SCP1 (15,13) and SCP7 (14,16) for which no significant differences were found.

The main results for the productive characteristics of the caper biotypes in two years of study showed that SCP2 and SCP5 achieved the best performance while SCP7 was the least productive biotypes.

The phenological analysis allowed to differentiate the biotypes based on the duration of the single phenological stage (Figure 5). For the SCP2 biotype (Figure 6), shorter plant dormancy and longer plant growth were found and, therefore, longer bud release and fruiting stage (which presumably contributed to the increase in yield). An early production phase inevitably led to a better use of the soil's water resources, accumulated during the autumn-winter period. Plant growth stage (297.02 days), emergence of flower buds (233.02 days), and fruiting (181.51 days) were also longer in adherence to SCP2.

The plant growth phase was shorter in SCP7 adhesion (258.01 days); this accession also recorded the shortest fruiting phase (165.52 days). However, the shortest bud emergence stage was the shortest for SCP6 (208.02). The phenological trend of the various accessions constitutes a further characterization factor of the accessions and is of great interest for the species and for the development of cultivation techniques.

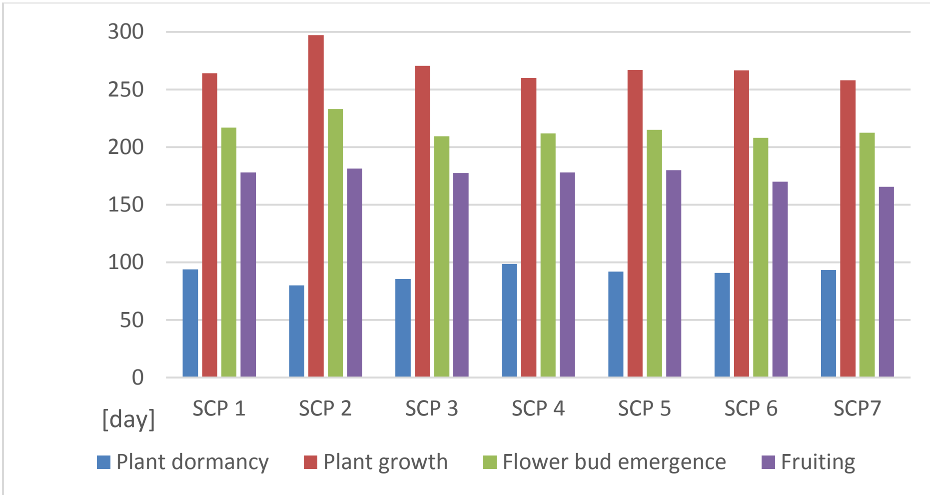

Figure 5. Average length of phenological stages based on accessions of *C. spinosa* subsp. *rupestris*.

Furthermore, the studies conducted by Melgarejo *et al.*, (2009) show that the phenological behavior is fundamental for the improvement of the cultivation techniques of this species as several edible parts are included in the term 'yield', (flower buds, young shoots and fruits) which cover the entire growth cycle annual.

Figure 6. Left: Growth stage of caper plants; Right: Flowering stage of caper biotypes.

Conclusions

The agronomic characteristics linked to resistance to drought and tolerance to high temperatures together with the use of biotypes with good production results, make this species a good candidate for use in marginal land from an environmental point of view. These soils are increasingly fragile due to climate change, which has caused not only a reduction in rainfall levels, but also anomalous intensity and uneven distribution.

The results of this study contribute to deepen the knowledge on the germplasm of the caper found on the island of Linosa. The biotypes that were analyzed showed good adaptability of the test environment and good yield results. Although the best results in terms of flower buds, primary branch length, number of nodes / primary branch and earliness were obtained with the SCP2 biotype, it is also worth noting that the results for the SCP1 and SCP5 biotypes were also satisfactory. Regarding quality parameters, such as average bud diameter and consistency, the best results for both years were obtained with SCP1.

This work can contribute to the ex situ conservation of the species, as the best biotypes can be propagated and cultivated. However, further research is needed to characterize caper accessions in terms of the chemical composition of flower buds, fruits and other parts of the plant with application in the food, cosmetic, pharmaceutical and medicinal sectors.

Abstract

In the context of global warming, the need to restore and expand forest areas is becoming an increasingly urgent task. In Moldova, the most suitable afforestation is the oak species *Quercus robur* L., *Quercus petrea* Liebl. and *Quercus pubescens* Willd. To optimize the selection of oak species for afforestation in specific areas, we have determined the resistance of these species to high temperatures. Additional problems appeared due to the slow growth and low viability of seedlings in the first three years after sowing acorns. Having carried out many studies under controlled conditions, we have developed methods that allow us to obtain some plants, which in terms of viability and habitus already in the first year after germination exceeded the plants of the control variant at the age of two to three years. This conclusion is supported by the values of the parameters of annual growth, the number of leaves per seedling, leaf size, and their photosynthetic activity. Another critical factor is that the experimental plants more fully utilize the reserve substances of the cotyledons, which leads to accelerated growth and plant resistance to stress factors. Thanks to these features, the selection of valuable genotypes can already be at the planting stage. Thus the risks of seedlings suppression during the first years after planting and the costs for afforestation are reduced.

Keywords: *oak, physiological methods, afforestation.*

Introduction

The possible consequences of climate change on the state of forests have had a pragmatic impact only after signing the Kyoto Protocol (1997). It explicitly states that one way to mitigate the serum effects is to increase the carbon accumulation in forest ecosystems. Special attention was paid to expanding forested areas with species best adapted to the new environmental conditions (Giurgiu, 2004). The risk of global warming (Hasselman, 1997) has necessitated particular concerns of the Ministerial Conferences for the Protection of Forests in Europe, so the strategies described in the "*Adaptation of Forests and People to Climate Change - a global assessment*" (Seppälä et al., 2009) have been jointly developed. The literature data state that the choice of species for afforestation must be made with great discernment, following their bio-ecological requirements. These species survive in certain environmental conditions with the specific level of excessive temperatures and drought. Scientists' predictions regarding the evolution of forest vegetation in line with alleged global warming foreshadow a significant increase in areas occupied by oak species throughout Europe (Barbu et al., 2016).
Over time, oak species in the temperate zone have adapted to changing environmental factors, especially climatic ones (Reif et al., 2010). In the last century, however, the number of climatic anomalies has increased, such as long periods of drought, precipitation variations and rain

intensity, late spring frosts, etc. (Zhang et al., 2007). As a result, only three spontaneous oak species are widespread in the forests of the Republic of Moldova:

- Pedunculate oak (*Quercus robur* L.)
- Sessile oak (*Quercus petraea* Liebl.)
- White oak (*Quercus pubescens* Willd.)

Low winter temperatures limit the spread of white oak to the north. Because of this, white oak gives way to competition in favor of sessile oak and pedunculate oak (Cuza & Florenta, 2017). Adaptations of different oak species to abiotic stress factors include strategies to avoid (reduce) the influence of stress factors (Cuza, 2017) and functional processes of adaptation (Dascaliuc, Cuza, 2011). Research showed that thermotolerance of the leaves of mentioned oak species differs by the specificity of the mechanisms to avoid the action of the stress factors and the effectiveness of the functional processes. After immersing the leaves in water with different temperatures (intensive factor) and durations (extensive factor) (Levitt, 1980) of heat shock, their ability to maintain electrolyte balance (Dascaliuc & Cuza, 2007) and photosynthetic activity (Dascaliuc & Cuza, 2011), it turned out to be different.

The above mentioned demonstrates the complexity of the problems that must be considered when choosing the suitable oak species for afforestation of different areas. We must also take into account the need to optimize the technologies for installing new oak forests. The low frequency of oak fruiting, acorn damage by parasites and rodents, the low growth rate of young plants are among the significant risk factors for installing oak forests by direct seeding of acorns (Dănescu et al., 2015). In addition to natural regeneration, foresters plant oak seedlings or directly sow acorns. The second procedure is more straightforward, cheaper, and the developed seedlings have deeper pivoting roots, which gives them a high survival rate in the first year and higher resistance to drought over time (Zadworny et al., 2014). Improving cultivating crops in the nursery allows obtaining seedlings of high quality (Villar-Salvador, 2004). When afforestation has used the seedlings of oak species grown in the cultivation room and then transplanted, the cut roots of the seedlings and their prolonged growth determine the slow growth of plantlets, especially in the first years of life (Harris et al. 2008).

The probability of oak seedlings' survival is related to their limited access to soil water during the summer, supplied through solid and deep roots. Among the main risk factors for direct sowing of acorns are rodents, which detect and consume the sown acorns (Bullard et al., 1992). Herbaceous vegetation reduces seedlings' growth due to competition. This situation leads to prolongation of the period in which the seedlings are susceptible to weed overwhelm (Valkonen, 2008). Both factors must be considered when practicing the direct sowing of oak acorns as a viable alternative to that of planting the seedlings.

In this paper, we present the results of initiation of plantation with pedunculate oak by sowing of acorns in autumn (1), sowing in early spring (2), and as well by planting in the field during the spring of seedlings obtained after germination of acorns, cultivation of plantlets in artificially conditions during the autumn and winter period (3). Thanks to the third method of oak plantation initiation, we have eliminated the risk of damage caused to acorns by rodents, substantially reduced the work of caring for plantations, and obtained vigorous and fast-growing seedlings.

Material and Methods

On the territory of the scientific reservation, "Plaiul Fagului" (Ungheni district) and in the Protection Area of the Institute of Genetics, Physiology, and Plant Protection (Chisinau) were established pedunculate oak (Quercus robur) plantations. The acorn was harvested from the trees aged 100-120 years to initiate forest plantations, which grow in the mentioned reservation.
For elaborating the optimal method for initiating oak plantations, three methodical procedures were tested: 1) autumn sowing was performed; 2) during autumn and winter, the acorns were incubated was kept at a temperature of 0-5oC mixed with wood sawdust and sown in spring; 3) immediately after collection the acorns were incubated for germination and plantlets growth in conditions with temperatures and artificial lighting created to expose to moderate doses of heat stress and nutrition, due to which, before planting in the spring, in the obtained seedlings were induced adaptation processes. Sowing of acorns was carried out in plots with a side of 7 x 7 m. In each separate lot, we prepared 64 nests at a depth of 6 - 8 cm and with a width of 30 cm. 5 acorns were evenly sown in each nest. After the first two years of cultivation, the most vigorous brood was selected in each nest, eliminating the others.
During the year, we provided phenological observations and plantation care works. In October of each year, we measured the height of trees with the ruler to the accuracy of ± 1 cm and the diameter of the stem - using the caliper (accuracy ± 0.1 mm). For each sowing period, indices of annual seedling growth were determined. We characterized the morphological parameters and physiological state of plants obtained after direct acorns sowing and those planted with seedlings grown in autumn-winter by the appreciation of total and annual growth in height and diameter of trees at the trunk level, average leaf area (Utkin et al., 2008) and the chlorophyll index using the SPAD apparatus (USA) (Diagnostics, 1988). Based on the experimental results, we calculated the mean and standard deviation of the means (Clewer et al., 2001).

Results and Discussion

Figure 1 shows the curves of the annual growth dynamics at the height of the oak seedlings obtained from acorns sown in autumn and spring. They show that the diversification of the growth rate of seedlings obtained from autumn and spring sowing was manifested only when the age of the plants exceeded three years. Subsequently, the differences between seedling height in the two experimental variants gradually increased until six years of age. Later, the differences between the size of the plants in these two experimental variants remained practically constant. At the age of 11, the average height of trees obtained from acorns sown in autumn and spring reached 560 and 635 cm, respectively. We note that the average diameter of the plant trunk diameters obtained from acorns sown in autumn was also smaller compared to that characteristic for seedlings obtained from acorns sown in spring, being, respectively, equal to 88 and 93 mm. The above results show that incorporating seeds into the soil in spring ensures a significantly faster rate of seedling growth than those obtained after sowing autumn acorns. The more rapid development of oak seedlings since spring sowing has been of practical importance. As a result of the reduction in the number of weeds needed in the plantation obtained after sowing in spring, compared to the number required for plantations brought by autumn sowing, the costs of seedling care work have been substantially reduced. The faster growth of seedlings from spring sowing led to the early formation of well-expressed branches and crowns. Due to this peculiarity of development, in the middle of the fourth vegetation season, the heights of these seedlings united, forming a joint shade at the soil's surface. Insufficient light on the soil surface caused the gradual inhibition of herbaceous species composition that competed with oak seedlings. The reduction of soil cover with accidental vegetation resulting from the union of oak crowns was beneficial for growing seedlings. Initially, this phenomenon caused the decline of competition between seedlings and weeds for mineral substances and unproductive soil moisture losses. The more rapid has also led to a reduction in the volume of seedling care work.

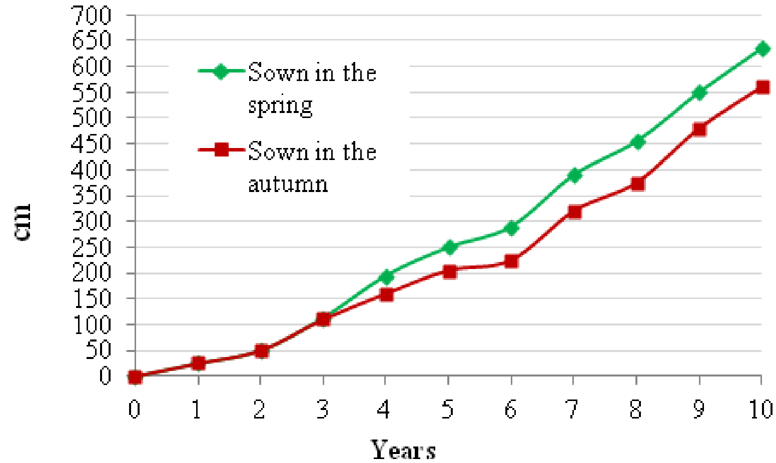

Figure 1. The dynamics of increasing the height of *Quercus robur* seedlings at different years after their initiation through autumn and spring sowing of acorns.

For seedlings that emerged from an autumn sowing, the phenomenon of mass closure was observed only in the sixth year of vegetation, i.e., one year later compared to those obtained in spring sowing. In the first year of life, oaks appeared both after sowing acorns in spring and autumn were cared for five times. In the fourth year after sowing, due to the strong growth of seedlings grown from acorns sown in spring, the crowns of the trees began to unite, and we made only two hoe. In the case of oaks obtained from an autumn sowing, the tendency of the crowns of seedlings to link was manifested only in the sixth year after sowing. In the sixth year after sowing, the oaks from spring sowing were plowed only once. Due to the faster growth of plants starting in the second year and ending in the sixth year after planting, the annual growth rate of seedlings obtained from acorns planted in spring significantly exceeded that characteristic for seedlings obtained from sown acorns. Due to this fact, in four years (years 3-6), the average height of the seedlings increased respectively from 50 cm to 290 cm and 225 cm, the annual growth rate being respectively equal to 60 cm and 44 cm. Over the next four years, the average yearly growth rate of seedlings obtained from acorns sown in spring and autumn was 86 cm and 84 cm, respectively, being practically identical for trees obtained from acorns sown in autumn and spring. It seems that due to the greater vigor of the seedlings obtained at spring sowing; their ability to compete with spontaneous plants for water and minerals has increased more effectively. We consider that due to the influence of these factors, the average annual growth rate of 2-6-year-old seedlings obtained from acorns sown in spring exceeded 1.36 times (60/44) the growth rate of those obtained by sowing acorns in autumn.
The number of necessary care works for the installation of oak plantations can be substantially reduced due to planting seedlings obtained in artificial conditions in autumn, grown during

winter, and planted in the open field in the spring. The data entered in the table 1 supports this view. They show that already at the beginning of the second year of growth, the height and diameter of seedlings planted after artificial germination was about 2.5 times higher compared to those grown after direct sowing in the field, autumn or spring. Due to this, in the first two months of the second year of vegetation in plants grown from planted seedlings, the number of leaves was about five times higher than that determined in plants obtained by direct sowing in autumn. We can also mention that in the plants obtained from the seedlings planted in spring, there is a tendency to increase the leaf surface, the chlorophyll content and decrease the water content in the leaves. These suggest that the vigor and size of seedlings obtained by planting artificially grown seedlings during the winter give them advantages in competition with spontaneous plants over that of the competitive capacity of plants obtained after autumn sowing. In this way, planting seedlings obtained by ensuring acorn germination immediately after their collection, grown artificially during the winter, and planted in the open field in early spring, is advantageous due to accelerating the growth rate of seedlings with high ability to adapt to stressors, such as and due to the decrease in the expenses necessary for the care of the plantations.

Table 1. Morphological and physiological parameters of the white oak plants in the second year of life obtained from acorns sown in the field in autumn and plants grown in laboratory conditions during autumn and winter and planted in field conditions in the spring.

Variant	Plant height, cm	Plant diameter, cm	Number of leaves per plant.	Average growth for May-June, cm	Average leaf area, cm^2	Chlorophyll index	Water content, %
Plants obtained from seedlings	39,7 ± 6,66	0,60 ± 0,07	33,3 ± 11,6	7,04 ± 2,2	32,6 ± 0,54	133,8 ± 13,03	48,5 ± 10,3
Plants obtained from acorns	13,2 ± 2,3	0,24 ± 0,01	5,88 ± 1,17	3,33 ± 1,17	31,35 ± 0,83	126 ± 10,42	52,3 ± 11,8

The conclusions indicated above are supported by the images presented in Figure 2. Analyzing these images, we can see that already in mid-June of the second year of cultivation, the size of plants obtained by planting seedlings grown under artificial conditions exceeds that of plants obtained by direct sowing. It also impresses with a large number of well-developed leaves, characteristic plantlets obtained from the seedlings.

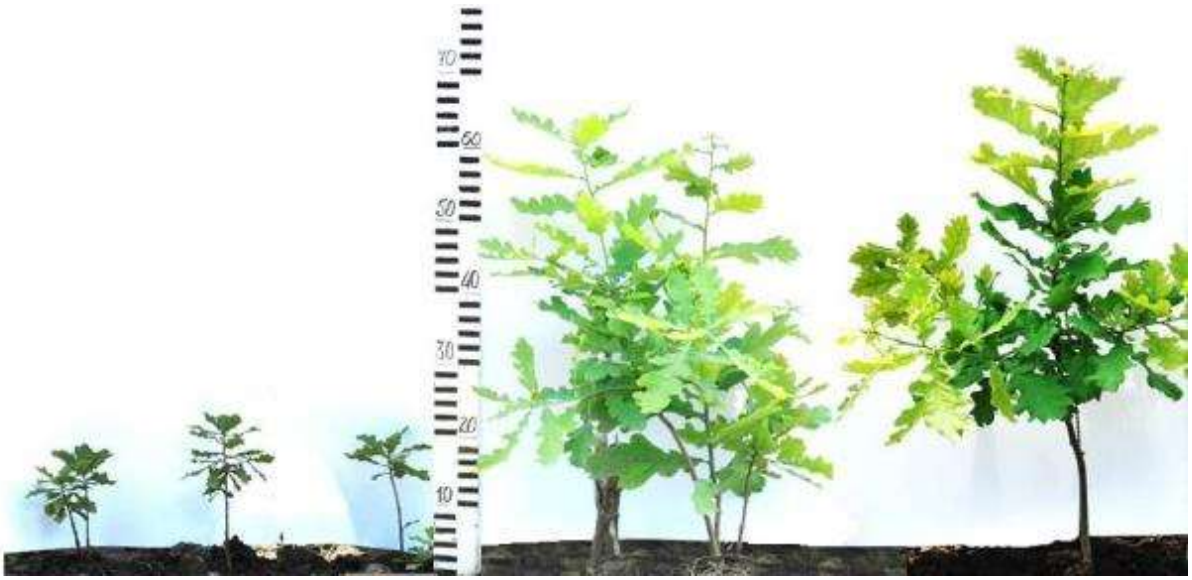

Figure 2. Image of oak seedlings in the second year of growth (made on June 15) obtained from acorns sown in the field in autumn (left) and those obtained from acorns that germinated in autumn, seedlings grown in artificially created conditions during winter and then transferred to open field in spring (right).

In general, the experiments performed to obtain the scientific and practical results presented in this article give the complexity of the biochemical and physiological processes that ensure plant survival during seed germination (Levitt, 1980) and plant development in ontogenesis. Incubation of acorns in ideal conditions during autumn and winter and their sowing in early spring ensured rapid germination, growth of the root system, and adaptation to the gradual increase in temperature in late spring and early summer. In embryos and seedlings obtained from acorns sown in autumn initially induced the adaptation to low temperatures. Later, the processes of reprogramming the expression and metabolism of the genes were performed to adapt the plants to high temperatures. The higher "*cost*" of changing the direction of adaptation processes during the germination of acorns sown in autumn compared to those sown in spring occurred during the first six years of plant growth, a conclusion confirmed by the data presented in Figure 1. To validate these suggestions, we compared the activity of growing and adapting plants obtained after sowing acorns in autumn (general control) with those that were planted after germination and growth in autumn and winter under artificial conditions (experiment). After the germination and growth stage, through hormetic mechanisms (Calabrese, 2006), in plants were induced processes that increase the vigor and adaptive capacity of the plants towards the stress factors. In addition, due to the implementation of this procedure, at the time of planting in the field, the roots of the seedlings were well developed; thus, the plants have better access to water and minerals if compared to the plants of control variant, especially in the first years of life. These priorities have already fully manifested themselves after the first year of life; see the data presented in the table 1 and figure 2.

Conclusions

Taking into account, the faster growth rate of pedunculate oak seedlings (Q. robur L.) obtained after spring sowing with layered acorns, as well as the reduction of the risk of winter damage to autumn seeds by wild boars and rodents, preferred sowing in the spring.
Even more appropriate is the organization of oak plantations by planting seedlings obtained after germination of freshly harvested acorns, cultivated under artificial conditions during autumn and winter, and transferring the seedlings to the open field in the spring.

VARIABLE COMPONENTS DETERMINING THE PRIMARY RESISTANCE TO EXTREME TEMPERATURES OF THE WHEAT SEEDS REPRODUCED IN THE DIFFERENT CLIMATIC ZONE

Alexandru DASCALIUC*, Tudor RALEA, Nina ZDIORUK

Institute of Genetics, Physiology & Protection of Plants, Chisinau, Moldova

Abstract

Specific results of our research have shown that the primary resistance of wheat genotypes varies depending on the conditions of seed reproduction. In laboratory conditions, based on the evaluation of the seeds' germination capacity after their exposure to shock with high or sub-zero temperatures, we determined the resistance of different wheat genotypes reproduced in Moldova and Ukraine. The wheat varieties can be differentiated in the accelerated mode after their primary resistance to extreme temperatures (excluding the influence of the adaptation processes carried out during plant ontogenesis) by exposing them to heat shock or shock with negative temperatures the well-prepared for germination seeds. The resistance of different wheat genotypes seeds to extreme temperatures can vary, being influenced by the environmental conditions of their reproduction. Only a tiny part of genotypes demonstrated at the same time the high resistance to high and sub-zero temperature. As a rule, genotypes with high resistance to negative temperatures have a low level of resistance to high temperatures. In most cases, the primary resistance to negative temperatures of seeds reproduced in Moldova was lower than those produced in Ukraine. Overall, the obtained data support the view that the resistance of seeds of different wheat genotypes to extreme temperatures reflects the interaction between the primary resistance of the genotype and the influence of epigenetic inheritance factors on the seed resistance.

Introduction

Plants are usually grown in environmental and agrotechnical conditions suboptimal, so they do not reach the genetic potential for growth and productivity (Rockstrom and Falkenmark, 2000). For example, in the United States, wheat productivity, in some years, was eight times lower than average (Boyer, 1982). Abiotic stressors can reduce crop plant productivity by more than 50% (Wang *et a*l., 2003). Overcoming these factors is detrimental to plant growth and productivity. The simultaneous or consecutive action of different stressors can have additive and even synergic deleterious effects. Therefore, knowledge of the mechanisms of plant response to the changing activity of various factors is essential for selecting genotypes with a broad tolerance spectrum, choosing appropriate conditions for their cultivation, and developing optimal agrotechnical technologies of plant cultivation. The final productive and agrotechnical potential we will achieve only after cultivating the plants in field conditions. Actual models of climate prediction indicate that in the next 50-100 years, the average temperature of the Earth's surface will increase by 3-5°C, which can lead to a drastic impact on global agricultural systems (IPCC, 2007).

The allocation of plant resources for growth and development under stress must be well distributed, as plant growth and productivity will depend on this ratio (Smith and Stitt, 2007). The analytical complexity of the interactions between different factors evaluated in most research programs aims to determine tolerance to one stress factor. It is not necessarily associated with simultaneous testing of susceptibility to other challenges. The result can have unintended consequences, as improved varieties can react unpredictably to interactions between different components when grown in the field. Furthermore, many ordinary stressors during the growing season are acting in combination (Mittler, 2006). The adaptation mechanisms to their action can operate in opposite directions, thus increasing the level of damages. Finally, we have to note that the risk of global warming (IPCC, 2007) also increases the likelihood of widening the range of variation between the extremes of high and low temperatures, indicating the need to select genotypes with increased resistance to high and to negative temperatures, i.e., with high plasticity. When optimizing the selection methods of genotypes resistant to excessive temperatures, it is possible to practice the principles developed for the accelerated determination of the stress resistance of technical devices (Levitt, 1980).

The theoretical generalizations and methods for evaluating plant resistance are summarized (Levitt, 1980; Dascaliuc *et al*., 2013). The effects induced in biological systems by the action of stressors depend on the nature and parameters of the exposure factors (Suzuki N. *et al.,* 2014). They are also specific for plant reactions at the sub-cellular, cellular (Levitt, 1980; Dascaliuc *et al*., 2013), tissue (Ivanov, 2003), organism (Dascaliuc *et al*., 2013), and at ecological levels (Zhuchenko, 1988). To determine the influence of seed reproduction conditions on their primary resistance to high temperatures and frost, we applied the approaches developed for the accelerated assessment of the stress stability of technical systems (Escobar *et al*., 2006). In our research, we chose the seeds as the object of study because the primary resistance of the genotype determines their response to the action of excessive temperatures, the components of adaptation to environmental conditions occurring during plant ontogenesis (Levitt, 1980; Lopes, 2010; Dascaliuc et al., 2013). We exposed the seeds to high temperatures by immersing them in water with different temperatures, thus ensuring the exclusion of the influence of avoidance phenomena on the resistance of the seeds. Our studies used seeds of different hexaploid wheat genotypes reproduced in climatic conditions in the Kharkiv region of Ukraine and the Chisinau area of Moldova. Thus, we developed a method of testing the primary resistance of wheat genotypes to excessive temperatures. As a result, it became possible to elucidate the potential contribution of epigenetic inheritance in modifying the primary wheat resistance to extreme temperatures.

Material and Methods

Our research used the seeds of 10 hexaploid wheat genotypes (lines 21, 111, 466, 517, 542, 1087, and varieties Samurai, Arctis, and Toulouse), reproduced in 2015-2016 in the Kharkiv region, Ukraine, and then reproduced in 2017-2018 in the Chisinau area, Moldova. Initially, the seeds intended for research were calibrated according to volume by passing through a sieve with a hole diameter equal to 2.4 - 2.6 mm. They were then disinfected for 20 minutes by incubation in a 0.1% aqueous solution of potassium permanganate, washed thoroughly with tap water, and then distilled water. After soaking in water at + 4°C for 36 hours, for determining the resistance of the seed to high temperatures, they were exposed to HS by immersion for a certain period in water with specified temperatures, maintained to an accuracy of ± 0,05°C using an ultra -

thermostat U10 (Germany). Finally, to determine the resistance to the action of negative temperatures, the seeds, prepared as mentioned above, were exposed to shock with negative temperature (SNT) by incubation in an air thermostat Rumed 3401 (Germany), maintaining the indicated air temperature with an accuracy of ± 0.5°C.

The first problem solved experimentally was to determine the unique value of the incubation temperature (positive or negative) and the duration of exposure, suitable for separating wheat genotypes according to their resistance to high temperatures or frost. Based on the data obtained in preliminary studies, for the distribution of wheat genotypes according to their primary resistance to frost or heat, we chose the doses of stress provided by exposing the seeds to -7°C or +50°C and the exposure time 8 hours or 30 minutes, respectively.

In these researches, we installed two control variants: the first for experiments determining the wheat genotypes frost resistance and the second for determining their resistance to high temperatures. In mentioned variants, before incubation for germination, the seeds were incubated at a temperature of + 24°C for another 8 hours or 30 minutes, respectively (periods equal to the duration of SNT or HS application in the experimental variants). The seeds of the experimental and control variants were then placed for germination in Petri dishes, 25 seeds each, in three repetitions, in the dark, at a temperature of 25°C and relative humidity of 75-85%. The response of seeds of each wheat genotype to SNT or HS was appreciated by assessing the percentage of seeds that germinated over 5 days after exposure to SNT or HS. During this period, in the control variants sprouted no less than 98% of the seeds. Therefore, we evaluated the seeds of different genotypes' response to SNT or HS directly based on seeds germination rate in experimental variants. Based on the experimental results, we calculated the average percentage of seed germination, the standard deviation of wheat genotype seeds' average response to SNT or HS (Clewer *et al*., 2001).

Results and Discussion

In Figure 1 included the data on the influence of SNT (A) and HS (B) on the germination rate of seeds reproduced in Ukraine and Moldova. The sequence of diagrams presentation in each figure are arranged in the order that correspond to the order of increasing the germination percentage of the genotypes seeds reproduced in Ukraine and exposed to SNT. We considered that the genotypes have low (I), medium (II), or high (II) resistance to SNT or HS, if after seeds exposure to SNT or HS they germinated up to 50% (I), between 50 and 70% (II), and more than 70% (III), respectively. The presented in Figure 1 A data suggests that the reproduced in Ukraine seeds of the genotypes the lines 466, 542, 111, 1108, varieties Samurai, and Arctis are characterized by low resistance; of lines 517 and 1087 - with medium resistance; those of line 21, and variety Toulouse - with high resistance to SNT. At the same time, analyzing the diagrams presented in Figure 1 A, we notice that after reproduction in Moldova, the seeds of all genotypes showed low resistance to SNT.

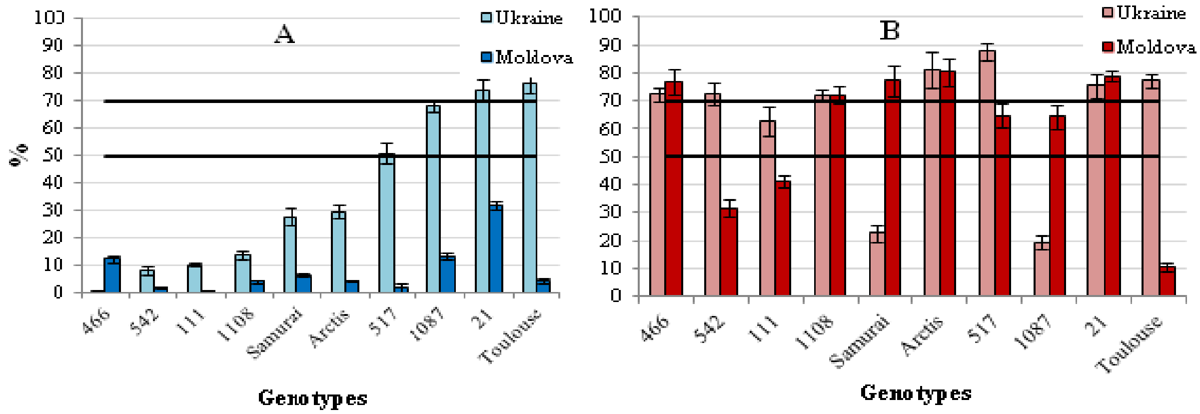

Figure 1. The percentage of the ten winter wheat genotypes, reproduced in Ukraine and Moldova, germinated during five days after exposure to SNT for 8 hours at -7^{o}C (A) and to HS for 30 minutes at 50^{o}C (B).

We analyzed the data from Figure 1 B, and we notice that after reproduction in Ukraine, the seeds of most genotypes have high resistance to HS. Only those of the variety Samurai and of line 1087 were sensitive, and those of line 111 showed medium sensitivity to HS. After reproduction in Moldova, the sensitivity to HS of some genotypes decreased (Toulouse, 111, 142), and of others increased (Samurai, 1087) substantially. The data presented in Figure 1 suggest that the primary resistance of seeds of different wheat genotypes to HS or SNT was influenced differently by the seed reproduction conditions. The direction of these changes was specific to different genotypes. In particular, this trend was manifested in the variation of the response of seeds exposed to HS. This is confirmed by the lower value of the correlation coefficient between the germination percentage after exposure to HS of seeds reproduced in Ukraine and those reproduced in Moldova compared to the correlation coefficient assessed after the application of SNT. The value of this coefficient was respectively equal to -0.017 and 0.481. At the same time, the correlation coefficient between percent of seeds germinated after exposure to HS and SNT, determined for seeds reproduced in Ukraine with those reproduced in Moldova, was equal to -0.058 and 0.434, respectively. Thus, although the primary resistance to SNT of reproduced in Moldova seeds decreased substantially, due to the same direction of changes for different genotypes, the correlation coefficient between seeds of two reproductions reached the value 0.434. At the same time, due to the different directions of changes of the primary resistance to HS of wheat genotypes, although on average the values of HS resistance of genotypes reproduced in Ukraine and Moldova was comparable, the correlation coefficient between resistance to HS of genotypes reproduced in Moldova and Ukraine was much lower than 0.434, being equal to -0.058. In general, obtained data show that for seeds reproduced in Moldova, independently of genotype, there was a tendency of decreasing their primary resistance to SNT. At the same time, for some genotypes reproduced in Moldova, the primary resistance to HS changed in different directions.

To analyze the complex processes of modifying the primary resistance of wheat genotypes to HS and SNT under reproducing their seeds in new environmental conditions, we appreciated the plasticity of genotypes' response to extreme temperatures. We mention that all theoretically possible values of the germination percentage of seeds representing different genotypes exposed to SNT or ST can occupy the range between 0 and 100%. Plasticity is influenced by the resistance to both types of temperature stress. Therefore its values can be estimated by the percent seeds germinated after exposure to HS plus that of those germinated after exposition to SNT. Theoretically, the values of this parameter of plasticity can vary between 0 and 200%. Since seed germination for all genotypes has practically reached 100% in the control variants, the values of the sum less than 200% of germination represent the plasticity of genotype response to extreme temperatures. The lower is the percentage of seeds germination after exposure to SNT, plus that after exposure to HS, the lower is the genotype plasticity. To differentiate the genotypes after their plasticity, we have divided them into three groups: I - the genotypes with low plasticity - the summary seed germination rate did not exceed 100%; II - the genotypes with medium plasticity - the summary seed germination rate lay between 100 and 140%; III - the genotypes with high plasticity - the summary seed germination rate exceeds 140%. Based on the results presented in Figure 2, we can mention that for reproduced in Ukraine seeds; high plasticity was specific to the variety Tuluza and line 21, medium - those of the variety Arctis and line 517, and the seeds of the variety Samurai and lines 11, 466, 542, 1087, and 1108, have the low plasticity. The seeds of line 21 reproduced in Moldova have high plasticity. In contrast, the plasticity of reaction to excessive temperatures of the seeds of nine other wheat genotypes was low.

Considering that the difference of frost resistance between wheat varieties increases with the adaptation processes' accomplishment, the traditional methods of determining the frost resistance of wheat genotypes ordinarily are after performing the adaptation processes (Flower *et al*., 2014). Therefore, it was considered that the resolution power of methods for differentiating genotypes according to their level of frost resistance turns out to be the highest precisely when the plants are in an adapted state. However, we have to consider that the duration of accomplishing the adaptation processes and the specificity of the kinetics of these processes in the plants of different genotypes depend on the environmental conditions (Dascaliuc *et al*., 2013). Although the maximum difference between the primary frost resistance of wheat varieties practically does not exceed 3^oC and that of adapted plants reaches 12^oC (Flowler *et al*., 2014), the relative simplicity and reproducibility of the procedures for determining the primary frost resistance of seeds inspired us to test in more detail the resolving power of this method. Later we posed the problem of determining the primary resistance of wheat genotypes to high temperatures, which ultimately allowed appreciating the plasticity of the reaction of different wheat genotypes to the action of excessive temperatures (positives and negatives). By soaking the seeds in water at a temperature of 4^oC, we brought the seeds to an equivalent pre-emergence physiological state. The effectiveness of synchronization was manifested by the germination in the control variant of practically 100% of seeds during the first 24 hours of incubation under favorable germination conditions. When seeds reach an equivalent physiological state, their reaction to HS or SNT mainly depends on the genetic specificity of the genotype.

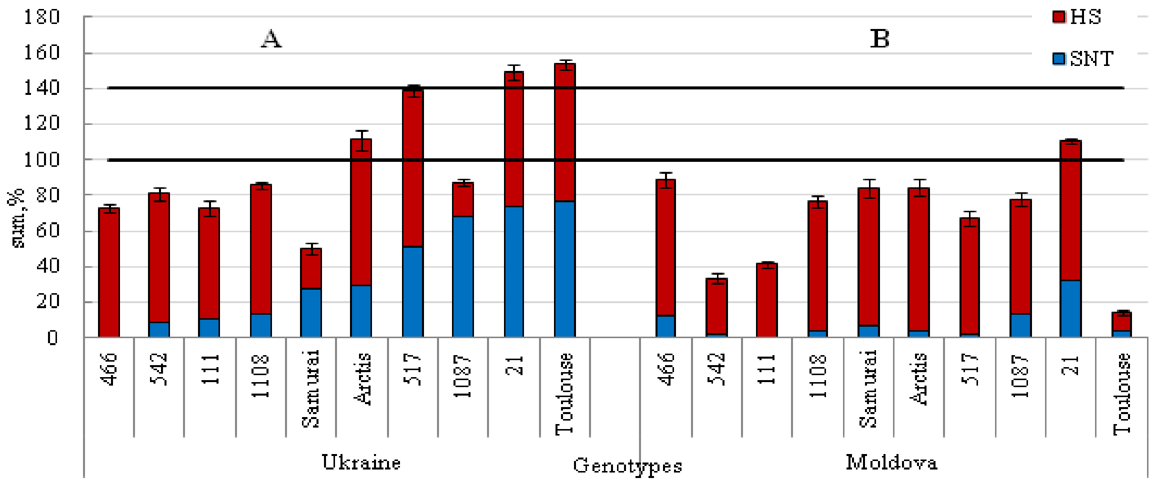

Figure 2. The percentage of seeds germinated during five days of the ten winter wheat genotypes expressed as a sum of the percentage of seeds germinated after 8 hours exposure to -7°C (blue) plus the percentage of those germinated after exposure for 30 minutes to HS at 50°C (red). A and B – the seeds were reproduced in Ukraine and Moldova, respectively.

The applicability of mentioned approaches for studying the primary resistance of plants to extreme temperatures (before the manifestation of adaptation processes) has repeatedly been confirmed in laboratory experiments. Compared to the methods of determining thermotolerance based on the influence of HS on plant growth parameters (Jelev, 2016), the simplicity and advantages of the proposed method are evident. Since the seeds were well prepared for germination but have not yet germinated, we avoided the contribution of ontogenetic adaptations. In this state, seeds represent a unique model to evaluate the primary resistance of wheat genotypes to the action of excessive temperatures. According to their primary resistance to extreme temperatures, the proposed method of wheat genotypes distribution is in strict accordance with the accelerated methodology of testing the resistance of the biosystems to stress factors (Escobar, 2006; Dascaliuc *et al*., 2013). In the accelerated test, the plant exposure temperatures exceeded the natural ones, but the exposure doses were within the tolerance range of the genotypes. This statement is supported by the data in Figures 1 and 2. The data given in these figures provide a qualitative and quantitative characterization of 10 wheat genotype resistance to high temperatures and frost. We mention that the resistance characteristics determined by us depend on genetic, biochemical, and physiological processes that characterize the response of wheat genotypes to the action of extreme temperatures. In our experiments, the reactions were not influenced by the complex mechanisms of avoiding the action of stressors, phenomena that have mainly been taken into account in the amelioration of wheat (Lopes *et al*., 2010; Fowler *et al*., 2014). The obtained data demonstrate that seeds resistance to both types of temperature shock is specific for different wheat varieties and is influenced by the seed reproduction conditions. Due to this adaptive variability of genetic and epigenetic nature (Jaligot, Rival, 2015)), wheat varieties and their descendants are characterized by high resistance and productivity in very different environmental conditions. The possibility of epigenetic inheritance suggests that it may influence wheat embryo primary frost or heat resistance. Their level of influence can be different depending on the conditions of seed reproduction. Because meteorological conditions vary from year to year, they can probably influence genotypes' primary resistance to heat stress factors even when reproduced in the same zone. Recently we obtained data showing that the distribution of seeds of wheat genotypes based on primary resistance to extreme temperatures does not change after one year of storage of seeds. Simultaneously, the data showed that the distribution of genotypes after the primary resistance to extreme temperatures varied when tested seeds reproduced in different years in the same zone.

Conclusion

The primary resistance of different wheat genotypes seeds to HS or SNT can vary, being influenced by the environmental conditions of their reproduction.
In general, the data obtained support the opinion that, due to the influence of epigenetic inheritance factors, the primary resistance of seeds wheat genotypes may vary depending on the cultivation area.

CONTENT OF BIOACTIVE COMPOUNDS IN BIOMASS OF NATURAL LAWN OF ARRHENATHERETALIA

Anđelka POPADIĆ

Department of Land and Mechanization, Faculty of Agronomy, Čačak, Serbia
*Corresponding author: andjelka.popadic@kg.ac.rs

Abstract

Natural meadows and pastures represent the most important resource in the production of bulky fodder in the hilly and mountainous area of Serbia. Yield and quality of grass biomass mainly depend on a large number of factors, among which are primarily floristic composition, which implies a share of quality grasses and legumes. The paper analyzes the influence of NPK application of mineral fertilizers with different nitrogen levels, where (A0- non-fertilized, A1-N60:P40:K40, A2-N100:P40:K40, A3-N140:P40:K40), on the content of total phenol, flavonoids, chlorophyll a and b and carotenoids in the biomass of natural grassland of the order Arrhenatheretalia in the municipality of Raska. It was observed that the application of increasing doses of nitrogen fertilizer did not significantly affect the phenol content in grasses and other plants. However, in legumes, it is noticed that the variant with the highest dose of nitrogen had a significantly lower phenol content compared to the control variant. The content of flavonoids in grasses and legumes did not change significantly depending on the application of different nitrogen levels. Phenolic compounds are considered to play the greatest role in the biological activity of extracts and their presence contributes to the antioxidant activity of the plant. The content of chlorophyll in grasses on the examined grass did not change with the application of increasing doses of nitrogen in the experiment, while unlike chlorophyll, the highest content of carotenoids in grasses of natural grass Arrhenatheretalia was achieved with the use of the highest amount of nitrogen in experiment N140.

Keywords: *natural grasses, bioactive compounds, order Arrhenatheretalia.*

Introduction

Grasses are one of the most widespread and numerous plant communities. A large number of genera and species are known in the world, and the ability to spread them quickly is attributed to the way they reproduce. The diet of domestic animals is largely based on fodder grasses. Great importance of grasslands also stems from the fact that they are the largest, and often the only source of bulky food in the mountainous area where they are considered to occupy 30-60% of agricultural land (Stošić and Lazarević, 2007). Grasses also participate in the repair and stabilization of soil properties, prevention of erosion and are important in the arrangement of urban areas (Erić et al., 2016). The main factor that affects the quality of natural lawns as well as the achieved yield is the floristic composition. In addition, soil properties, light, amount and distribution of precipitation have a significant impact, but of course also adequate agro-technical measures, which are often the cause of unstable and low yields.
Over 3000 flavonoids were isolated and studied from plants, which, according to the degree of oxidation of the central Piran ring, were divided into twelve classes. In addition to being plant pigments, flavonoids also contribute to the taste, most often bitterness, and astringency of the

plants in which they are found. This class of compounds undoubtedly participates in the defensive chemistry of plants, because the hardness they give to plants is unpleasant to herbivores, and they also protect the plant from the harmful effects of UV radiation (Zhishen et al., 1999; Harborne et al., 2000). Phenolic compounds represent a widespread heterogeneous group of secondary plant metabolites and one of the most important classes of natural antioxidants. They have been shown to be synthesized in response to increased concentrations of some metals in soil, such as aluminum (Petrović et al., 2005).

Chlorophyll is the main photosynthetic pigment present in all photosynthetic organisms. It is one of the most important bio-organic compounds in general, primarily due to its central role in the process of photosynthesis, the most important global physico-chemical process on our planet, in which light energy is converted into chemical energy for use in the final result - synthesis of organic sugar. The arrangement of double bonds along the outer periphery of the porphyrin structure is conjugative (alternating arrangement of single and double bonds), which is crucial for the role it plays in photosynthesis, because it shifts the absorption maximum towards longer wavelengths, in the visible region of the solar spectrum (Woodward et al. , 1960).

Carotenoids are polyunsaturated hydrocarbons composed of isoprene units. The structural formula of carotenoids contains a significant number of conjugated double bonds, the most important being α- and β-carotene, lutein, lycopene, and β-cryptoxanthin (Thurnham, 1994). In addition to being a β-carotene precursor of vitamin A, it is important for carotenoids to point out that they have important antioxidant activity (Nagata and Yamashita, 1992).

The aim of this study was to analyze the effect of NPK application of mineral fertilizers with different nitrogen levels on the content of phenols, flavonoids, chlorophyll a and b and carotenoids in the biomass of natural grassland of the order Arrhenatheretalia.

Material and Methods

Samples of represented plant species from the natural grassland of the order Arrhenatheretalia, previously dried and classified and divided into three groups: grasses, legumes and weeds, were used for the examination. Samples were taken in 2020, from a natural meadow of the order Arrhenatheretalia, located on the slopes of Kopaonik, municipality of Raska. The experiment was set up in three replications according to a completely randomized block system, where the plot size is 7,5 m^2, on black soil on dolomite pH 6.5. Fertilization variants are as follows:

- non-fertilized - control (A0),
- N60:P40:K40 (A1),
- N100:P40:K40 (A2),
- N140:P40:K40 (A3).

Mowing was done in the phase of grading or brooming of the most common grass species, the second mowing, on September 3, 2020. The total amount of green mass per plot was measured, after which a sample of 500 g was taken from each plot. The weight share of grasses (family Poaceae), legumes (family Fabaceae) and other plants (weeds, medicinal plants, etc.) was determined from the sample.

The following analyzes were performed from the prepared material:

- Determination of total flavonoid content by spectrophotometric method (Sharma et al., 2011);
- Determination of total phenol content by Folin-Ciocalte method (Singleton et al., 1999);
- Determination of chlorophyll a and b spectrophotometric method (Wettstein, 1957);
- Determination of carotenoids - spectrophotometric method (Nagati and Yamashiti, 1992).

Results and Discussion

Total phenol content

The content of total phenols was determined by the Folin-Ciocalte method and on the basis of the calibration diagram of the standard, gallic acid, the content of phenolic compounds in the tested extracts was determined (Figure 1).

The absorbances of different concentrations of gallic acid standards were measured at 765 nm and the following values were obtained:

- for a solution with a concentration of 0.05 mg / mL, an absorbance of 0.011 was measured;
- for a solution of concentration 0.1 mg / mL, absorbance 0.028 was measured;
- for a solution with a concentration of 0.25 mg / mL, the absorbance of 0.058 was measured;
- for a solution of concentration 1 mg / mL, absorbance of 0.097 was measured;
- for a solution of 2.5 mg / mL, the absorbance of 0.209 was measured.

Fertilization	Grasses	Legumes	Other plants	$\bar{x}$
A 0	0,163	0,1117^{a}	0,129	0,134
A 1	0,070	0,0663^{ab}	0,258	0,131
A 2	0,153	0,0913^{a}	0,301	0,182
A 3	0,172	0,0390^{b}	0,065	0,092
$\bar{x}$	0,139	0,07707	0,188	

Values marked with different lowercase letters per column differ significantly (P <0.05), according to the LSD test

The application of increasing doses of nitrogen fertilizer did not have a significant effect on the phenol content in grasses and other plants. However, in legumes, it is noticed that the variant with the highest dose of nitrogen had a significantly lower phenol content compared to the control and A2 variant (Table 1). The phenol content determines the pharmacological properties of the plant and in medicinal plants the phenol concentration is from 0.23 to 2.85 mg GAE/g of fresh sample, while the phenol concentration in culinary plants is from 0.26 to 17.51 mg GAE/g of fresh sample (Zheng, 2001). The highest content of phenolic compounds has a culinary plant from the genus Origanum, about 20 mg GAE/g of fresh sample (Lagouri and Boskou, 1996). The content of total polyphenolic compounds measured by the Folin-Ciocalte method does not provide a complete picture of the quantity and quality of polyphenolic compounds in extracts, due to the possible presence of interfering compounds (sugars, aromatic amines, sulfur dioxide, vitamin C, organic acids and other non-polyester substances).), which affect the unrealistic increase in results (Singelton et al., 1999). Therefore, complete qualitative and quantitative identification of polyphenolic compounds, using the HPLC method, is necessary.

Total flavonoid content

The antioxidant activity of flavonoids depends on the structure and substitution of hydroxyl groups (Sharififar et al., 2008). Flavonoids are present in almost all plants and, thanks to their chemical structure, they have anti-inflammatory and anti-allergic properties. The results of spectrophotometric determination of the content of total flavonoids in the methanol extract of selected species are presented with the help of routine diagrams.

At 430 nm, the absorbances of previously made different concentrations of routine standards were spectrophotometrically measured:

for a solution with a concentration of 0.01 mg/mL, the absorbance of 0.056 was measured;
for a solution with a concentration of 0.05 mg/mL, an absorbance of 0.060 was measured;
for a solution of 0.1 mg/mL, the absorbance of 0.197 was measured;
for a solution with a concentration of 0.25 mg/mL, the absorbance of 0.238 was measured;
for a solution 0.5 mg/mL, an absorbance of 0.756 was measured.

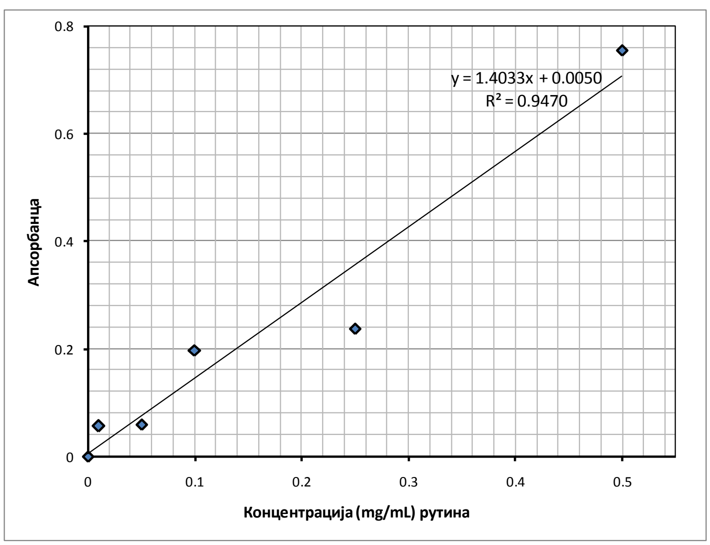

Figure 2. Calibration diagram of routines

Table 2. Flavonoid content in natural grass biomass of the order Arrhenatheretalia (mg/mL)

Fertilization	Grasses	Legumes	Other plants	$\overline{x}$
A 0	0,451	0,692	0,419[ab]	0,520
A 1	0,331	0,373	0,566[a]	0,423
A 2	0,364	0,950	0,524[ab]	0,613
A 3	0,290	0,588	0,095[b]	0,324
$\overline{x}$	0,359	0,651	0,401	

Values marked with different lowercase letters per column differ significantly ($P < 0.05$), according to the LSD test

Comparing all variants of fertilization in relation to the control variant in grasses and legumes, it can be concluded that there are no significant differences in the content of total flavonoids. In other plants, a significantly higher content of flavonoids was achieved on A1 compared to the A3 variant. If we look at the average values, legumes show a higher content of flavonoids than the other two groups, ie grasses and other plants. Phenolic compounds are considered to play the greatest role in the biological activity of extracts and their presence contributes to the antioxidant activity of the plant. A large number of studies indicate that the role of flavonoids, as phenolic compounds, is of special importance. Of the structural elements that are important for the antiradical activity of flavonoids, hydroxyl groups are of the greatest importance (Yang et al., 2001; Heim et al., 2002). In the research conducted within this final master's thesis, the highest average flavonoid content was found in legumes (0.651 mg/mL).

Chlorophyll a, b and carotenoid content

The content of chlorophyll and carotenoids was determined by the procedure with ethanol solution and absorbance measurements at 649 and 665 nm for chlorophyll and 470 nm for carotenoids, respectively (Petrović et al., 2005).

Table 3. Chlorophyll content in the biomass of natural grassland of the order Arrhenatheretalia (mg kg^{-1})

Fertilization	Grasses	Legumes	Other plants	$\overline{x}$
A 0	518	795[b]	1409	907,3
A 1	659	1355[ab]	1523	1179,0
A 2	1665	1497a	1555	1572,3
A 3	1615	1392[ab]	1415	1474,0
$\overline{x}$	1114,2	1259,7	1475,2	

Values marked with different lowercase letters per column differ significantly ($P < 0.05$), according to the LSD test

The values obtained for the share of chlorophyll in grasses show that there are no significant differences between the application of different fertilization variants in relation to the non - fertilized (control) variant. In legumes, the highest chlorophyll content was recorded in variant A2 and differed significantly in relation to the non-fertilized variant (Table 3). In other plants, there are no significant differences between the control variant and the application of different amounts of nitrogen fertilizers.

Table 4. Carotenoid content in natural grass biomass of the order Arrhenatheretalia (mg/mL)

Fertilization	Grasses	Legumes	Other plants	$\bar{x}$
A 0	0,186[b]	0,130	0,400	0,239
A 1	0,432[ab]	1,030	0,170	0,544
A 2	0,383[ab]	0,830	0,950	0,721
A 3	0,812[a]	1,530	0,830	1,057
$\bar{x}$	0,453	0,880	0,730	

Values marked with different lowercase letters per column differ significantly (P <0.05), according to the LSD test

By comparing the values for the content of carotenoids in the biomass of natural grassland of the order Arrhenatheretalia, the fertilization variant A3 shows a significant difference in relation to the control variant (Table 4). By comparing all variants for the obtained values of carotenoids in legumes and grasses, it was also determined that there are no significant differences in relation to the control variant. On average, the highest value was observed in samples of leguminous plants.

Conclusions

On average, the highest phenol content was achieved in grasses. Observing individual values, the highest phenol content in grasses is observed when applying the highest dose of nitrogen, while in legumes the highest content is in the variant without fertilization, which can be related to the fact that legumes, unlike grasses, require the least amount of nitrogen fertilizers due to nitrogen fixation;

Higher content of flavonoids was obtained by using dried plant material, but the content of flavonoids did not change significantly in relation to different levels of nitrogen fertilizers, so it can be concluded that the mineral diet with these doses of nitrogen and constant doses of phosphorus and potassium had no effect on plant antioxidant activity stimulated by flavonoids;

Statistical data processing showed that in legumes only the variant with the applied average dose of nitrogen A2 significantly affected the chlorophyll content in relation to the control variant, while there was no statistically significant difference in the share of carotenoids for legumes and weeds compared to different fertilization variants. Variant A3 differed statistically significantly in terms of chlorophyll content from control and other fertilized variants in grasses of natural grassland of the order Arrhenatheretalia.

Abstract

The study researched the influence of five clonal rootstocks on the sensitivity of flower buds to frost damage during the period of ecological dormancy and production properties of sweet cherry cultivar 'Kordia'. The study was carried out during five years at an orchard located at the experimental estate "Radmilovac" of the Faculty of Agriculture in Belgrade. Cultivar 'Kordia' was grafted on the following rootstocks: 'Gisela 5', 'Gisela 6', 'Ma×Ma 14', 'Colt' and 'Oblačinska sour cherry'. Winter frosts occurred during the ecological dormancy on March 14th and 15th. The intensity of frost was –7 °C. The percentage of damaged and non-damaged flowers per fruiting branches was determined by counting (100 flower buds per tree were taken from each part of the canopy and fruiting branches). The highest damage of flowers buds had trees grafted on 'Oblačinska cherry', (an average 61.2% of flower buds), while the lowest had trees grafted on 'Ma×Ma 14', (an average 12.3% of total flower buds). The significantly higher sensitivity of flower buds had a short fruiting branch compared to long fruiting branch. Trees grafted on 'Colt' had significantly higher values of TCSA (31.2 cm^2). The highest yield per tree cultivar 'Kordia' had grew on rootstock 'Ma×Ma 14', while the lowest had on 'Oblačinska cherry', 6.5 kg and 2.5 kg respectively. The biggest fruits had trees that grew on 'Colt' (12.5 g), while the smallest had trees that grew on 'Gisela 5' (9.8 g). The highest productivity had trees grafted on 'Gisela 5', 'Gisela 6' and 'Ma×Ma 14'.

Key words: *Dormancy, flower bud, frost damage, yield, fruit quality.*

Introduction

Production of sweet cherries has an increasing trend in Europe. In many countries sweet cherry is one of the most popular summer fruits (Dekena et al., 2020). A satisfactory fruit crop in sweet cherry significantly depends on the quality of flowering and fruit set (Dziedzic et al., 2019). Many authors researched the flowering of sweet cherry, especially the differentiation of generative organs, and the effect of rootstock on fruit setting and quality (Zhang et al., 2015; Radunić et al., 2017). One of the key factors in sweet cherry production is the suitability of cultivar-rootstock combinations to local climate conditions, together with soil and growing technologies (Pal et al., 2017). The rootstock used for growing fruit trees affects many traits of trees and fruits, such as tree vigour, flower bud induction and regular bearing (Koutinas et al., 2010), productivity index (Bielicki and Rozpara, 2010), fruit mass (Gratacós et al., 2008), or cracking susceptibility (Brüggenwirth and Knoche, 2016). In the last two decades, the new dwarfing and semi-dwarfing cherry rootstocks for sweet cherry growing enables obtaining high yields of high quality fruit. Many authors were examined following rootstocks: 'Gisela 5', 'Gisela 6', 'Edabriz', 'Pi-ku 4.20', 'Weiroot 72', 'Weiroot 158', 'Weiroot 13', 'Ma×Ma 14' and 'F 12/1' (Gratacos et al., 2008; Usenik et al., 2008; Bielicki and Rozpara, 2010).

The sweet cherry is vigourously growing tree, and because of that requires the use of dwarf growing rootstocks in modern orchards. Clonal rootstocks are mostly used in intensive cherry production, and the most important of them are 'Gisela 5', 'Gisela 6', 'PiKu 1' (Lanauskas et al., 2012: Milatović et al., 2013). A very strong effect of dwarf growing rootstocks was observed on the growth and yielding of sweet cherry cultivars (Usenik et al., 2008). Also, the rootstocks influence the flowering time (Blažkova et al., 2010), the intensity of flowering (Gratacos et al., 2008), fruits quality of sweet cherry (Balmer, 2008), cracking susceptibility. Nevertheless, growers prefer dwarfing rootstocks for producing hand-picked cherries for fresh markets, which allow planting densities of up to 1.000-5.000 trees per hectare (Musacchi et al., 2015). Also, the influence of rootstocks to grafted cultivars is expressed as differences in the efficiency of water usage, advance or delay of flowering, and harvesting, survival and yield efficiency (Cantin et al., 2010). The rootstocks also influence the response of grafted cultivars to low temperature (Hrotko et al., 2009).

Producing sweet cherry in Serbia has a long tradition. But, most cultivars were grafted onto vigorous seedling rootstocks (Prunus *avium* L. and P. *mahaleb* L.). Nevertheless, one of the prerequisites for the successful production of sweet cherries is the testing of new cultivars and rootstocks in climatic and soil conditions before its use on a large scale. The study aimed to examine the influence of different clonal rootstocks on cold hardiness in the ecological dormancy of sweet cherry cultivar 'Kordia' in Belgrade's environmental conditions. Also, the authors examined the influences of those rootstocks on fruit quality and yield of trees.

Material and methods

The study was carried out at a commercial orchard located at the experimental estate "Radmilovac" of the Faculty of Agriculture in Belgrade, in the five growing years (2020). The area has a temperate continental climate with an average annual rainfall of 650 mm. The orchard was established in spring 2016 with high-quality 1-year-old nursery trees. Sweet cherry cultivar 'Kordia' was grafted on five clonal rootstocks ('Colt', 'Gisela 5', 'Gisela 6', 'Ma×Ma 14' and 'Oblačinska sour cherry'). Trees were planted at a distance of 3.5 m × 1.6 m (1.750 trees/ha).

In the study was researched the influence of winter frost on damages of flower buds of the cultivar 'Kordia' grafted on different clonal rootstocks was researched. Winter frosts occurred during the ecological dormancy of sweet cherry, on March 14th and 15th. During the early morning hours temperature was –5°C, and another day –7^{o}C. The sensitivity of flower buds was represented like the percentage of damage and non-damage flower buds per fruiting branches. The study also included the following generative properties: several of flowers per flowers buds on fruiting branches, time of blooming and harvesting, trunk cross-sectional area (TCSA), yield per tree and yield efficiency, the mass of fruit, a diameter of fruit, soluble solids contents (SSC), total sugars (TS), total acids (TA) and sugars/acids ratio (TS/TA).

The experiment was conducted by a random field with four repetitions (100 flowers buds per tree were taken from each part of the canopy and fruiting branches, five trees were taken for a one repeat). The physical properties of fruits were determined with four repetitions, and each repetition included 50 fruits. Chemical properties were determined with three repetitions. Physical properties were determined used standard morphometrics methods. SSC was determined by refractometer (Atago, pocket PAL-1. Kyoto, Japan). TA was determined by titrating 25 g of fruits with 0.1N NaOH up to pH 7.0 and expressed in %. TS, was determined by the Luff-Schoorl method and expressed in %. Analysis of variance has been done with STATISTICA 9 software package. The significant differences between means determined at P<0.05, were measured with the LSD test.

Results and discussions

Grafted rootstock had a significant influence on the sensitivity of flower buds to winter frost (Table 1). The highest percentage of damaged flowers had trees grafted on 'Oblačinska sour cherry' and 'Colt', (on average 61.7% and 45.8% of total numbers of flowers, respectively) while trees grafted on 'Ma×Ma 14' (12.3%) had the lowest. All trees had a higher percentage of damaged flowers on short fruiting branches (SFB) compared to long fruiting branches (LFB). Average to the all cultivars percentage of damaged flower buds on SFB was 41.5%, while on LFB was 29.3%. Trees on 'Ma×Ma 14' only had less than 10% of damaged flowers on LFB. Further, trees grafted on 'Gisela 5' had similar percentage of damaged flowers on both types of branches. Also, the significantly sensitivity of flower buds of sweet cherries cultivar grafted on 'Gisela 5' to the winter frost was recorded by other authors (Milatović et al., 2013).

Table 1. Percentage of damage and number of flowers per generative buds in different fruiting branches of sweet cherry cultivar'Kordia' grafted on different vegetative rootstocks.

	Frost damaged flower buds (%)			Number of flowers per a flower bud	
Rootstock	*SFB (%)	LFB (%)	Average (%)	SFB	LFB
Colt	57.7 a	42.6 a	45.8 a	2.3 b	2.9 ab
Gisela 5	48.5 ab	44.3 a	44.7 a	2.4 b	2.8 ab
Gisela 6	28.4 b	21.4 b	24.6 b	2.5 b	2.5 b
Ma×Ma 14	19.6 b	8.9 c	12.3 b	2.9 a	3.2 a
Oblacinska sour cherry	65.1 a	45.2 a	61.7 a	2.3 b	2.8 ab
Lsd, p <0.05	21.2	11.5	17.3	0.3	0.4

*SFB – short fruiting branch; LFB – long fruiting branch

The rootstocks had a significant influence on flower buds differentiation. The highest number of flowers per a generative buds on SFB had trees grafted on 'Ma×Ma 14' (2.9), while the lowest had trees grafted on 'Colt' and 'Oblacinska sour cherry' (2.3). On LFB trees grafted on 'Ma×Ma 14' had the highest number of flower per buds (3.2), while the lowest had trees on 'Gisela 6' (2.5). All trees had a higher number of flowers per a generative buds in LFB compared to SFB.
The earliest beginning of the blooming had trees grew on 'Oblačinska sour cherry', while trees grafted on 'Ma×Ma 14' had the latest (Table 2). The earliest full blooming stage had trees grafted on 'Oblačinska cherry and 'Gisela 5'. Fruits of the cultivar 'Kordia' had the earliest ripening on rootstocks 'Gisela 5' and 'Oblačinska sour cherry', while trees grafted on 'Ma×Ma 14' had the latest ripening of fruits. The longest period of full blooming to harvesting had trees grew on 'Colt', while shortest on 'Gisela 5' and 'Ma×Ma 14'. The shortest duration of blooming period had trees grew on 'Oblačinska cherry' (13 days), while trees on 'Ma×Ma 14' had the longest (16 days).

The worldwide trends are driven towards controlling tree vigour with dwarfing rootstocks (Ayala and Lang, 2017). Trees grafted on 'Colt' had significantly higher values of TCSA compared to other rootstocks, only trees grew on 'Ma×Ma 14' had similar values. Significantly higher value of TCSA of sweet cherry trees grafted on 'Colt' compared to 'Ma×Ma 14' rootstocks was recorded by Hrotko *et al*. 2009. Cultivar 'Kordia' had the highest yield per tree when grafted on rootstock 'Ma×Ma 14', while the lowest had on 'Oblačinska sour cherry', 6.5 kg and 2.5 kg respectively.

Table 2. Pomological parameters of sweet cherry cv 'Kordia' grafted on clonal rootstocks.

Rootstock	Beginning of blooming	Full blooming	End of blooming	Time of harvest	TSCA (cm^2)	Yield per tree (kg)	Yield efficiency (kg/cm^2)
Colt	01 April	06 April	13 April	01 Jun	31.2 a	3.5 b	0.11 c
Gisela 5	30 March	05 April	11 April.	28 May	21.2 b	5.2 ab	0.25 ab
Gisela 6	31March	06 April	11 April	30 May	24.6 b	6.1 ab	0.25 a
Ma×Ma 14	03 April	10 April	16 April	01Jun	27.3 ab	6.5 a	0.24 a
Oblacinska sour cherry	29 March	05 April	10 April	28 May	13.9 c	2.5 b	0.18 b
Lsd, p<0.05					5.4	2.3	0.05

The highest yield efficiency had trees grafted on 'Gisela 5' and 'Gisela 6' (0.25 kg/cm^2), while statistical significant lower yield efficiency had trees grafted on 'Oblačinska cherry' (0.18 kg/cm^2) and 'Colt' (0.11 kg/cm^2). Cantin et al. (2010), noticed that the highest yield efficiency of trees grafted on 'Gisela 5' and 'Gisela 6' rootstocks was due to its low trunk cross-sectional area. Similar results were obtained by Rubauskis *et al*. (2014). Also, Hrotko et al. (2009) recorded that trees with higher values of TCSA had significantly lower values of yield efficiency, which confirmed in our results.

Table 3. Physical and chemical properties of fruits of cv 'Kordia' grafted on clonal rootstocks.

Rootstock	Mass of fruits (g)	Diameter of fruits (mm)	Soluble solids (%)	Total sugars (%)	Total acids (%)	Sugar/acid ratio
Colt	12.5 a	30.6 a	17.1 ab	14.8 ab	0.9 a	16.4 b
Gisela 5	9.8 b	26.3 b	16.5 b	14.6 ab	0.8 a	18.3 b
Gisela 6	11.8 ab	29.8 ab	17.6 ab	16.1 ab	0.9 a	17.9 b
Ma×Ma 14	11.6 ab	28.9 ab	18.9 a	17.3 a	0.8 a	21.6 a
Oblacinska sour cherry	10.2 b	27.2 b	16.2 b	14.9 b	0.7 a	21.3 a
Lsd, <0.05	2.1	2.2	2.1	1.9	0.2	2.3

The biggest fruits had trees that grafted on 'Colt' (12.5 g), while the smallest had trees that grafted on 'Gisela 5' (9.8 g). According to Whiting et al., 2005, trees on the dwarfing rootstocks had strong tendency to overcrop, resulting in a much lower leaf-to-fruit ratio, and subsequently smaller fruit size and suppressed vegetative growth. Usenik et al., (2008) noticed that higher leaf area per trees affected significantly fruits mass and diameter. Increased yield efficiency and reduced tree volume of sweet cherry on dwarfing rootstocks affected low fruit quality (Usenik et al., 2006). Aglar and Yildiz (2014) recorded that fruits weight varied according to the rootstock used in a study, and the biggest fruits were produced on trees grafted on 'Ma×Ma 14' and 'SL 64' rootstock, while the trees grafted on 'Gisela 5' had the smallest fruit. Rootstock type had a significant effect on the contents of SSC and TA, and a lowest values were found in fruits from the trees which grew on vigour rootstock (Dziedzic and Blaszczyk, 2019) which is not confirmed in ours study. Trees grown on 'Gisela 5' and 'Oblacinska sour cherry' had fruits with the smallest content of soluble solids. It might be due to the lower leaf-to-fruit ratio which caused a decrease in synthesising of carbohydrates. Also, because of the leaf size variability, a source-to-sink ratio of 200 cm^2 leaf area per fruit is the standard lower limit providing fruit mass of 10–12 g (Ayala and Lang, 2017). The highest values of sugars/acids ratio had the fruit of trees grown on 'Ma×Ma 14' and 'Oblačinska sour cherry'.

Conclusion

In a view of the importance of sweet cherry for fruit growers, the determination of the influence of clonal rootstocks on biological and pomological properties to cultivars is very important. The results indicated that cultivar 'Kordia' grafted on 'Ma×Ma 14' and 'Gisela 6' had the lowest percentage of frost damaged flower buds (less than 25%). Also, trees that grew on those rootstocks had higher yield and better physical properties of fruits. The highest values of yield efficiency had trees grown on 'Gisela 5' and 'Gisela 6'. According to present study and obtained preliminary results, a growing of cultivar 'Kordia' on rootstocks 'Ma×Ma 14' and 'Gisela 6' can be recommended to producers of sweet cherries in similar agroecological conditions.

Abstract

The paper presents the two-year results of research regarding the impact of calcium chloride ('Stopit') on changes in morphometric properties of the fruit, firmness and the soluble solids content (SSC) in apple cv 'Red Chief', at harvest and during storage of fruits (60 and 120 days) in the regular cold chamber. Foliar treatments were performed in four replications during vegetation (on June 7th, July 2nd, July 20th, August 15th – in 2018; June 14th, July 5th, July 26th, August 16th – in 2019). The obtained results indicate that fruit weight was significantly influenced by the calcium treatment and storage duration, while fruit dimensions varied under influence of storage duration only. The firmness and content of soluble solids was changing under the influence by all tested parameters and interaction effect of the study year and calcium treatment as well as storage duration. In the first year, fruits had higher weight (190.4 g), dimensions and firmness (12.4 N), whereas the SSC content was significantly higher in the second year of the study (16.2 °Brix). The fruits treated with calcium chloride had higher firmness (10.3 N) and soluble solids content (14.2 °Brix), especially after storage of 60 and 120 days (14.9 and 15.1 °Brix) compared to the soluble solids content in fresh fruits (11.5 °Brix). The stated results were confirmed by the highest values of the SSC recorded in the second year of the study after 60 days of fruit storage (17.9 °Brix). Based on the obtained results, it can be concluded that foliar application of calcium chloride during vegetation can be an effective measure with which losses in quality of apple fruit during storage in the regular cold chamber can be avoided with no negative effect on consumer acceptability.

Keywords: *apple, calcium treatment, morphometric properties, soluble solids.*

Introduction

Apple (*Malus × domestica* Borkh.) is one of the most represented and economically most important fruit species. World apple production in 2019 amounted to 87.236.221 t. In the Republic of Serbia, apple has been grown on (an area of) 26.089 ha, with total production of 499.578 t (Faostat, 2019). In the overall structure of fruit production, apple ranks fourth, behind agrumes, grapes and bananas (Milošević et al., 2019), representing the most important temperate fruit species. Fruits of apple can be consumed fresh immediately after harvest or after a pre-defined storage period (Folta and Gardiner, 2009). They are most often stored for a longer period at low temperatures in a controlled atmosphere. However, during storage, there comes to the fruit quality and nutrient deterioration. Losses in quality are mainly caused by relatively high metabolic activity of the fruit during storage. Sams et al. (2008) report that many physiological and pathological disorders of apple fruit during storage are conditioned by low calcium content (Ca^{2+}) in the fruit tissue. Calcium concentration in plant tissue has an extremely significant role in maintaining fruit quality after harvest. Numerous authors (Hossain et al., 2005; Misra and Gupta, 2006; Naeem et al., 2009) emphasize that application of the calcium based product has positive effects on stabilization of the cell membrane and fruit maturation delay, maintain fruit firmness, reduce occurrence of the so called 'bitter pits' and internal fruit decay. (Raese and Drake, 2002; Dierend and Rieken, 2007; Suljevic et al., 2011). In this regard, all ageing processes flow much faster in the lack of calcium, and fruits have lower storage capacity. There are a number of calcium containing products on the market which can be applied before or after harvest and thus delay fruit maturation with no negative effects on consumers. (Lester and Grusak, 1999). One of the products with which lack of calcium can be prevented or removed, and thus, affect the quality of apple fruit, is 'Stopit', where calcium is in the form of calcium chloride. In the last decades, one of economically most important and demanded apple cultivars on the market is 'Red Chief'. Fruit size, flesh firmness and red skin colour are considered the most important characteristics due to which consumers prefer this apple cultivar (Iglesias et al., 2002). Since apple storage in an atmosphere with utterly low oxygen content (ULO) is expensive and to a larger extent, not available to developing countries, it is important to determine the effect of calcium chloride on changes in the fruit quality of apple cultivar 'Red Chief' stored in normal atmosphere (NA).

Material and Methods

The research was conducted in the period 2018–2019 in the production and experimental plantation of apple cultivar 'Red Chief' at the experimental field of Fruit Research Institute in Čačak (43° 89' 40" SGŠ, 20° 43' 42" IGD, altitude 233 m) in Serbia. The plantation was established in 2006, and the seedlings were grafted at rootstock M9. The training system was (slender) spindle bush and the spacing 4 × 1 m (2.500 trees ha^{-1}). During the research period, standard agro and pomotechnical measures were applied. The research included foliar application of the 'Stopit' product, with concentration of calcium chloride 224 g L^{-1}. Foliar application of fertilizer 'Stopit' was applied on 20 trees in four replications (a total of 80 trees per treatment), from the beginning of June until the middle of August (from the beginning of flowering until the end of maturation phenophase, i.e. from the fruit pigmentation phase until harvest). In both years of research, the product was applied four times, of which in 2018 was on June 7th, July 2nd, July 20th, and August 15th and in 2019, on June 14th, July 5th, July 26th and August 16th. Foliar application was done by a motor sprayer SR 420 (STIHL International GmbH Waiblingen, Germany), with usage of 1.000 L ha^{-1}. The product was applied in the amount of 7,5 L ha^{-1} (150 mL on 10 L water). Trees of apple cultivar 'Red Chief' that were not treated with calcium chloride, served as control. Morphometric properties of the fruit (weight, width, height), fruit firmness and the soluble solids content. The stated parameters were determined at harvest (I) and after 60 (II) and 120 days (III) of fruit storage in a cold chamber with normal atmosphere. Testing of weight (g), height and width (mm), fruit firmness (N), as well as the soluble solids content in fruit (°Brix) were done by standard morphometric methods on a sample of 80 fruits (four replications with 20 fruits each). Fruit weight (g) was determined by measuring on a technical scale (Adventurer Pro AV812M, Switzerland), while fruit length and width (mm) were determined using a digital calliper (Carl Roth, Germany). Fruit firmness was determined by a digital penetrometer (Model FHT-803, Italy), and the obtained values were expressed in N. The soluble solids content in apple fruit was determined using a digital refractometer (Carl Zeiss, Jena) at room temperature (20 °C), and the values were expressed in °Brix. The results were presented as mean ± standard error of mean (SE). Differences between mean values were compared by Duncan's test in a three-way analysis of variance (ANOVA) using MSTAT-C statistical computer package (Michigan State University, East Lansing, MI, USA). Differences with p values of ≤ 0.05 were considered insignificant.

Results and Discussion

Results of studying the influence of year, treatment and duration of storage on morphometric properties, firmness and the soluble solids content in the fruit of apple 'Red Chief', depending on calcium chloride application, were shown in Table 1. By analysis of variance, it was found that all studied parameters were under significant influence of fruit storage duration. The fruit firmness and soluble solids content varied significantly under influence of the year and treatment. Fruit height was changing under the impact of the study year, while fruit weight was changing under the impact of calcium chloride application. Interaction effect of year and treatment as well as the year and duration of fruit storage, exhibited a significant impact on the soluble solids content in the apple fruit.

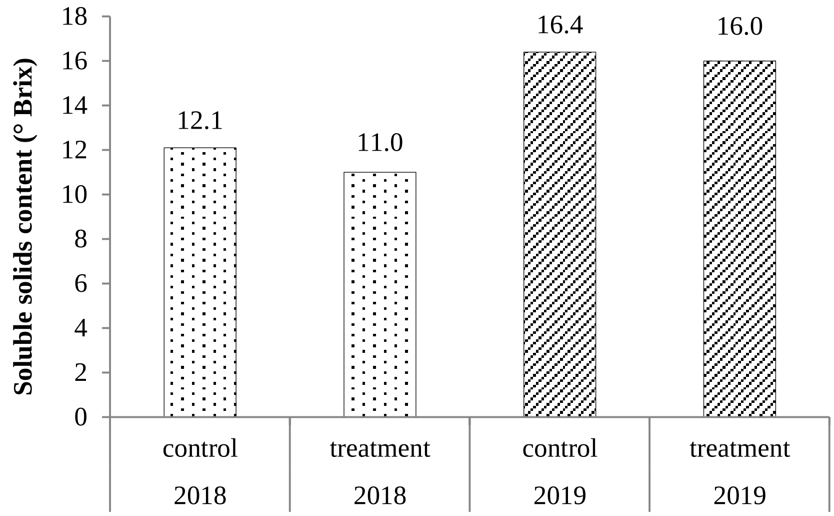
Fruit weight of apple cultivars varies from 70 to 500 g, of which edible part accounts for 98% (Mišić, 1994). According to Mišić (2004), fruits of apple cultivar 'Red Chief' belong to the group of middle large to large (120 – 200 g). Average values of the fruit weight in our research varied from 183.7 to 196.2 g, values of height and width from 67.9 to 70.5 mm, that is, from 73.9 to 76.3 mm, of firmness, from 7.1 to 12.4 N, while the soluble solids content varied from 11.5 to 16.2 °Brix. According to Gvozdenović (1998), fruits of attractive apple cultivars should have fruit dimensions from 65 to 75 mm, which is in accordance with results obtained in our research.

Morphometric properties of apple fruit are genetically conditioned, although their varying could, to a significant extent, be caused by environmental factors (Krgović, 1990; Krpina et al., 2004). In 2018, the fruits had higher values of height (70.5 mm) and fruit firmness (12.4 N) in comparison with those in 2019. On the other side, the soluble solids content was significantly higher in 2019 (16.2 °Brix). Values of fruit weight and width did not vary significantly under the influence of the study year.

Fruit firmness represents one of the significant physical properties, that is, an indicator of fruit ripeness dictating the duration of fruit storage as well as their timely appearance on the market. Apple producers are capable to prolong the time of bringing fruits on the market by keeping them in cold chambers and delaying ripening, i.e. by maintaining the stability of fruit firmness. Fruits treated with calcium chloride had higher firmness (10.3 N) and the soluble solids content (14.2 °Brix) compared to control, while the fruit weight had higher values in the control (192.8 g). Research results obtained in this work are consistent with statements of Asgharzade et al. (2012) that treating apple with calcium chloride before harvest significantly affects the increase of fruit flesh. In addition, Benavides et al. (2002) and Casero et al. (2004) report that their application reduces softening and keeps fruit firmness in apple during storage. Positive effects of calcium chloride application are most likely associated with the calcium content in fractions of covalently bound pectins (Siddiqui and Bangerth, 1995). Moreover, calcium affects stabilization of cell membranes and thus can prevent physiological disorders prescribed to its deficit (Saure, 2005). Influence of the calcium chloride-based product on fruit dimensions was not statistically significant. During the fruit storage, values of the studied parameters were declining and the lowest were recorded after fruit storage for 120 days in a cold chamber with normal atmosphere, except for the soluble solids content. The highest values of weight (196.2 g), height (70.5 mm), width (76,3 mm) and fruit firmness (11.6 °Brix) were recorded at harvest while the highest value of the soluble solids content (15.1 °Brix) was recorded after storage of fruits for 120 days.

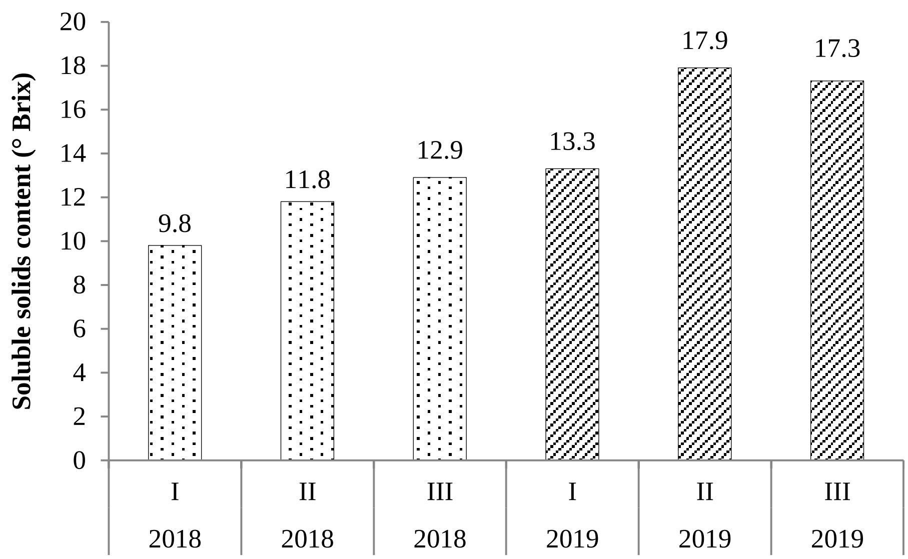
Results of studying the influence of year and calcium chloride treatment as well as the year and duration of fruit storage on the soluble solids content in the fruit of apple cultivar 'Red Chief' were shown in the graphics 1 and 2.

Interaction effects year/treatment and year/storage duration had a significant impact on the soluble solids content in the fruit of apple cultivar 'Red Chief'.



Graph 1. Influence of year and treatment on the soluble solids content in the fruit of apple cultivar 'Red Chief'

Generally, values of the soluble solids content were lower in 2018 compared to those in 2019. Calcium chloride treatment did not significantly affect changes in the content of the soluble solids content compared to control.



Graph 2. Influence of year and storage duration on the soluble solids content in the fruit of apple cutivar 'Red Chief'

In addition, observing the influence of interaction effect of year and storage duration on the soluble solids content, those recorded in the second year of the study can be said to prevail. Fruits analyzed at harvest period had the lowest while the fruits stored for 60 and 120 days in a cold chamber with notmal atmosphere had the highest values of soluble solids in both study years. Also, Netravati et al. (2018) report that after the calcium chloride treatment and apple fruit storage in cold chambers, the soluble solids content increases.

The soluble solids content is one of the most important parameters determining quality, and thus consumer acceptability. It is increased with fruit ripening, representing the basic indicator of apple fruit ripeness. The soluble solids content higher than 11,0% in fruit growing practice is considered the lower threshold of consumer acceptability for an apple cultivar, and if values of this parameter are higher than 13,5%, consumer acceptability is better.

Conclusions

Based on the results obtained, it can be concluded that foliar application of calcium chloride during vegetation can be an efficient measure with which losses in apple fruit quality can be avoided, prior to all in firmness and the soluble solids content, during storage in a cold chamber with normal atmosphere. In this regard, producers may be given some guidelines for enhancement of apple growing technology through application of a calcium-based product, all aimed at obtaining high quality fruits without negative effects on consumer acceptability.

Abstract

Legumes have multiple functions in sustainable agriculture, but also are a favourable ingredient of functional nutrition. Antioxidants in legumes have several beneficial physiological properties and provide protection against chronic diseases. In this study, we compared the antioxidant activities of the seed fractions (outer and inner) for two different legumes: mung bean (*Vigna radiata* L.) and soybean (*Glycine max* L). The antioxidant activity was estimated using a modified DPPH (2, 2-diphenyl-1-picrylhydrazyl) assay in a 96-well microplate. We showed that mung bean hulls possessed significantly higher ($p<0.05$) DPPH free radical scavenging activity (80.80 % ± 0.19) compared to their inner fraction (10.94 % ± 0.23), as well as to both fractions of the soybean. On the other hand, the soybean seeds' inner fractions (21.00 % ± 0.32) exhibited a significantly ($p<0.05$) higher activity than the hulls (8.78 % ± 0.71) and the inner fraction of the mung bean. The obtained results indicated that in each of the two analysed legume species, inner and outer seed fractions exhibited different antioxidant activities regarding to the elimination of the free radicals. The obtained results indicate that antioxidant capacity may be a useful indicator in the estimation of the quality of legume seeds as food and feed.

Keywords: *Antioxidant activity, Soybean, Mung bean, DPPH, Food quality.*

Introduction

Leguminous seeds are considered as significant source of nutrients (proteins, essential amino acids, starch, fibers, minerals, vitamins) but they also, depending on the biological variety of the plants and their origin, contain different bioactive substances including phenolics. Secondary metabolites are involved in protection of the seeds against plant pathogens, wounds caused by insect pests and herbivores, UV radiation and other biotic and abiotic stress conditions (Yusnawan et al. 2019). Antioxidant activity of various phenolic compounds from legume seeds (flavonoids, alkaloids, tannins, phenolic acids) is important both from nutritional and technological points of view (Amarowicz and Pegg 2008). Legumes are excellent functional food ingredients and a great dietary source of antioxidants due to their nutrient composition (Ganesan and Xu, 2018). Health benefits related to antioxidants contained in edible food sources include reduced risk and prevention of developing major chronic diseases such as cancer, diabetes or cardiovascular diseases (Singh et al. 2017). Phenolic antioxidants and polyphenols, that protect the seeds against the harmful effect of oxygen free radicals, are typically present in high content in seed hulls. Mung bean seeds are consumed as a whole or after separation the hulls while soybean seed hulls are usually discarded as a byproduct. This biowaste has a high polyphenol content which could be extracted and used as nutraceuticals, a source of natural antioxidants, or used as animal feed (Singh et al. 2017).

Mung bean (*Vigna radiata* L.), a summer cultivated legume widely distributed and consumed throughout Asia, has a high nutrient value comparable to that of soybean (*Glycine max* L) (Shi et al. 2016; Orak et al. 2018). Mung bean also contains bioactive food components and polyphenols which possess a high antioxidant capacity (Orak et al. 2018). Soybean is an annual self-pollinated diploid leguminous plant, predominantly grown for use in human and animal diet and as a major source of protein and oil (Gaonkar and Rosentrater 2019). Aside from the nutritional value, soybean contains isoflavones and certain phenolic compounds (Wang and Komatsu 2017). The antioxidant potential of soybean has also proven to have health benefits, especially in their seed coat (Peiretti et al. 2019).

In the present study, differences in antioxidant capacity between two seed fractions (inner and outer) of the two different legume species, soybean and mung bean, were examined. Aqueous-ethanol extracts of both seeds and hulls were examined for their respective radical scavenging activity with DPPH (2,2-Diphenyl-1-picrylhydrazyl) reagent. In a reaction with antioxidants, DPPH is reduced to DPPH-H while the color changes from purple to yellow and the decrease in absorbance maximum at 517 nm is spectrophotometrically detected (Khan et al. 2017).

Material and Methods

Sample preparation

Soybean and Mung bean were purchased from the local market in Belgrade, Serbia. Seed hulls have been separated from the seed endosperm before homogenization, and considered as outer fractions. The rest of the seed (endosperm and embryo) was the inner fraction. Both fractions of the seed were grinded separately in a mill. The samples were further powdered in a mortar with pestle with liquid nitrogen and stored in the dark at 5 ± 3 °C until use.

DPPH Assay

Antioxidant activity (AA %) of both legumes (mung bean and soybean) seeds and hulls, was carried out separately using DPPH (Sigma-Aldrich, St. Louis, MO, USA) test (Khan et al. 2017). Compared to the original method, described by Khan et al. 2017, the procedure was modified in terms of absorbance measurement; smaller sample volumes were required since a microplate reader was used instead of UV/VIS Spectrophotometer. This method enables rapid analysis and possibility of screening a large number of samples.

Powdered samples (8 mg) were extracted with 3 ml of 70 % ethanol. To each sample, 1 ml of freshly prepared 0.4 mM DPPH solution in 96 % ethanol was added to a final concentration of 0.1 mM. After 30 minutes of incubation with constant shaking in the dark, 200 μl aliquots were taken and absorbance at 517 nm was measured using a UV-VIS microplate reader (Tecan Infinite M Nano+, Switzerland). Blank consisted of pure deionized water without any additions. Control contained 0.1 mM DPPH in 96 % ethanol solution. Antioxidant activity was calculated using the following equation (Khan et al. 2017):

$$A\ \% = 100 - \left(\frac{A_{sample} - A_{blank}}{A_{control}}\right) \times 100$$

The results were presented as a percentage of depleted DPPH-reagent. Readings were carried out in four replicates for each analysed seed fraction and, based on obtained data, the standard error was calculated. Mann-Whitney sum rank test has been used for statistical analysis of the obtained results.

Results and Discussion

Images of mung bean and soybean seeds are shown in Figure 1. The obtained results indicate that mung bean seed coats possessed significantly higher ($p<0.05$) DPPH radical scavenging activity, according to Mann-Whitney test ($p=0.021$), 80.80 % ± 0.19, compared to their inner fraction of the seed being only 10.94 % ± 0.23 (Figure 2). Our results are consistent with previously reported studies showing that mung bean hull contained higher antioxidant capacity compared to the inner fraction of the seed (Singh et al. 2017). Pigmented grain such as mung bean contains a higher concentration of secondary metabolites especially in the seed coat. These phytochemicals contributing to antioxidant activity, such as phenolic acids and flavonoids (flavones, flavonoids, isoflavone, and isoflavonoids), are distributed unevenly through the seed fractions (Yusnawan et al. 2019). Some of the major polyphenols (caffeic acid, syringic acid, chlorogenic acid, ferulic acid and *p*-coumaric acid) have been detected in mung bean (Singh et al. 2017). Furthermore, water-soluble polysaccharides (containing mannose, rhamnose, and galactose) from mung bean hulls exhibit high DPPH radical-scaveninging activities (Ganesan and Xu, 2018).

Figure 1. Image of mung bean (left) and soybean (right) seeds.

Figure 2 shows antioxidant activity (AA %) of both inner and outer fractions of soybean. Soybean seeds' inner fraction showed a significantly higher antioxidant activity compared to the soybean seed coats, 21.00 % ± 0.32 and 8.78 % ± 0.71, respectively. These results are in accordance with Lim et al. (2021), who showed higher antioxidant activity in cotyledon compared to the seed coat.

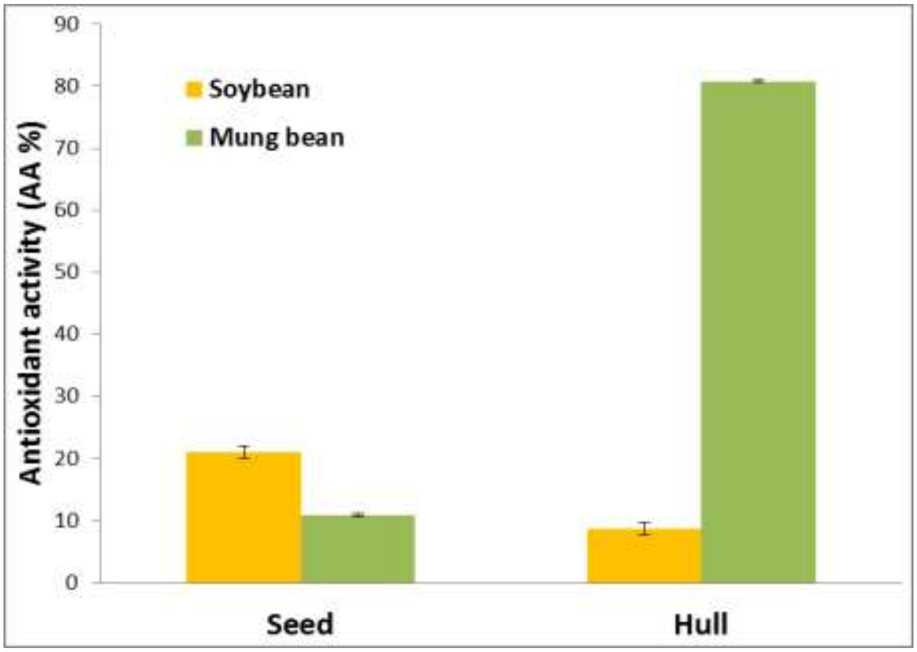

Figure 2. Antioxidant activity (AA %) of both inner and outer fractions of soybean and mung bean. Each value is expressed as the means out of 4 replicates with standard error.

Conclusions

The obtained results indicate that comparing the two analysed legumes, the highest antioxidant capacity was exhibited in the mung bean hulls, almost 10 times higher than the activity of the same seed fraction of soybean. Each of the analysed legume seed fractions had a different antioxidant capacity. Antioxidant activity may be a reliable indicator of seed quality. Efficient radical scavenging activity of the outer fraction of the mung bean suggests that this legume may be evaluated as a functional food ingredient. The seeds possessing higher antioxidant potential could be suggested as a better food source due to their health benefits. The growing interest in the functional properties of mung bean and soybean has focused the attention of research studies towards bioactive compounds and their health benefits.

Abstract

The objective of this study was the isolation and characterization of *Azotobacter*, *Pseudomonas* and *Bacillus* species from the rhizospheric soil of *Mellisa officinalis* and to examine the effect of isolates application on the seed germination and seedling growth. Isolation, physiological, biochemical, and plant-growth-promoting activity characterization of isolates were done. Monitoring the effects of isolates application on seed germination and seedling growth were evaluated in controlled conditions. The number of germinated seeds, the shoot and root length of seedlings, vigour index and biochemical stress markers (lipid peroxidation intensity and total phenols) were measured. From the rhizosphere of plant 2 *Azotobacter* (denoted as A5 and A6), 5 *Pseudomonas* (denoted as P27, P28, P29, P55 and P56) and 6 *Bacillus* (denoted as B64, B65, B66, B67, B68 and B69) bacteria were isolated. *Azotobacter* isolates showed the ability to live in the condition of low (5) and high (9) pH. The isolates varied in terms of the utilization of carbon sources. Both isolates produced pectinase, hydrogen cyanide (HCN) and utilized organic and inorganic phosphorus. *Pseudomonas* isolates had optimal growth at 10 ºC and 37 ºC, and on medium with pH 5 and 9. All *Pseudomonas* isolates could produce pectinase, lipase, amylose, IAA, siderophores and HCN. All *Bacillus* isolates could grow on a medium containing 7% NaCl. Two isolates (B65 and B67) showed intensive growth on medium with pH 9. Only two isolates (B64 and B67) produced IAA, and all of them siderophores and HCN. *Bacillus* isolates (B64 and B67) increased, while other isolates reduced stress which was observed by lowering the amount of stress molecules in seedlings. The best effect on the seed germination had *Pseudomonas* (P28) and *Bacillus* (B65, B66) isolates. *Azotobacter* isolates had the greatest stimulatory effect on seedling growth.

Key words: *medicinal plants, plant-growth-promoting microorganisms, seedling, total phenols.*

Introduction

The interaction between plants and microbes occurs in three different layers: endosphere, phyllosphere, and rhizosphere. The region of contact between root and soil is rhizosphere. Plant growth-promoting rhizobacteria (PGPR) are bacteria colonizing rhizospheres of plant and enhance plant growth and plant resistance to biotic and abiotic stresses through various mechanisms, such as nitrogen fixation, solubilization of phosphate, production of phytohormones, siderophores, antibiotics, enzymes, etc. (Bhattacharya and Jha, 2012; Etesami and Beattie, 2017). PGPR include many genera and species, among which bacteria belonging to the genera *Bacillus*, *Azotobacter*, and *Streptomyces* are well known for colonizing plant roots and stimulating plant growth (Adesemoye *et al.*, 2008).

Bacillus is the most widespread genus of bacteria in the rhizosphere. In the rhizospheric soil of different plants, *B. subtilis, B. mycoides, B. pumilus, B. megaterium, B. thuringiensis* and *B. firmus* are the most present species of this genus (Garbeva *et al.*, 2003). These bacteria are known to synthesize a large number of secondary metabolites that affect their environment, thus increasing the availability of nutrients to plants (Barriuso and Solano, 2008). Bacteria of the genus *Bacillus* increase the yield and growth of various plants (Mumtaz *et al.*, 2017; Gontia-Mishra *et al.*, 2017). It was reported that *Bacillus* isolates promoted pepper growth and tolerance to drought stress (Lim and Kim, 2013). *Bacillus* sp. isolated from the rhizosphere of green tea (*Camellia sinensis*) had the ability to produce IAA and thus stimulated plant growth (Chakraborty *et al.*, 2006). In addition to providing essential nutrients for plants, some *Bacillus* sp., known as selenobacteria, can remarkably increase the accumulation of selenium in plants (Eswayah *et al.*, 2016; ul Abadin *et al.*, 2017)

Pseudomonas species are gram-negative bacteria, whose PGP activity has been well known for many years (Lucas *et al.*, 2004). The distribution of this genus is very high. Many species have been isolated from the rhizosphere of various plants, from different soils, and also from ponds, wastewater, and even food. Some species of this genus produce metabolites such as antibiotics, hydrogen cyanide (HCN) and IAA (Kim *et al.*, 2014), some produce high-affinity siderophores, and exopolysaccharides (Rolli *et al.*, 2015). All these metabolites strongly influence the environment, by inhibiting the growth of certain harmful microorganisms, and on the other hand, by increasing the availability of nutrients to plants. According to the results of Rokhzadi *et al.* (2008), the application of *Pseudomonas fluorescens* had positive effects on pea growth and yield, while Menhaz *et al.* (2009) found a positive influence of these bacteria on fresh and dry sugar cane mass.

Azotobacter is a group of Gram negative, free-living, nitrogen fixing aerobic bacteria. According to many studies, bacteria of the genus *Azotobacter* synthesize auxins, cytokinins, and giberelin acid-like substances that have been found to be directly associated with improved plant growth (Wani *et al.*, 2013). *Azotobacter* species are able to convert atmospheric nitrogen to ammonia, which can be utilized by the plants (Prajapati *et al.*, 2008). In addition to its beneficial impact on plant growth, *Azotobacter* strains are also known to be associated with the suppression of pathogenic diseases of plants (Wani *et al.*, 2013).

The investigation of microorganisms from the rhizosphere of medicinal plants is very significant because these microorganisms have a great impact on plant growth and on the yield quality of the medicinal herbs (Bafana and Lohiya, 2013). For this reason, the objective of this study was the isolation and characterization of *Azotobacter*, *Pseudomonas* and *Bacillus* species from the rhizospheric soil of *Mellisa officinalis* and to examine the effect of isolates application on the seed germination and seedling growth.

Material and methods

Microorganisms were isolated from rhizospheric soil of *Mellisa officinalis*, from chernozem.

A Gram-negative, rod-shaped cell that synthesize pigment fluorescein, were chosen as *Pseudomonas* isolates. A catalase and Gram-positive, rod-shaped cells that create endospores were selected as *Bacillus* isolates. Isolates which were stated as Gram-negative, coccoid-shaped cell that synthesize large quantities of capsular slime and could grow on N-free medium were selected as *Azotobacter* isolates.

The *Pseudomonas, Bacillus* and *Azotobacter* isolates were incubated at different temperatures (3, 13, 37 and 45 °C), pH levels (4, 5, 6, 9), and salt concentrations (5 and 7%), for 4 days, on the following growth media: King-B, Nutrient agar, and N-free medium, respectively. The colony width of each isolate was measured and compared to a colony of the same isolate grown in optimal conditions (at 28 °C, pH 7 and salt concentration 3%). Based on the comparison, the growth of isolates was described as: - absence of growth; + minimal growth; ++ optimal growth; +++ intense growth.

Utilization of carbon sources was tested using Hugh-Leifson medium with different carbon source (glucose, fructose, lactose, sacharose, galactose). In the case of a positive reaction, the colour of medium around the isolates colony changed from greenish to yellow.

Lipase production was performed on medium (pepton 10g l^{-1}, NaCl 5g l^{-1}, $CaCl_2$x H_2O 0,1g l^{-1}, agar 15g l^{-1}) with Tween 80 addition. Formation the cloudy zones around the colony are evidence of lipolytic activity. Starch hydrolysis was assayed on starch agar, following the protocol as reported by Cappuccino and Sherman (1992).

Production of pectinase was tested on pectin agar. Incubation lasted 24 h at 37 °C, after which colonies overflowed with lugol. The appearance of uncolored zones around the colony is evidence of pectinase activity (Soares *et al*., 2001).

Cellulase production was performed by flooding a solution of Congo-red (1mg cm^{-3} H_2O) on isolates grown on CMC agar (Kasing, 1995). The presence of halo zone around the colony was the proof of the cellulose decomposition. Investigation of indol-3-acetic acid (IAA) production by bacterial isolates was observed using Etesami *et al.* (2015) method. Isolates capability to produce the siderophores was examined on chrom-azurol S (CAS) medium (Milagres *et al.*, 1999).

Isolates were screened for PGP activities on HCN induction medium (Tryptic Soy Broth 30 g l^{-1}, Glycine 4.4 g l^{-1}, agar 15 g l^{-1}) for HCN production (Frey-Klett *et al*., 2005).

Bacterial ability to solubilize sparingly soluble Ca_3 $(PO_4)_2$ was examined on Pikovskaya (1948) medium. Phosphate solubilization was confirmed by transparent zone around isolates colonies.

The ability of the mineralization of phosphorus organic compounds was assayed on Menkina medium (Menkina, 1961). The appearance of clear zone around the colony indicate the ability of isolate to dissolve phosphate.

Evaluation of isolates for their plant growth-promoting (PGP) potential on plant

The effect of selected isolates on seed germination and initial growth of *Mellisa officinalis* was examined in controlled conditions. Fifty seeds inoculated with the appropriate bacteria were placed on filter paper at 22ºC on germination. After three days, the number of germinated seeds were determined. The shoot and root length of germinated seeds were measured after seven and ten days. Vigour index and biochemical stress markers (lipid peroxidation intensity and total phenols) were measured after ten days. The vigour Index (VI) was calculated as: VI (%) = (mean root length + mean shoot length) × germination %.

The intensity of LP is determined based on the MDA content extracted from fresh plant material using a mixture of 2-Thiobarbituric acid (TBA) and Trichloroacetic acid (TCA) (Jambunathan, 2010). Total phenols in methanol extracts of seedlings were determined based on the reaction of phenols with Folin-Ciocalteu reagent (Makkar *et al.*, 2007).

Statistical analysis

The data were statistically processed using the Statistics 13.3 software (TIBCO Software Inc.). The significance of the difference between the applied treatments was determined using Fisher's LSD test.

Results and discussion

Based on the morphological description of colony and cells, from the rhizospheric soil of *Mellisa officinalis,* five isolates from the genus *Pseudomonas*, six isolates from the *Bacillus* and two isolates from *Azotobacter* genus, were isolated. *Pseudomonas* isolates were denoted by letter P, *Bacillus* isolates by B, and *Azotobacter* isolates by letter A. Physiological and biochemical properties of the isolates are presented in Table 1.

Table 1. Growth of isolates at different temperature, pH, NaCl levels, and with various source of carbon

Isolates	Temperature (°C)					pH				NaCl (%)		Source of carbon				
	3	10	28	37	45	4	5	6	9	5	7	L[b]	F	G	S	Ga

Legend: [a] - absence of growth; + minimal growth; ++ optimal growth; +++ intense growth; [b] L- lactose; F- fructose; G- glucose; S- sacharose; Ga- galactose

According to Wang *et al.* (2014), temperature is one of the most frequent abiotic stress factors that influence plant growth and microbial activity very strong and adversely. In this study, optimal growth for all isolates was detected at 28 ºC. Almost all isolates could grow at 10 and 37 ºC, but non at 3 and 45 ºC.

The optimum pH for growth of vast majority of the isolates was 6 and 9, while two *Bacillus* isolates, denoted as B65 and B67, had intense growth at pH 5. It is especially interesting that *Azotobacter* isolates had minimal growth in acidic and alkaline conditions. Previous research on *Azotobacter* isolates show that they are very sensitive and not able to survive low and high pH values (Jnawali *et al.*, 2015).

On medium containing 7% NaCl, minimum growth was observed for all *Bacillus* isolates, and three *Pseudomonas* isolates (P27, P28, P29). *Azotobacter* isolates, could not grow on medium containing these amounts of NaCl. The isolates varied in terms of utilization of carbon sources such as lactose, fructose, glucose, sacharose and galactose. The ability of *Pseudomonas* and

Bacillus strains to grow at extreme pH values and temperatures and at high concentrations of NaCl is reported by Karagoz *et al.* (2012). According to the same author, metabolic diversity allows these bacteria to adapt to adverse environmental conditions. The results of this work indicate the adaptability of these isolates, especially *Bacillus* isolates, showing that they have a good ability to survive under different environmental conditions. *Azotobacter* isolates showed the weakest adaptability to different abiotic factors.

Important traits of PGPR, that may directly and indirectly influence the plant growth, is the production of different kind of enzymes, phytohormones, siderophores, hydrogen cyanide (HCN), and ability to solubilize compounds of phosphorus (Beneduzi *et al.*, 2012; Shameer and Prasad, 2018). In this study it was found that all isolates have good PGP potential (Table 2.).

Table 2. Plant-growth-promoting properties of the isolates

Isolates	Lytic enzyme production[a]				Plant growth promoting traits				
	Lipase	Amyl	Pectinase	Cellulase	IAA[b]	Siderophore[c]	HCN[d]	Phosporus[e]	
								organic	inorganic
P27	-	+	+	-	+	8	+	-	++
P28	+	+	+	-	+	6	+	-	-
P29	++	+	+	-	+	3	+	-	-

A6	-	-	+	-	-	-	+	++	++

Legend: [a] Lipase, amylase (Amyl), pectinase, cellulase activities: + hydrolysis; - no hydrolysis; [b] Production of indole-acetic acid: - not detected; + IAA production; [c] Production of siderophores; width of orange zone; - no zone; [d] Production of HCN; + HCN production, – not detected; [e] Mineralization of phosphorus organic compounds and phosphate solubilization- evaluated according to zone diameter: + represents 4mm/day (weak activity); ++ represents 5-8mm/day (moderate activity) +++ ≥8mm/day (high activity)

All *Pseudomonas* isolates showed the ability to produce amylase and pectinase, IAA, siderophore and HCN. Only one isolate (P55) could produce cellulose. Among *Bacillus* isolates, all isolates had the ability to produce siderophore, HCN and to solubilize phosphorus organic compounds. No isolate had the ability to produce amylase and cellulase. *Azotobacter* isolates could produce pectinase, HCN, and had the ability to do mineralization of phosphorus organic compounds and phosphate solubilization. Similarly to our results, several studies demonstrated the *Bacillus*, *Pseudomonas* and *Azotobacter* isolates ability to produce biologically active substances that promote plant growth (Khan and Joergensen, 2009; Suresh *et al.*, 2010; Ahmad *et al.*, 2012; Alina *et al.*, 2015).

In this study, the applied inoculants had different effects on the seed germination, and on the root and shoot length (Table 3.). The highest percentage of germination (86%) was found in the variant in which isolate *Bacillus* sp. B69 was applied, while in the variant with *Bacillus* sp. B67, germination percentage was the lowest (60%).

Table 3. The effect of selected isolates on seed germination, root and shoot length and vigour index (VI)

Isolates	Seed germination (%)	No. of germinated seeds (out of 50 seeds)	Root length (mm)		Shoot length (mm)		VI (%)
			7 days	10 days	7 days	10 days

* The different letter above the number indicates significant difference at $P<0.05$ according to Fisher`s test

Application of all *Bacillus, Pseudomonas* and *Azotobacter* isolates, compared to the control, had a positive effect on the number of germinated seeds. This result is in accordance with Shaukat *et al.* (2006), where the introduction of *Azospirillum*, *Azotobacter* and *Pseudomonas* in the rhizosphere of sunflower and wheat had a positive effect on the germination and the length of the seedlings. Also, Niranjan *et al.* (2004) reported that the application of *P. fluorescens* had a positive effect on germination of millet grains.

After seven days, the greatest impact on the root length had the application of *Azotobacter* isolates, while on the shoot length the best results were achieved with *Bacillus* isolates (B64, B69). Application of *Azotobacter* isolates and *Pseudomonas* sp. P28, after ten days, had the greatest effect on root length. After ten days, all *Bacillus* and *Azotobacter* isolates positively affected shoot length. The highest VI was detected in variant where isolate B68 was applied. *Pseudomonas* isolate, denoted as P56, negatively acted on the root and shoot length. Similarly to this, Heydari *et al.* (2008) determined the inhibitory effect of the *Pseudomonas* isolates on the germination, and seedling growth of wheat and rye. However, there are more studies whose results confirm the positive effect of microorganisms application, especially of the genera *Bacillus*, *Pseudomonas* and *Azotobacter*, on the germination, initial growth and yield parameters of different plants (Khaosaad *et al.*, 2006; Arpanahi *et al.*, 2019; Mohammadi *et al.*, 2018).

According to Yasmin *et al.* (2019), the PGP microorganisms play an important role in promoting tolerance of plants to abiotic stresses. The total phenols and the intensity of lipid peroxidation indicate the plant response to stress. Higher values of these two parameters mean greater possibility that the cell is in oxidative stress. When the values obtained in the variants with the applied isolates were compared with the values obtained in the control variant, it was found that all isolates, except B67 and B64, reduced stress by lowering the amount of stress molecules, while these two isolates increased it (Figure 1.).

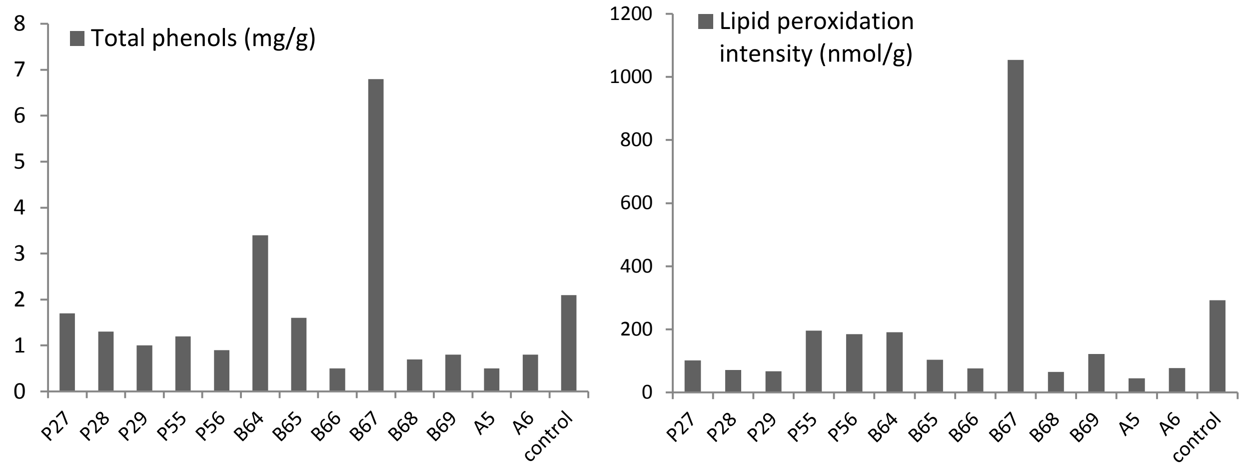

Figure 1. The effect of isolates on biochemical stress markers

Kumar *et al.* (2016) examined the influence of PGPR on the levels of total phenols and the intensity of lipid peroxidation in chickpea. The results showed that the application of PGPR reduced the stress molecules levels in plants, which is in accordance to our study.

Conclusions

Having great PGP traits, all isolates, except one, showed good PGP potential. The isolates that stand out are *Bacillus* isolates B64, B68, B69, and *Pseudomonas* isolates P27 and P29.
Bacillus isolates (B64 and B67) increased, while other isolates reduced stress which was observed by lowering the amount of stress molecules in seedlings.
The best effect on the seed germination had *Pseudomonas* (P28) and *Bacillus* (B65, B66) isolates. *Azotobacter* isolates had the greatest stimulatory effect on seedling growth. Isolate P56 negatively affected root and shoot length.

Abstract

Almond production in Serbia is very small. The main reason for this is the frequent occurrence of late spring frosts during flowering. Present study was carried out to evaluate phenological characteristics (flowering and maturity times), productivity, and characteristics of the nut and the kernel (nut weight and dimensions, shell thickness, weight of kernel, kernel share, oil and protein contents) in 13 almond genotypes of a different origin growing in the region of Belgrade. The average flowering time was the second half of March and the first decade of April. The flowering began first in 'Nessebar', 'Selection 25', and 'Tétényi kedvenc' (16th of March), and latest in 'Francoli', and 'Texas' (29th of March). Beginning of the fruit maturity was recorded in the range of 13 days, from August 15th ('Tétényi bőtermő' and 'Tétényi keményhéjú') to August 28th ('Glorieta'). The average productivity was the lowest in 'Glorieta' and 'Francoli' and the highest in 'Tuono'. In March 2017 late spring frost that significantly reduced yield in early flowering cultivars was recorded. Nut weight ranged from 1.95 g ('Budatétény') to 5.58 g ('Marcona'). Shell thickness varied from 1.71 mm ('Budatétény') to 5.06 mm ('Marcona'). Kernel weight was the lowest in 'Selection 25' (0.80 g) and 'Tuono' (0.81 g), and the highest in 'Texas' (1.30 g). Kernel share was the lowest in 'Selection 25' (16.03%), and the highest in 'Budatétény' (57.93%). Oil content ranged from 44.35% ('Glorieta') to 57.52% ('Budatétény'), and protein content ranged from 21.72% ('Budatétény') to 30.51% ('Selection 25'). Obtained results indicate that Belgrade region is suitable for growing of late flowering almond cultivars.

Keywords: *Prunus dulcis, flowering, maturation, productivity, nut and kernel characteristics.*

Introduction

Almond [*Prunus dulcis* (Mill.) D.A.Webb syn. *Prunus amygdalus* (L.) Batsch] is a species of genus *Prunus* and subgenus *Amygdalus* (*Rosaceae,* subfamily *Prunoideae*). It originated from Central Asia and dispersed through cold and xeric environments in the mountainous areas and deserts of western China into Iran (Watkins, 1976). Over the time, the almond culture has extended to colder areas. In the winter rest period, the almond can tolerate temperature of -20 to -24°C, thus it is also grown in countries with a more severe climate, such as Hungary, Czech Republic, Bulgaria and Romania (Bulatović, 1985). Almond cultivation in Serbia is limited to a small number of locations, including Slankamen Hill (Čolić and Zec, 2007; Čolić et al., 2009). Due to early flowering and a weak growing tradition, Serbia has very small areas under almonds. Commercial almond production in Serbia is low considering the demand and economic potential. In Serbia, except early-flowering cultivars, in the experimental trials are also present late-flowering cultivars, which bloom after apricot cultivars (Zec et al., 1999). The most intensive studies were performed on the almond population in the area of Slankamen hill (Čolić and Zec, 2007; Čolić et al. 2009, 2012), while Zec et al. (1999) and Milatović et al. (2013, 2017) evaluated agronomic characteristics of introduced almond cultivars grown in the area of Belgrade. The aim of this study was to evaluate phenological traits, yield and fruit characteristics of 13 almond cultivars originated from several European countries. The best performing cultivars will be recommended for growing in the region of Belgrade, as well as in other regions with similar environmental conditions.

Materials and methods

Study was carried out in the almond orchard at the experimental station 'Radmilovac' of the Faculty of Agriculture in Belgrade, in the period 2017 - 2019. The orchard was planted in 2014. The study included 12 introduced almond cultivars: 'Budatétény', 'Tétényi bőtermő', 'Tétényi kedvenc', 'Tétényi keményhéjú' and 'Tétényi rekord' from Hungary; 'Francoli', 'Glorieta', 'Marcona' and 'Masbovera' from Spain, 'Nessebar' from Bulgaria; 'Texas' from USA; 'Tuono' from Italy and 'Selection 25' from Serbia. All cultivars were grafted on the clonal rootstock 'GF 677' and were represented with five trees. Training system is open vase, and planting distance is 5 × 3.5 m. Flowering was monitored according to the recommendations of the International Working Group for Pollination: beginning of flowering - when 10% of flowers open, full flowering - 80% of open flowers, and the end of flowering - when 90% of petals fall off (Wertheim, 1996). The samples of 30 fruits per tree were randomly harvested at full maturity (hulls fully desiccated and opened along the suture). Yield was determined by ranking from 0 to 5. Nut and kernel length, width and thickness were measured with a digital calliper, whereas nut and kernel were weighted on a digital scale. Kernel/nut ratio was expressed as a percentage. The oil content was determined by extraction with petroleum ether in a Soxhlet apparatus (Faithfull, 2002.). The nitrogen content in the kernel was determined by the Kjeldahl method, and the content of crude protein was obtained by calculation, multiplying by a factor of 5.18 (Faithfull, 2002). The data for nut characteristics were statistically analyzed using analysis of variance. The significance of differences between mean values was determined using Duncan's multiple range test at 0.05 level of probability.

Results and discussion

Almonds are characterized by a short period of deep winter dormancy and early flowering time. Almond bloom lasts 5 to 25 days depending on the cultivar, rootstock and the temperature (Bulatović, 1985). In our study significant differences in flowering time were observed (Table 1). Cultivars 'Nessebar' and 'Tétényi kedvenc' as well as 'Selection 25' began to bloom the earliest (March 16th) whereas the cultivars 'Francoli' and 'Texas' had the latest (March 29th) beginning of flowering. Zec et al. (1999) recorded that the cultivar 'Texas' in the conditions of the Pančevo started to bloom on April 5th. A significant difference in the flowering time could be influenced by micro location and climate change. The difference between the earliest and the latest flowering time was 13 days which is five days shorter compared to the results obtained by Milatović et al. (2017). Segura et al. (2017) state that almonds have the widest range of flowering time among of all fruit and nut trees. Almond nuts are ready for harvesting when the hull separates from the shell easily. Hungarian cultivars 'Tétényi bőtermő' and 'Tétényi keményhéjú' had the earliest harvesting time (August 15th). The latest harvesting time was recorded for 'Glorieta' (August 28th). Cultivars 'Marcona' and 'Texas' also had a late ripening time (August 27th), only one day before 'Glorieta'. All the observed cultivars were harvested prior to autumn rains. According to Zec et al. (1999) cultivars 'Marcona' and 'Texas' under the conditions of Pančevo had an average ripening time 7 days later in comparison with the obtained results. Observed differences were caused by the location climate differences.

Table 1. Phenological characteristics and productivity of almond genotypes (2017-2019 average).

Genotype	Origin	Start of flowering	End of Flowering	Duration of flowering (days)	Date of harvest start	Yield (0-5)*
Budatétény	HUN	March, 18	April, 1	14	August, 16	3.3
Francoli	ESP	March, 29	April, 12	14	August, 23	3.0
Glorieta	ESP	March, 26	April, 8	13	August, 28	3.0
Marcona	ESP	March, 23	April, 5	13	August, 27	3.8
Masbovera	ESP	March, 25	April, 8	14	August, 23	3.5
Nessebar	BGR	March, 16	March, 29	14	August, 18	3.8
Selection 25	SRB	March, 16	March, 30	15	August, 18	3,7
Texas	USA	March, 29	April, 11	13	August, 27	4.0
Tétényi bőtermő	HUN	March, 19	April, 2	14	August, 15	3.3
Tétényi kedvenc	HUN	March, 16	March, 29	13	August, 17	3.5
Tétényi keményhéjú	HUN	March, 17	April, 1	14	August, 15	3.8
Tétényi rekord	HUN	March, 20	April, 3	14	August, 18	3.2
Tuono	ITA	March, 24	April, 6	13	August, 24	4.5

*Scale: 0-without yield, 1- very low, 2-low, 3-good, 4-very good, 5-high.

The average yield was the lowest in 'Glorieta' and 'Francoli' (score 3.0) and the highest in 'Tuono' (score 4.5). In March 2017 late spring frost was recorded, which significantly reduced yield in early flowering cultivars. The majority of the tested cultivars (7) had medium yield, above 3.5.

Table 2. Characteristics of the nut of almond genotypes (2017-2019 average)

Genotype	Weight (g)	Length (mm)	Thickness (mm)	Width (mm)	Shell thickness (mm)
Budatétény	1.95 d	35.7 ab	17.8 b	12.3 d	1.71 e
Francoli	3.53 cd	34.3 abc	20.7 b	15.3 bc	3.80 c
Glorieta	4.98 a	38.9 a	24.8 a	17.8 a	4.70 ab
Marcona	5.58 a	31.5 bc	25.4 a	18.4 a	5.06 a
Masbovera	4.30 b	38.2 a	24.8 a	17.8 a	4.06 bc
Nessebar	2.30 d	30.9 bc	18.6 b	12.4 d	2.48 de
Selection 25	5.00 a	35.1 ab	20.8 b	15.2 bc	3.79 c
Texas	3.92 bc	32.6 bc	19.3 b	12.8 cd	3.63 c

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at P≤0.05.

Data for nut characteristics (Table 2) showed large differences for the weight, dimensions of the nut and shell thickness. The fruit weight varied from 1.95 g ('Budatétény') to 5.58 g ('Marcona'). The highest values of the nut dimensions were recorded in 'Glorieta' and 'Marcona'. The 'Tuono' had the smallest fruit length, while the width and thickness of the nut were smallest in 'Budatétény'. The shell thickness varied from 1.71 mm ('Budatétény') to 5.06 mm ('Marcona').

Table 3 shows characteristics of the kernel of almond cultivars. The kernel weight was lowest in the 'Selection 25' (0.80 g) and highest in the 'Texas' (1.30 g). According to the classification given by Socias i Company et al. (2008) the largest number of examined varieties (eight) had a medium-sized kernel (weight 1.1-1.4 g). Three cultivars ('Francoli', 'Glorieta' and 'Tétényikeményhéjú') were classified to the group of genotypes with a small kernel (0.9-1.1 g), while the cultivars with a very small kernel (below 0.9 g) were 'Tuono' and 'Selection 25'.

Table 3. Characteristics of the kernel of almond genotypes (2017-2019 average)

Genotype	Kernel weight (g)	Kernel share (%)	Oil content (%)	Protein content (%)
Budatétény	1.13	57.93	57.52	21.72
Francoli	0.91	25.88	50.21	25.72
Glorieta	1.07	21.43	44.35	24.48
Marcona	1.16	20.78	55.19	28.00
Masbovera	1.25	29.10	52.87	23.45
Nessebar	1.04	45.35	53.87	23.23
Selection 25	0.80	16.03	48.00	30.51
Texas	1.30	33.08	54.52	22.72
Tétényi bőtermő	1.12	49.73	51.11	21.81
Tétényi kedvenc	1.11	43.26	47.10	27.78
Tétényi keményhéjú	1.00	31.26	55.13	24.62
Tétényi rekord	1.17	34.08	46.60	25.51
Tuono	0.81	23.26	47.57	27.58

The kernel share varied from 16.03% ('Selection 25') to 57.93% ('Budatétény'). Based on the kernel share and according to the classification given by Batlle et al. (2017) five studied cultivars have a very hard shell (kernel share below 30%), four cultivars have a hard shell (kernel share 30-40%), three cultivars ('Nessebar', 'Tétényibőtermő' and 'Tétényi kedvenc') have a semi-soft shell (kernel share 40-50%), while the cultivar 'Budatétény' was characterized by soft shell (kernel share 50-60%).

The oil content in the kernel varied in the range from 44.35% ('Glorieta') to 57.52% ('Budatétény'). According to the classification given by Torabi et al. (2011) only kernels of the 'Budatétény' have a very high oil content (above 55%), five cultivars have a high oil content (50-55%), and four cultivars fall into the category with a medium oil content (45-50%). Our results are in range with data reported by Kodad (2017) and reviewed by Čolić et al. (2019) which showed variability from 20 to 67.5% for commercial and local almond cultivars/selections.

Among the nut fruits, almonds are considered to be a good source of high-quality proteins. Protein contents of the commercial almond cultivars ranged from 13% to 29% on a dry weight basis (Kodad, 2017). Drogoudi et al. (2013) analysed variation in the protein content among 72 almond genotypes found in Greece, France and Italy, and concluded that protein content depends on the genotype rather than the origin. The analysis of results for protein content indicates significant differences among cultivars, varied from 21.72 to 30.51%. This is similar to results of Askin et al. (2007), where in the study of almond selection from Elazig (Turkey), the obtained values varied from 16.07 to 31.46%.

Conclusions

The average flowering time of the examined almond varieties was in the second half of March and the beginning of April. The latest flowering time and good yield had the varieties 'Texas', 'Marcona' and 'Tuono', which were introduced a long time ago and therefore are well adapted to the agro-ecological conditions in Serbia. Other late-flowering varieties ('Francoli' and 'Glorieta') had lower yields, so they cannot be recommended for cultivation. The 'Texas' and 'Masbovera' varieties had the largest kernel weight, but also medium kernel share (about 30%). Varieties 'Budatétény', 'Nessebar', 'Tétényi bőtermő' and 'Tétényi kedvenc' had high kernel share and can be recommended as parents for hybridization with late flowering genotypes.
Based on obtained results 'Texas', 'Marcona' and 'Tuono' can be recommended for growing in the wider surroundings of Belgrade. Due to the limited almond assortment in Serbia, introduction and evaluation of newer late-flowering genotypes should be continued.

Abstract

Production of barely is possible even at higher altitudes and wider latitudes, but it is most frequently grown in temperate climate (autumn and spring sowing), as well as in semi-arid subtropical climate (winter sowing). The aim of this paper is to present the quantitative and qualitative characteristics of three varieties of livestock feed winter barley, namely of the varieties *KG Zlatnik, Nonius* and *Amorosa*, as well as to draw conclusions about the best variety which is to be grown under tested conditions on the basis of fertility characteristics of the tested varieties. The experiment was conducted in the area of the city of Niš in the course of 2018 and 2019, according to a random block system with four replications and the basic plot size of 5 m^2. After the harvest, the grain yield from the basic plot was measured and converted into kilograms per hectar. The obtained results were processed by means of variance analysis. In the second year of research, due to favourable climatic conditions, the length of spikes in all varieties was bigger in comparison to the first year. The maximum length of spikes for both research years was measured for the variety *Zlatnik*, indicating an increase in the number of grains per spike, and consequently a higher total yield. On average, for all varieties in the experiment, 39 grains per spike were formed in the second year of research, which is six grains more per spike than in the first year of research. The largest number of grains per spike had the variety *Zlatnik*, which also had the largest spike length.

Keywords: *livestock feed winter barley, agro-ecological conditions, fertility traits, variety.*

Introduction

Due to its widespread use, barley (*Hordeum sativum* L.) is one of the most important plant species in the world, in terms of both human and animal nutrition and industrial use. It is a cereal grain most widely adapted to different growing conditions, exhibiting great tolerance to drought, cold and soil salinity. Production of barley is possible even at higher altitudes and wider latitudes, but it is most frequently grown in temperate climate (autumn and spring sowing), as well as in semi-arid subtropical climate (winter sowing). Currently, 55% to 60% of barley in the world is used for livestock, 30% to 40% for malt production, while the rest is used for the purposes of food production and for other industrial purposes. Regardless of its purpose, the main goals with respect to breeding barley are as follows: an increase in grain yield and its stability, low protein content in malting barely (less than 11,5%), as well as high protein content in livestock barely (over 13%), high content of fine extract (over 80% sm), an increase in the total biological yield while retaining the harvest index (0,40-0,50), an increase in grain-filling

rate, given the current length of grain-filling rate, as well as resistance to major diseases and stress conditions, especially to drought (Pržulj et al., 2000).
The aim of this paper is to present the quantitative and qualitative characteristics of three varieties of livestock feed winter barley, namely of the varieties *KG Zlatnik*, *Nonius* and *Amorosa*, as well as to draw conclusions about the best variety which is to be grown under tested conditions on the basis of productivity traits of the tested varieties.

Materials and Methods

The aforementioned research studies examined fertility characteristics of three genotypes of winter barley (*Hordeum sativum* L.). The experiment was conducted in the area of the city of Niš in the course of 2018 and 2019, according to a random block system with four replications and the basic plot size of 5 m^2. In accordance with agro-climatic conditions, standard production technology was applied in terms of plant care and protection measures. In the full maturity phase, each plot was sampled for the purposes of determining the examined parameters. After the harvest, the grain yield from the basic plot was measured and converted into kilograms per hectar. The evaluation of morphological, production and physiological characteristics was performed by resorting to the usual methods. The obtained results were processed by means of variance analysis, and individual differences in the means were tested by means of Fisher´s least significant difference test (LSD).
The *Amorosa-Delta* seed variety is a six-row winter malting barley for animal nutrition, with excellent amino acid composition. It offers high rust and cold resistance, as well as tolerance to low temperatures. It produces good quality grain with 15% protein content.
The *Nonius-NS* seed variety is a six-row medium-early winter barley intended primarily for animal feed (high percentage of easily digestible protein). It is highly resistant to low temperatures, flattening and diseases. The concentration of protein is over 13%. The variety is recommended for growing in all soil types.
The *KG-Zlatnik* seed variety is a two-row medium malting winter barley intended for animal feed. It is highly resistant to diseases and tolerant to low temperatures. It produces good quality grain with the concentration of protein up to 14%.

Results and Discussion

The basic yield components whose economic product is grain are as follows: number of plants per m^2, number of productive spikes per plant, number of grains per spike and the weight of 1000 grains. Maximum fertility implies the achievement of the most favourable balance between yield components. By analysing the connection between the yield and its components in two-row barely, Barczak and Majcherczak, (2009) indicated that the largest interdependence had been obtained between the grain yield and number of spikes per m^2 and between the grain yield and number of grains per spike, regardless of the level of nutrients in the soil.

Table 1. Spike length, number of grains per spike and number of plants per unit area.

Variety	Spike length (cm)			Number of grains per spike			Number of plants per m^2		
Cultivar	2018.	2019.	average	2018.	2019.	average	2018.	2019.	average
Nonius	6.5	7.1	6.80	29	36	32.5	323	343	333.0
Zlatnik	7.2	7.5	7.35	33	40	36.5	346	359	352.5
Amorosa	6.3	6.8	6.55	31	33	32.0	333	338	335.5
average	6.7	7.1	6.90	33	39	36.0	334	347	340.3
LSD 005	0.8	0.6		3	5		12	15	
001	1.1	0.8		5	8		20	21	

Before the aforementioned authors, the same results had been obtained by Dofing and Knight, (1994) who analysed the grain yield and yield components and stated that an increase in the number of grains per spike had caused a slight reduction in grain weight. By analysing the interdependence between yield and its components Madić et al., (2005) indicated that there was a high positive correlation between harvest index and grain yield (0,68). Positive values of the correlation coefficient were also recorded between harvest index and the number of grains per spike (0,51), biological yield (0,42) as well as the hight of stalks (0,42), while negative value was recorded between harvest index and grain weight per spike (-0,34). The highest significant positive correlation existed between biological yield and grain yield (0,83), then between the hight of stalk and biological yield (0,65). The number of grains per spike was in the highest positive correlation with the hight of stalk and grain yield, as well as with biological yield and harvest index. On the basis of two years of test results, barley varieties have achieved different values for yield components depending on climatic conditions. Thus, the spike length is a trait which mostly depends on climatic conditions during the vegetative stages of growth (Table 1). In the second year of research, due to favourable climatic conditions, the length of spikes in all varieties was bigger in comparison to the first year. The maximum length of spikes for both research years was measured for the variety *Zlatnik*, which indicates an increase in the number of grains per spike, and consequently a higher total yield. Multiple-row barley essentially has a larger number of grains per spike, reaching the number of 100 and more grains, and with two-row barley that number is between 30 and 40. Stojanović, et al., (1998) believe that the number of grains is one of the most important yield components. On average, for all varieties in the experiment 39 grains per spike were formed in the second year of research, which is 6 grain more per spike than in the first year of research. The largest number of grains per spike had the variety *Zlatnik*, which also had the largest spike length. In the second year of research there were a bigger number of plants per m^2 in comparison with the first year. Thus, in the course of two years of research, the largest number of plants was achieved in the variety *Zlatnik*, while other varieties had statistically significant smaller number of plants per m^2. The number of spikes is the most important yield component of all small grains. The amount of seed directly influences the number of spikes. Barely is a small grain which has the largest coefficient of tillering. It depends on genotypes, as well as on plant nitrogen nutrition (Madić et al., 2006). The number of spikes directly influences the number of grains per spike. Paunović, et al., (2007) asserts that greater sowing density affects an increase in the number of spikes. In the first year of research the largest number of spikes per m^2 was found with the variety *Nonius* (481), while in the second year it was with the variety *Zlatnik* (551). On average, in the second year we have achieved 40 spikes more than in the first year.

Table 2. The number of spikes per m^2, the number of stalks per m^2 and the grain weight per spike.

Variety	The number of spikes per m^2			The number of stalks per m^2			The grain weight per spike (g)		
Cultivar	2018.	2019.	average	2018.	2019.	average	2018.	2019.	average
Nonius	481	473	477	777	806	792	1.008	1.035	1.021
Zlatnik	472	551	511	890	900	895	1.040	1.045	1.042
Amorosa	453	502	477	769	879	824	1.032	1.026	1.029
average	469	509	489	812	862	837	1.026	1.035	1.030
LSD 005	18	35		162	76		0.019	0.017	
001	25	42		176	87		0.033	0.023	

The number of stalks per unit area, provided the same sowing norm, the same seed quality and the same production conditions, is not the same in all varieties and depends on their biological characteristics. In the case of winter varieties, the number of plants per unit area mostly depends on their resistance to low temperatures, but also on hereditary characteristics of a variety and the ability of a stronger or weaker tillering. The number of offshoots which are formed in the early stages of ontogeny represents the basis in terms of crop uniformity and directly influences the number of spikes per unit area (Madić, et al., 2006). In the course of both years of research the largest number of stalks was recorded in the variety *Zlatnik* 890 stalks per m^2 in the course of the first year, and 900 stalks per m^2 in the course of the second year. If one considers the average for both years of research, in the second year there were 50 stalks more per m^2 than in the first year.
Production per spike is a yield component which depends on the number of grains, as well as on the size and density of a grain. Two years of research into the weight of grain on a barely spike show statistically significant differences between the examined varieties. The average grain weight for all varieties was 1,030 g. A significantly larger grain weight on a spike in comparison to other varieties was exhibited by the variety *Zlatnik* (1,042 g), while a significantly smaller grain weight on a spike was exhibited by the variety *Nonius* (1,021 g).The weight of 1000 grains (Table 3) depends on the size of a grain, i.e. on its dimensions and density. Full, healthy grain of a regular shape provides a large percentage of the first and second class grains. The weight of 1000 grains, however, is not merely a yield component, but also a very important quality component of malting barley grains (Ullrich, 2002). The results regarding the weight of 1000 grains show that in the course of the first year of research the best results were exhibited by the variety *Amorosa* (53,1 g), while in the second year it was the variety *Zlatnik* (56,2 g).

Table 3. The weight of 1000 grains, hectolitre weight and grain yield.

Variety	1000 grain weight (g)			Hectolitre weight (kg hl^{-1})			Grain yield (kg ha^{-1})		
Cultivar	2018.	2019.	average	2018.	2019.	average	2018.	2019.	average
Nonius	49.10	51.10	50.10	60.20	60.50	60.35	4 480	4 520	4 500
Zlatnik	52.30	56.20	54.25	68.80	69.40	69.10	5 380	5 410	5 395
Amorosa	53.10	54.50	53.80	66.10	67.20	66.65	4 750	4 790	4 770
average	51.50	53.93	52.71	65.03	65.70	65.36	4 870	4 906	4 888
LSD 005	3.75	4.75		2.35	7.56		581	614	
001	4.25	5.45		2.85	8.12		785	865	

The results regarding hectolitre weight of the examined barley varieties indicate that there are statistically significant differences between the examined varieties. In the course of both years of research the highest values were achieved by the variety *Zlatnik*, while the influence of a particular year on the achieved values in the examined varieties is considered inconsequential. Aside from its impact on the grain quality, a great hectolitre grain weight significantly influences the increase in yield, which is in compliance with our results.
With an increase in the planting density and mineral nitrogen nutrition, the number of spikes per m^2 increases as well, and with an increase in the number of spikes, grain yield increases as well (correlation coefficient 0,63). Hesselbach, (1985) indicates that an increase in barley grain yield in recent years is mostly the result of an increase in the number of grains per spike. The number of spikes per unit area remained the same, while the grain weight varied. Barley varieties differed according to the realised average grain yields. The largest grain average yield was prodiced by the variety *Zlatnik* (5.395 kg ha^{-1}), and the smallest by the variety *Nonius* (4.500 kg ha^{-1}). Significant differences have been established between the examined varieties. According to the result by Pržulj et al., (2000), the varieties of malting barely and animal feed barely which we produce have the yield potential up to 11 tons per hectare, i.e. 8 tons per hectare in spring barely. Depending on the year, yields of barley varieties from Kragujevac in macroexperiments moved from 4.23 to 6.20 tons per hectare Madić, et al., (2006), which is consistent with our results.

Conclusions

The results obtained by examining yield components of the three aforementioned varieties of winter barley in agro-ecological conditions of the Niš District indicate that the genotype and growing conditions have significantly influenced the values of the analysed characteristics. From the standpoint of spike length, number of grains per spike, number of plants per m^2, number of spikes per m^2, number of stalks per m^2, grain weight per spike, weight of 1000 grains and hectolitre weight, the variety *Zlatnik* provided the best results, both according to the years of research and according to the average for both years. On the basis of high values for all examined yield components the variety *Zlatnik* has produced a significantly larger grain yield in comparison to other examined varieties. The average grain yield for both years of research in case of the variety *Zlatnik* was 5.395 kg ha^{-1}, in the variety *Amorosa* 4.770 kg ha^{-1}, while the lowest yield was produced by the variety *Nonius* 4.500 kg ha^{-1}. The yield variation per years of research was the lowest in the variety *Zlatnik* which, aside from a high fertility potential, indicates a great genetic stability of the variety.

Abstract

One of the goals in eggplant breeding (*Solanum melongena* L.) is higher yield, as well as adaptation to different environments. Our study included 20 different eggplant genotypes. The experiment was conducted at three different locations (Smederevska Palanka, Vranovo and Kusadak) using a randomized complete block design in three replications. The length and width of fruit were examined, characteristics important both for the shape and the weight of the fruit. Two-factors ANOVA determined a statistically significant influence of genotype and locality for fruit length and width. Average fruit lengths ranged from 134.86 mm (K19) to 246.07 mm (K38). The mean value of fruit length from the Kusadak locality was significantly ($p<0.01$) higher than the general average (181.58 mm), and significantly longer fruit length was recorded in 10 genotypes: K6, K13, K15, K16, K21, K22, K22, K25, K36 and K39. The highest average fruit width (120.05 mm) was recorded in genotype K19 and differed significantly in relation to the average values of other observed genotypes. The lowest average fruit width was recorded in the K38 genotype at Smederevska Palanka and Kusadak localities (54.33 mm and 54.82 mm). According to AMMI analysis, the least stable locality in terms of fruit length was Kusadak, while the most stable was Smederevska Palanka with an AMMI stability coefficient of 7.00. The most stable genotype was K3 (0.76). The locality Smederevska Palanka was the most stable for fruit width (9.50), while the most stable genotype was K7 (0.28). The least stable locality was Vranovo.

Keywords: *eggplant, environment, fruit length, fruit width, AMMI analysis.*

Introduction

Eggplant (*Solanum melongena* L.) is a agronomically and economically important plant member of *Solanaceae* family with a significant foundation source of various vital pharmaceuticals and nutraceuticals compounds (Naeem and Ugur, 2019). In 2018, world production of eggplants was 54 million tonnes on more than 1.8 million ha, led by China with 63% of the total and India with 24% (FAOSTAT, 2019). The presence of good fiber and various vitamins and minerals in fruits (rich source of iron, manganese) is of great benefit to human health. Eggplant also contain high phenolic contents that act as antioxidants (Cao et al., 1996; Stommel and Whitaker, 2003; Caguiat and Hautea, 2014). Foods that contain antioxidants may help prevent a range of diseases. Among the antioxidants in eggplants are anthocyanins, including nasunin, lutein, and zeaxanthin. Eating foods containing certain flavonoids, including anthocyanins, helps reduce inflammatory markers that increase the risk of heart disease (Fallah et al., 2020). The color of purple skin cultivars is due to the anthocyanin nasunin (Noda et al., 2000). The browning of eggplant flesh results from the oxidation of polyphenols, such as the most abundant phenolic compound in the fruit, chlorogenic acid (Prohens et al., 2007). In addition to being used as an important vegetable plant, eggplant is also used in traditional medicine (Khan, 1979). Various research shows that the eggplant extracts have superb healing effects on different disorders like burns, warts, inflammatory infections, gastritis, stomatitis and arthritis (Im et al., 2016). A research conducted by Afshari et al. (2016) proved that extracts from eggplant have a extra toxic result on cancer cells than on normal cells. Chlorogenic acid also shows anticarcinogenic functions by making apoptosis in many human cancer cells, such as leukemia and lung cancer cells (Tajik et al., 2017). One of the goals of the eggplant breeding has a higher yield and better quality fruits, as well as adaptation to various environmental (Borgato et al., 2007). Minor changes in nutrient composition occur with season, environment of cultivation (open field or greenhouse), and genotype (San José et al., 2014). The effect of environmental factors may also affect the divergence. Many of the forms are created as a form of adaptation to environmental conditions. The environments especially significantly influences the form of expression of quantitative properties. Variability is observed even within the same form in terms of plant height, fruit size and yield depending on the climate, exposure, place and method of cultivation (Prodanović et al., 2015). In this experiment the influence of two parameteres: genotype and locality on the length and width of the fruits were examined, characteristics important both for the shape and the weight of the fruit, ie. yield.

Material and methods

The research included 20 different genotypes that are part of the collection of the Institute of Vegetables, Smederevska Palanka. 16 genotypes originated from Serbia, 2 from the Netherlands (K22 and K25), one from Italy (K19) and one from Israel (K38). The experiment was conducted at 3 different localities: Smederevska Palanka (44°21'24.79"N, 20°56'55.70"E, altitude 103 m), Vranovo (latitude 44°36'6,35"N, longitude 20°59'55.47"E, altitude 87 m) and Kusadak (latitude 44°24'6,73"N, longitude 20°56'30,52"E, altitude 175 m). The localities differed in soil type and climatic conditions. In Smederevska Planka, the type of land was alluvial smonica, while in Vranovo and Kusadak was grove. The average air temperatures in all three different localities were higher than the multi-year average. During the period of development of vegetative organs and flowering in eggplant plants, average temperatures ranged from 20.5 - 29.2 °C at the locality Smederevska Palanka, Kusadak 19.8 -26.5 °C and Vranovo 21.0 - 27.8 °C. The total amount of precipitation at the localities Kusadak (152.2 mm) and Vranovno (139.6 mm) was lower compared to the multi-year average precipitation. In Smederevska Palanka, it was 240.7 mm, which is more than the multi-year average. Sowing was carried out in individual pots of 11 cm diameter, filled with sterile substrate and kept in a protected area. The seedling were maintained in a common manner, i.e. every 15 days fertilized with NPK 20:20:20 (25g / 10l of water) and treated with pesticides as needed. Planting was carried out at the beginning of June and during the vegetation, identical agro-technical measures were implemented at all three localities. The area of the basic plot was 56 m^2. In each replication, 10 plants were placed in a row for each genotype. The length of the rows was 4 m, the distance between the rows was 0.70 m, while the distance between the plants in the row was 0.40 m. The length and width of the fruits were examined, characteristics important both for the shape and the weight of the fruit, ie. yield. The trials was conducted in the Randomized Complete Block Design (RCBD) with 3 replications.

The influence of 2 factors on the measured parameters was observed: genotype and locality. All data is statistically processed in StatSoft Inc. STATISTICA, version 8.0 (2007) and shown as the mean value ± standard error. Statistical data processing implied analysis of the variance of the four-factor experiment (ANOVA) and the comparison of mean values with the LSD test (least significant difference) at the level of significance $P \leq 0,05$.
Stability of the observed traits were analyzed using the AMMI (Additive Main Effects and Multiplicative Interaction) analysis (Gauch, 1988; 1992). GxE interaction was interpreted based on the AMMI2 biplot graph - abscissa representing value of PC1, and ordinata representing value of PC2. AMMI stability value (ASV) was calculated according to the formula (Purchace, 2000):

$$ASV = \sqrt{\left[\frac{SS_{PC1}}{SS_{PC2}}\ x\ (PC1\ value)\right]^2 + [PC2\ value]^2}$$

SS = sum of the squares; PC1 = the first major component; PC2 = the second major component.

AMMI analysis was performed using the R software, version 2.15.2 (A Language and Environment, Copyright 2012).

Results and discussion

Fruit length and width are very important features for fruit shape formation, and have been studied by a number of researchers (Chadha et al., 1987; Singh and Singh, 1985). Analysis of variance (ANOVA) revealed statistically significant differences between the studied genotypes, localities and genotype × environment interactions for both traits, fruit length and width (Table 1).

Table 1. Analysis of variance (ANOVA) for fruit length (A) and width (B)

	Source of variation	Df	SS	MS	F value	F – tabular 0,05	F – tabular 0,01
A. fruit lenght	Repetition	2	1,94	0,97	$0,28^{nz}$	3,07	4,80
	Genotype (G)	19	110.455,81	5.813,46	$1.705,77^{**}$	1,68	2,06

Df- Degrees of freedom; SS - The sum of the squares; MS - The middle of the square

Average fruit lengths ranged from 134.86 mm (K19) to 246.07 mm (K38). In both genotypes, a statistically significant deviation from the mean value of the general average was observed. The highest average fruit width (120.05 mm) was recorded in genotype K19 and differed significantly in relation to the average values of other observed genotypes. Genotype K19 also had the highest average value of fruit width at the localities Smederevska Palanka and Vranovo, 123.50 mm and 117.33 mm respectively. The lowest average fruit width was recorded in the K38 genotype at Smederevska Palanka and Kusadak localities (54.33 mm and 54.82 mm). The mean value of fruit length from the Kusadak locality was significantly ($p<0.01$) higher than the general average (181.58 mm), and significantly longer fruit was recorded in 10 genotypes: K6, K13, K15, K16, K21, K22, K22, K25, K36 and K39.

Table 2. Analysis of AMMI model variance for length (A) and fruit width (B)

Df- Degrees of freedom; SS - The sum of the squares; MS - The middle of the square

AMMI analysis of eggplant fruit length and width showed significant differences between localities, genotypes, and their interactions (Table 2). 78.73% of the total sum of squares refers to the effect of genotype in the case of length (Table 2A) and even 91.78% in the case of fruit width (Table 2B). A large sum of squares of genotypes indicates a very pronounced divergence between the observed genotypes for the examined traits. For the length of the fruit, the sum of the squares G × L is ten times higher than the sum of the squares of the locality (Table 2A), while for the width of the fruit it is even 58 times higher (Table 2B). Based on the large sum of the squares of the interaction, we can conclude that there were significant differences between the reactions of the genotypes within different environments.

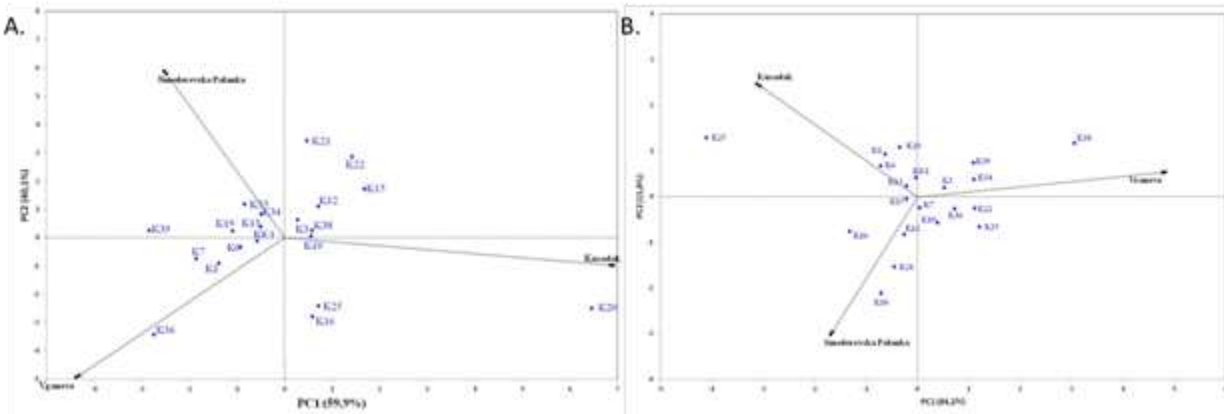

Figure 1. AMMI2 biplot for 20 genotypes of eggplant at three localities for the fruit length (A) and fruit width (B)
Legend: Locations: Smederevska Palanka, Kusadak, Vranovo; Genotypes: K1, K3, K6, K7, K8/1, K10, K12, K13, K15, K16, K19, K20, K21, K22, K25, K34, K35, K36, K38, K39

Figure 1. shows the relationship between the first and second main components - the G × L interaction is shown graphically. A smaller angle between the vectors represents a greater similarity in their interaction (Babić et al., 2010). The genotypes grouped on the graph have similar adaptability (Balalić, 2010), those located near the center of the section can be considered the most stable, while those furthest from the center of the section are the least stable.
The least stable locality, in terms of fruit length, was Kusadak, while the most stable was Smederevska Palanka, which means that there was the least variation of this trait at that locality. The least stable genotype K20 corresponded to the conditions of the locality Kusadak, where the most stable results for the observed trait were recorded. In addition, the conditions in this locality also affected the genotypes: K3, K10, K38. The most stable results for fruit length at the locality Vranovo were recorded in genotypes K36, K1, K6, K7, K8/1, while in Smederevska Palanka genotypes K13, K34 and K35 stood out in terms of stability (Figure 1A).
For the fruit width, the least stable locality was Vranovo, while the most stable was Smederevska Palanka. Environmental conditions at the Kusadak site favored genotypes K1, K6, K13, and they had the greatest stability in the conditions of this locality. The least stable genotype K25 was affected by the environmental conditions that characterized Kusadak, and the genotype K38, which was also unstable, was affected by the environmental conditions in Vranovo. The most stable results for fruit width at the locality of Smederevska Palanka were observed in genotypes K7, K12, K10, K21, while in Vranovo genotypes K3, K22, K34, K36 were singled out (Figure 1B).

Conclusion

Analysis of variance determined a statistically significant influence of all examined factors (genotype, locality and genotype × locality interaction) on the observed traits: fruit length and width. Also based on AMMI analysis for all analyzed traits in this experiment, there were significant differences between genotypes, localities and their interactions.

Abstract

Crop yields are highly depended on germination and early stages of plant growth. Numerous priming techniques are being developed aimed to improve germination. Biopriming represents a sustainable approach based on seed treatment in bacterial suspension of selected plant growth promoting strains. One of the most promising plant growth promoting bacteria is *Azotobacter chroococcum*. The aim of the research was to evaluate the effects of *A. chroococcum* F8/2 as a biopriming agent on germination of various cultivable plants: basil, white mustard, cucumber, tomato, wheat, canola, and soybean. After surface sterilization, seeds were bioprimed in the bacterial suspension (10^7CFU/ml). Uninoculated seeds represented control treatment. Germination test was conducted with 100 seeds per treatment and the germination was monitored for 7 days. Following germination parameters were determined: germination percentage, germination index, mean germination time, vigor I, vigor II, length and dry biomass of the seedlings. The bacterial inoculation caused higher germination percentages of cucumber, tomato, wheat and soybean. The highest increase in germination index was observed in wheat (an increase of 19.8%). Tomato and basil were the only plants where vigor I was not increased by inoculation. Generally, the most favorable effects of *A. chroococcum* biopriming were observed in wheat where vigor I was increased more than twice, and vigor II was higher by 75.4% in inoculated seeds. The results indicate a significant potential for *A. chroococcum* use in biopriming. The observed effects of seed priming on germination parameters were crop-specific, with the most prominent potential in wheat biopriming.

Keywords: *Azotobacter chroococcum, Biopriming, Germination, Seedlings' growth.*

Introduction

The current agricultural, plant production concerning the needs of the world human population is out of step. Limited soil resource, its increased compaction, salinity, absence of organic matter, presence of pollutants are just some of the abiotic factors that compromise this production. However, the disturbed balance in the agroecosystem reflects its destructive impact on all other ecosystems and their living components. The introduction of new technologies that respect natural laws are and will be the key to sustainable crop production. Among them, bioprimig technology contributes to increasing the yield and quality of crops by using natural potentials while respecting the principles of sustainability. Biopriming involves the use of bioagents in seed treatment by various methods. Microbiological inoculation is the most desirable and most frequently used biopriming method based on the application of rhizosphere microorganisms as bioagents in the form of bacterial suspension (Ashraf and Foolad, 2005). This significant population of microorganisms from the soil of the narrow root zone (rhizosphere) has properties that in the interaction with the plant promote physiological events resulting in the good yield.

Therefore, they are defined as plant growth bacteria (Plant Growth Promoting Bacteria / Rhizobacteria, PGPR) (Kloepper and Schroth, 1978). They are active participants in the plant's nutritional cycle, phytohormonal modulation, biocontrol and elimination of toxic substances (Sumbul *et al.*, 2020).
Since the seeds are the starting material in plant production and carry a huge potential responsible for plant growth and development, biopriming is focused on the seeds and the initiation of their potential, which occurs in germination. Germination is defined as a crucial and critical phase in the life of a plant and its good start is a prerequisite for the promotion of yield and quality (Sanchez *et al*., 2014; Houle et al., 2001**).** The yield can be increased in the range of 25-65% (Ahmad *et al.,* 2016) with an improvement in crop quality at the same time (Revillas *et al.,* 2000). By microbiological inoculation, selected PGPR strains will successfully colonize the seed structure **(**Mahmood and Kataoka, 2018) and after stimulating germination and seedlings' growth, will continue to actively participate by various mechanisms in the plant life in the rhizosphere (Yadav *et al*., 2015). Among the most common inoculants is *Azotobacter* due to its prestigious PGP traits such as the ability to provide nutrients to plants, especially nitrogen through the process of nitrogen fixation, synthesis of phytohormones, siderophores, antibiotics, participation in biocontrol and degradation of toxic compounds (Nosrati *et al.*, 2014; Sumbul *et al*., 2020; Kumari *et al*., 2017). However, the positive effect is far greater and reflected in the improvement of the quantitative and qualitative properties of the soil while preserving its diversity (Jeffries *et al.*, 2003).
Bearing in mind the importance of biopriming, the aim of this work was focused on the bioagent, *Azotobacter chroococcum* F8/2 and its influence on germination and seedlings´ condition. The success of germination was determined by germination parameters such as final germination percentage (FGP), germination index (GI), average germination time (MGT), vigor I and II, seedling length, and their dry weight. In addition to the choice of inoculant, the results of germination are influenced by numerous factors, among which the plant species is of exceptional importance. Thus, different plant species are used to test the effect of the proposed biopriming.

Material and methods

Bacterial strain

The isolated strain belongs to the collection of the Department for Ecological Microbiology, the Faculty of Agriculture. Growing on the selective Fiodorov medium, based on cell morphology, colony appearance, and biochemical profile the isolate was identified as *Azotobacter chroococcum.*

Plant species and seed pre-treatment

Seven plant species are selected, important for national and worldwide agricultural production: basil (*Ocimum basilicum*), mustard (*Synapsis alba*), cucumber (*Cucumis sativus*), tomato (*Solanum lycopersicum* L.), wheat (*Triticum aestivum*), canola (*Brassica napus* L.), and soybean (*Glycine max.* L.). All seeds were uniform, compact in structure, and subjected to sterilization with 70% alcohol (v/v) / 2 min and 0.02% NaOCl (v/v)/ 2 min. After thorough rinsing with sterile deionized water, they were set to dry in sterile conditions. Ten seeds were selected for each plant species, placed on MPA medium, and incubated for 24 hours at a temperature of 30 °C to check the success of sterilization.

Inoculum preparation and seed inoculation

48h-old bacterial culture of *A. chroococcum* F8/2 was "scratched" from solid media, and resuspended in the sterile saline (0,9% NaCl) until the inoculum suspension of 10^7 CFU /ml was reached. Previously prepared seeds were immersed in the inoculum suspension and incubated in a rotary shaker (130 rpm) for 1 hour at the temperature of 28±2 °C.

Germination assay

Germination test was performed by applying the slightly changed filter paper method (ISTA; 1999). Sterile Petri dishes were used in which sterile filter papers were placed on the bottom. Before placing the seeds, the filter paper was moistened with sterile water. 100 seeds for each plant species were arranged in 4 replicates of 25 seeds, except for soybeans, where due to the size of the seeds, the number of replicates was 10 with 10 seeds each. Non-inoculated seeds were set up in a completely identical way as control. Previously dried and inoculated seeds were placed on Petri dishes and left at natural light and an average room temperature of 25°C for 7 days. Sterile water was added when needed to maintain optimal humidity.

The number of germinated seeds was recorded daily based on a radical emergence and its length of 2 mm. After 7 days, representative seedlings from each replicate were chosen, randomly for measuring their length. Thereafter, they were dried overnight at 90 °C and their dry weight was recorded. Advanced germination measurement tool (Argon Info-Tech) was used to calculate germination parameters such as the final germination percentage, germination index (GI), mean germination time (MGT), vigor I, and vigor II.

Statistical analysis

The analysis was conducted by Tukey's test comparing the differences between means of obtained results from the inoculated seeds vs control at the 5% level of probability.

Results and discussion

Data obtained from the conducted experiment show differences in plant species response to the applied biopriming with A. chroococcum F8/2. Significant increases in FGP were achieved in cucumber (12.70%), tomato (8.79%), soybean (14.58%), and wheat which showed the largest increase of 19.58% compared to the control (Tab. 3, 4, 5, and 7). Although a desirable reduction in MGT was observed in some plants, it did not indicate a significant difference between biopriming and control treatments. A slight increase in germination index (GI) was observed in canola, tomato, and wheat, while GI of inoculated treatments was significantly higher compared to control in cucumber for 28.30%, and soybeans for 56.72% (Tab. 3 and 7).

Vigor I was determined as the common value of the germination percentage and the length of seedlings. Statistically significant increases were observed in wheat of 110%, soybean (124%), and canola (48.71%). However, a significant decrease of 46.61% was presented in cucumber. Analyzing the data of Vigor II, increases were recorded in soybeans (23.36%), followed by mustard (30%), tomatoes (37.39%), and wheat of 75.39%, which was the most significant increase achieved by Azotobacter biopriming. Considering the seedlings' length, the promotion was noted in cucumber (108.84%), soybean (100%), and wheat (81.96%). The inhibitory effect of inoculation treatment was evident in tomatoes where a reduction of the seedlings length was 27.78%. Although the inoculation had an inhibitory effect on the length of seedlings in tomatoes, it contributed to an increase in their dry matter by 25%. Also, an increase of 30% in dry mass was recorded in mustard. However, according to the results, the most prominent dry mass increase was in the wheat of even 51.11%.

Since germination is a complex physiological event that determines the entire future plant development and its final production, all of the studied parameters were in purpose for a better assessment of germination success influenced by Azotobacter biopriming. Biopriming stimulates pre-germinative processes in the seed contributing to better germination (Bradford, 1986). The selected bioagent, A. chroococcum F8/2, initiated significant promotion of the germination percentage in most of the plants, as the best in wheat. Although the germination percentage is an important determinant of germination success it is not crucial. Previous studies have given priority to vigor as a powerful seed potential in the realization of final yield under given conditions (TeKrony, 2003). The phytohormonal activity of A. chroococcum is obvious by analyzing seedling length. The ability to modulate hormonal balance among ethylene, GAs, and auxin is most likely the reason for the increase in seedling length and the direct reason for the improvement of vigor I. The stimulating effect of Azotobacter inoculation on seedlings' development is reflected through dry weight increase that affects vigor II as an indicator of seedlings' ability to continue to develop successfully in the later life stages. Also, germination and vigor are genetic traits (Wu et al., 2017). It is known that germination depends largely on the vitality of the embryo and the depth of dormation (Martinez, 2013). The result of germination may be influenced by the different strain affinity for a certain plant species and its exudates (Lugtenberg et al.,2001; Kumar et al., 2007; Compant, 2010) that are released in the imbibition phase, significantly affecting the colonization process and metabolic activity of biopriming agents (Brelwey and Black, 1993).

Conclusion

The effect of biopriming using *Azotobacter chroococcum* F8/2 is specifically dependent on plant species, with best results in germination promotion in wheat. *A. chroococcum* biopriming of soybean, wheat, tomato and cucumber seeds may trigger the promotion of germination, but also could help the creation of a compatible connection between inoculant and plants providing useful activities in the rhizosphere in later crop development stages. The final results of the application of *Azotobacter* biopriming could be more far-reaching, including agronomic, ecological, and economic aspects.

Abstract

The practice of preserving green crops by fermentation as silage has increased dramatically in recent years. Successful ensiling can be difficult due to numerous problems such as: high moisture content, high feed buffer capacity, insufficient amount of fermentable carbohydrates etc. The aim of this investigation was to determine the suitability for ensiling field pea:oat and common vetch:oat mixtures grown at different seeding rate and harvested at different stages of growth. Field pea, common vetch and oat were grown in pure stands and in the mixtures of 75:25, 50:50 and 25:75 ratios and harvested at three stages of plant development: beginning of field pea and common vetch flowering, forming the first pods in field pea and common vetch and at the forming green seeds in 2/3 field pea and common vetch pods. The most favorable ratio of sugar and buffer capacity for the established level of dry matter in the examined crops was stated in pure oat crop. The results obtained in the mixtures of field pea and oat are based on the ratio of sugar and buffer capacity and can successfully ensile in all three examined relations of germinating grains of field pea and oats. The highest sugar content (182.1 g kg^{-1} DM) and the highest buffer capacity were determined in the 50:50 field pea:oat mixture at the pea flowering stage of development. The least favorable ratio of sugar and buffer capacity was found in pure common vetch.

Keywords: *field pea, common vetch, ensiling.*

Introduction

In the conditions of an increasingly pronounced deficit and high food prices, Đorđević et al. (2000) found out that ensiling is the most acceptable solution in order to obtain cheap and quality animal feed. However, succesful ensiling can be difficult due to numerous problems such as: high moisture content, high feed buffer capacity, insufficient amount of fermentable carbohydrates, soil pollutions, etc. The most important factors that should be taken into account before preparing silage is to ensure adequate dry matter content in the biomass for ensiling as well as adequate sugar content, buffer capacity, and acidity coefficient (Knicky, 2005). According to Đorđević et al. (2001), the dry matter content in plant material should be above 35%, to ensure succesful fermentation. In these circumstances the work of most plant and bacterial enzymes is inactivated, which reduces nutrient losses matter. Sugars are the main source of fermentable compounds during the preperation of silage and together with buffer capacity act on the process of silage preparation. That is why they are expected to be useful indicators of crop conservation potential. Sugars necessary for ensiling include mainly monosaccharaides – glucose and fructose, disaccharides – sucrose and polysaccharides -

fructans. The concentration of thes sugars depends on the plant species and the stage of growth of plant exploatation. The sugar content of grasses and cereals increases as the proportion of the stem increases. On the other hand, legumes contain low sugar concentrations. One of the very important parameter for the success of ensiling process represents the buffer capacity of the plant biomass. The objective of this study was to determine the content of dry matter, sugar content, buffer capacity and sugar:buffer capacity ratio in investigated mixtures of pea – oat and common vetch – oat depending on the stage of growth and seeding rate in the mixtures in order to determine the suitability this crop mixtures for ensiling.

Materials and methods

Field pea and oat as well as common vetch and oat were grown in binary mixtures at the experimental field of the Institute for forage crops Kruševac, Serbia (21° 19' 35" E, 43° 34' 58" N). The study area was situated at altitude of 166 above sea level in South East Serbia. Soil type was with humus content of approximately 3.5% and a pH in H_2O 6.87, pH in 1N KCl 5.85; nitrogen content of 0.176%; Al-soluble P_2O_5 and K_2O 3.6 and 28.6 mg 100 g^{-1}, respectively. Experiment was established in autumn in 2015, on October the 20th, and plant samples were taken in 2016. The experiment was designed with three replication according to a randomized complete block. All mixtures were sown on plots of 20 m^2. The experiment was performed using three different cutting stages: A_1 – beginning of pea and common vetch flowering – 10% of flowering; A_2 – forming the first pods on 2/3 pea and common vetch plants and A_3 – forming green seeds in 2/3 pods of pea and common vetch plants. The pea-oat and common vetch-oat mixtures were tested in the pure stands and at three different mixture rates: P:O 25:75 – 25% pea + 75% oat, P:O 50:50 – 50% pea + 50% oat; P:O 75:25 – 75% pea + 25% oat; CV:O 25:75 - and 25% common vetch + 75% oat; CV:O 50:50 - 50% common vetch + 50% oat; and CV:O 75:25 - 75% common vetch + 25% oat. The ratio was formed according to the number of germinating grains of legumes and oat in the mixtures, where the germinating legumes grain per m^2 was taken as a reference for determining the ratio in the mixtures. The reference parameter for pea was 120 germinating grains per m^2, while 250 germinating grains per m^2 was taken for common vetch. Based on this values, the ratio of germinating grains in mixtures were formed. Forage was cut and a sample of the whole plants was collected. Dry matter was determined by the drying out samples at 65° C. Buffering capacity of the samples was assessed according to the procedure of Prohászka and Baron (1980) and expressed as the quantity (Meq) of 0.1N lactic acid required to acidify 100 g of the sample to pH 4. Fermentable coefficient was calculated using formula: FC = DM% + 8 x S/BC by Olt et al. (2005). Total carbohydrates and mosaccharides were determined by spectrophotometric method with phenol-sulfuric acid according to Dubois et al. (1956) and Hall et al. (1999). All results are calculated in order to dry matter basis determined by drying samples to a constant weight at 105°C. The data were processed by the analysis of variance in a randomized block design. The significance of differences between arithmetic means was tested by Fisher test ($p < 0.05$).

Results and discussion

The obtained results for the dry matter content, buffer capacity, content of monosaccharides and total carbohydrates, the ratio of sugar and buffer capacity and fermentable coeficient of oat, pea and common vetch pure stands and investigated mixtures of pea:oat and common vetch:oat depending on the stage of plant development are presented in the Table 1.

The stage of plant development significantly influenced ($p < 0.05$) the dry matter content in oat, pea and common vetch pure stand, as well as in the investigated pea:oat and common vetch:oat mixtures. The highest dry matter content was established at the third stage of plant development – at forming seeds in 2/3 pods of pea and common vetch in allmost all investigated mixtures. Only in the mixture contained 75% of pea dry matter decreased with plant growth and development from 40% to 31%. The most dominating and therefore most important factor in controlling the fermentation in a given crop is the dry matter content of the crop. Increased dry matter content also favours the growth of lactic acid bacteria, and in particular, restricts the development of *Clostridia* (Spröndly and Pauly, 2008). The earlier works by Silliker et al. (1980) showing that dry matter contents above 40-45% inhibits *Clostridia* growth in silage and well confirmed by recent experiments by Kaiser et al (2005) and Pauly et al. (2008), both clearly showing that a high dry matter content inhibit the development of *Clostridia*.

Intercropping of cereals with legumes is an alternative for monocropping and has a number of advantages, for example lower inputs, lower costs of production and better silage quality than monocrop systems (Dewitto et al., 2008). Successful fermentation depends on a sufficient content of carbohydrates – mainly glucose, fructose, fructosans, saccharose and maltose – and has a positive impact on palatability of ensiled forages.

The obtained results of this study for the ratio of sugar and buffer capacity of pure crops oat, pea, common vetch and investigated mixtures of pea with oat and common vetch with oat depending on the stage of development are presented in the Table 1. The most favorable ratio of sugar and buffer capacity for the established dry matter level in the tested crops was found in pure oat crop. Optimal content of fermentable sugars in pea:oat mixtures conditioned this ratio to be over 2.0 in almost all tested stages of plant development and in all investigated pea:oat mixtures. The lowest value of sugars and buffer capacity was observed at the second stage of oat monocrop, which could be explained by lower dry matter content.

Fermentable coeficient calculated according to the previously mentioned formula given by Olt et al. (2005) in the pure oat, pea and pea:oat mixtures had values greater than 45.0, which showed that the ratio of sugar and buffer capacity of this crops was optimal and that these mixtures can be successfully ensiled. The problem would be represented in a low dry matter content of common vetch:oat mixtures and lower values of sugar and buffer capacity. The lowest values for ratio of sugar and buffer capacity, as well as fermentable coeficient were observed in pure common vetch crop.

Fermentable coeficient ranged from 32.28 at the second stage of plant development to 36.72 at the third stage of plant development in pure stand of common vetch show that the common vetch belongs to a group of plants that are difficult or imposible to ensile on their own. This observation confirmed by the results obtained for 75:25 and 25:75 common vetch:oat mixtures for fermentable coeficient at all investigated stage of plant development. High buffer capacity and low monosaccharides and total carbohydrates content in pure common vetch stand at all three stages of plant development influenced low TC/BC ratio and low fermentable coeficient. On the other hand, the pure stand of common vetch contained the lowest dry matter, which also may affect inadequately fermentable processes during ensiling.

It is necessary to emphasize that in relation to the small suitability of this plant species for ensiling, a much bigger problem is the pronounced lodging feature of the plant, and it is necessary to grow common vetch in a mixture with cereals. This practically solves the biological problem of this plant species in relation to lodging, and at the same time the necessary sugar minimum would be achieved (Đorđević and Dinić, 2003).

Conclusions

According to the results obtained in this investigations we can conclude that the annual forage legumes, especially common vetch, is not suitable for ensiling process, mostly due to the low sugar content and high buffer capacity, which can be compensated by their cultivation in a mixture with cereals. The effect of maturity at harvest and increasing the pea content of bi-crop on suitability for ensiling have been evaluated in this study. Due to the low dry matter content at the cutting and the low sugar content and high buffer capacity, the common vetch can be successfully ensiled only with the high proportion of cereals in the mixtures.

Abstract

Stability of grain yield, 1000 kernel weight and sedimentation value were analyzed in 10 winter wheat cultivars (Perfekta, Toplica, KG-52/3, Merkur, Vizeljka, Talas, NS 40S, Zvezdana, Javorka and Pobeda), created in different breeding institutions in Serbia. The experiment was carried out during 2019/2020 in two localities: Centre for Small Grains in Kragujevac and Institute for Forage Crops in Kruševac, Serbia. The analyses of variance showed highly significant differences in grain yield, between genotypes, investigated localities, as well as their interaction. The influence of the locality did not show statistical significance on the expression of 1000 kernel weight and sedimentation value. The highest average values were recorded by Perfekta for grain yield, Zvezdana for 1000 kernel weight and KG-52/3 for sedimentation value at both localities. The AMMI model was used for analysis of genotype × environment interaction. The most stabile cultivars were Vizeljka, NS 40S and Perfekta with values above the average for grain yield. Cultivars Talas, KG-52/3 and Javorka showed the highest stability for the 1000 kernel weight. Cultivar Javorka had the highest, while Talas and KG-52/3 had the lowest average values for this trait. Vizeljka and KG-52/3 were the most stable genotypes for sedimentation value, with KG-52/3 achieving the highest values of the observed trait at the level of the entire experiment. Both analyzed locations had high interaction value for all three analyzed traits.

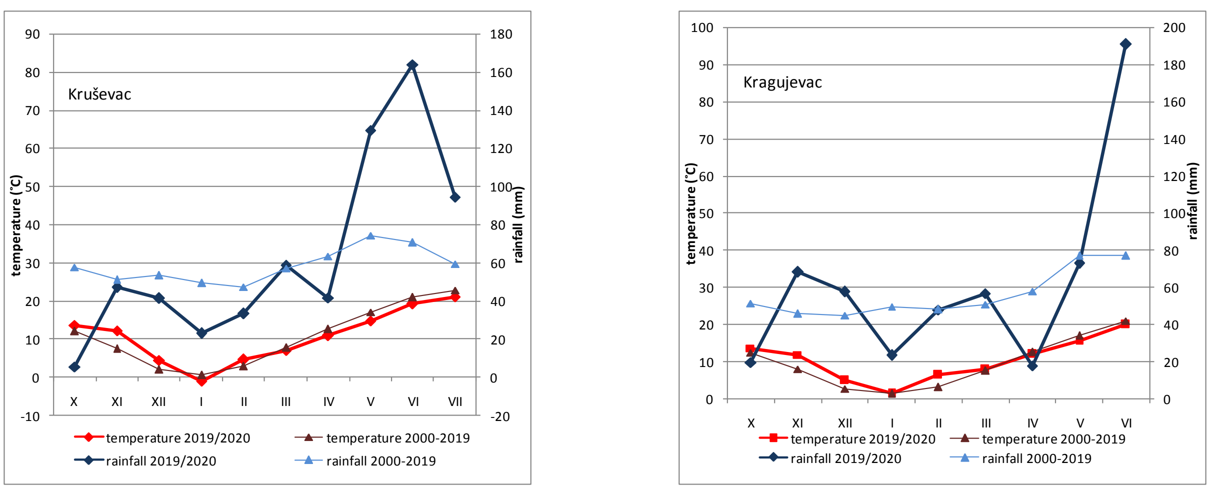
Keywords: *wheat, yield, quality, AMMI, stability.*

Introduction

Varieties of winter wheat represented in agricultural production have genetic potential for grain yield over 10 t ha^{-1} and good or satisfactory quality of grain and flour. However, average yields and grain quality, from year to year are extremely unstable. This variability can be largely attributed to unfavorable climatic conditions that accompany changes in the intensity and distribution of precipitation in critical phases of plant growing, as well as inadequate production technology (Luković et al., 2019; 2020; Ruiz et al., 2019; Senapati and Semenov, 2020). Poor soil preparation, late sowing, weeds, insufficient mineral nutrition of plants and inadequate protection significantly reduce grain yield and directly affect the unsatisfactory utilization of the genetic potential of the variety. In addition to climatic characteristics and applied production technology, the adaptation of varieties to agroecological conditions of a certain area has a significant impact in achieving high yields and grain quality. Yield stability and grain quality are crucial for agricultural producers when deciding on the choice of variety for sowing, especially in agroecological areas with less favorable climatic and edaphic factors. The aim of this study was to evaluate the stability and adaptability of yield and quality of divergent wheat varieties, based on the results of experiments performed in central Serbia, where soils are heterogeneous and less fertile.

Material and Methods

As research material in this paper, 10 varieties of winter wheat were used, which were produced in three breeding institutes in Serbia: Center for Small Grains in Kragujevac (Perfekta, KG-52/3 and Takovčanka), Institute PKB Agroekonomik in Belgrade (Merkur, Vizeljka and Talas) and Institute for Field and Vegetable Crops in Novi Sad (NS 40S, Zvezdana, Javorka and Pobeda). The field experiments were performed during 2019/2020 at two locations: Center for Small Grains in Kragujevac and Institute for Forage Plants in Kruševac. The experiments were set in field conditions according to a completely random block system, in three replications with the size of the basic plot of 5 m^2. After the harvest, grain yield was measured for each plot and then converted to yield in t ha^{-1}. The 1000 kernels weight and sedimentation value were determined according to international standard methods (JUS E.B1.200; Zeleny, ICC No. 116/1, 1972, respectively). The AMMI model (Gauch and Zobel, 1996) was used to assess genotype × environment interaction. Statistical analysis of the data was performed using the computer statistical program GenStat 12th (GenStat, 2009).
The average values of the monthly air temperatures and the sum of precipitation by individual months, in the period of conducting the experiment, are shown in graph 1.



(a) (b)

Graph. 1. Average monthly air temperatures and total amount of precipitation for Kruševac (a) and Kragujevac (b) during the vegetation period 2019/2020

The year of the experiment was marked by a pronounced deficit of precipitation in October at both localities. The winter was mild with a lower amount of precipitation compared to the multi-year average. The periods of the intensive vegetative growth and anthesis of wheat, during April and May, had similar temperature conditions in both localities, with the amount of precipitation differing significantly by localities. The dry period with an extremely low amount of precipitation was characterized by April in Kragujevac (17.8 mm compared to 57.9 mm), while in May the amount of precipitation was around the multi-year average. In May, 129.4 mm of precipitation occurred in Kruševac which was 50 mm higher than the multi-year average for this time of the year. Finally, the stage of grain filling and grain maturity during the June were under extremely unfavorable weather conditions. During this period 163.8 mm of precipitation was recorded in Kruševac and 191 mm in Kragujevac, which represents twice and three times higher amount of precipitation compared to the multi-year average.

Results and Discussion

Analysis of the variance of the AMMI model showed that all sources of variation (genotype, environment and G × E) had statistically significant effects (p <0.01) on grain yield expression, while the influence of locality was not statistically significant on the expression of 1000 kernel weight and sedimentation value (Table 1). Significant genotype / environment interaction indicates the existence of differences in stability between the examined genotypes, which justify application of AMMI analysis.

Table 1. AMMI analysis of variance for 1000 kernel weight, grain yield and sedimentation value

Source of variation	df	1000 kernel weight (g)		Grain yield (t ha^{-1})		Sedimentation value (ml)	
		MS	F	MS	F	MS	F

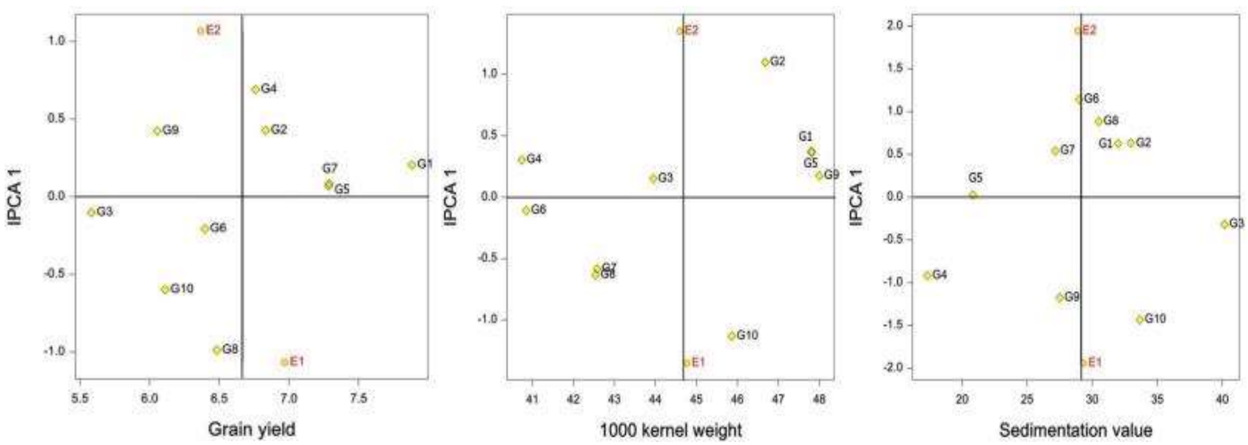
IPCA	9	4.46	3.66**	1.73	62.62**	18.96	12.64**
Error	36	1.22	-	0.03	-	1.50	-
Total	59	9.20	-	0.81	-	42.82	-

** Significant at P = 0.01 level, ^{ns} Non significant

The AMMI 1 biplot (Graph 2 a) shows the ratio of the average grain yield value and the value of the first main component (IPCA1). According to the value of the first main component (IPCA1), the highest stability was recorded in the varieties Vizeljka, NS 40S and KG-52/3 (G5, G7 and G3), followed by Perfekta and Talas (G1 and G6). At the same time, the variety Perfekta achieved the highest grain yield at the level of the whole experiment (7.88 t ha^{-1}) and stood out as the most productive variety. Varieties NS 40S and Vizeljka also had high yield (7.28 t ha^{-1}; 7.29 t ha^{-1}, respectively), while Talas and KG-52/3 although showed high stability, achieved a lower grain yield than the average of the experiment (6.4 t ha^{-1}; 5.58 t ha^{-1}, respectively). Zvezdana (G8) proved to be the least stable variety. Both environments showed a high value of interaction where by Kragujevac standing out as a more productive environment with higher average values compared to Kruševac. The most stable varieties for the 1000 kernel weight were Talas, KG-52/3 and Javorka (G6, G3 and G9) according to the values of the first main component (Graph 3 b), of which Javorka achieved higher, and Talas and KG-52/3 lower values

of the analyzed trait than the general average. The greatest effect of interaction and thus the least stability was observed in the cultivars Takovčanka and Pobeda (G2 and G10).
In the analysis of expression stability for sedimentation value, Vizeljka and KG-52/3 (G5 and G3) stood out as the most stable cultivars, followed by NS 40S, Perfekta and Takovčanka (G7, G1 and G2). However, although they expressed high stability, the cultivars Vizeljka and NS 40S achieved lower than average values (20.8 ml; 27.7 ml, respectively), while Perfekta, Takovčanka and KG-52/3 had above average values of the observed traits. At the same time, KG-52/3 proved to be superior in comparison with other varieties, achieving the highest value of sedimentation value at the level of the overall experiment (40.2 ml). This genotype also stood out in terms of quality traits in 2015, characterized as a year with extremely high rainfall during the periods of flowering and the beginning of grain filling, achieving high average values of sedimentation value at three sites in Serbia (Lukovic, 2020). The variety Pobeda (G 10), which represents a quality standard in experiments of Commission for the approval of new varieties, had the lowest stability (Graph 2 c).



(a) (b) (c)

Graf. 2. Average grain yield (a), 1000 kernel weight (b) and sedimentation value (c) in relation to the value of the first principal component of interaction for 10 wheat cultivars in two localities (Kragujevac, Kruševac);
Legend: 1-Perfekta; 2-Takovčanka; 3-KG-52/3; 4-Merkur; 5-Vizeljka; 6-Talas; 7- NS 40S; 8-Zvezdana; 9-Javorka; 10-Pobeda

Grain yield and quality depend on genetic differences between varieties, environmental factors as well as their interaction (Zečević et al., 2013; Đurić et al., 2020). Aktas (2020) emphasizes the predominant influence of the external environment on the variability of yield and grain quality. Similar results were published Mut et al. (2010) who state that the most stable variety (Bezostaya) gave the highest value to protein sedimentation. In the research of Gómez-Becerra et al. (2006) the most productive genotype was also the least stable, i.e. adapted to specific agroecological conditions. Hristov and Mladenov (2005) emphasized the Kremna variety as a stable genotype, with above-average values of protein sedimentation. In research of Khazratkulov et al. (2015) in addition to stable and high grain yields, singled out wheat genotypes which possess stable and good grain quality and can serve as desirable parents in wheat breeding programs. The year 2020 is characterized by a dry period in April in Kragujevac and exceptionally large amounts of precipitation in June at both localities. In Kruševac alone, 163.8 mm of precipitation was recorded in June, and 191 mm in Kragujevac. Such unfavorable weather conditions negatively affected the processes of grain filling and maturity of grains, causing the formation of the poorly filled grains with lower quality. In such an unfavorable year, wheat genotypes without standing high stability of grain yield and quality were determined, so they can be considered as adapted to different agroecological conditions. In addition to stable yield, the stability of quality traits is an important characteristic of varieties, especially in years with unfavorable climatic conditions. Such varieties represent a valuable raw material in the milling and baking industry necessary for obtaining a quality end product.

Conclusion

Using the AMMI model, high stability of the varieties Vizeljka, NS 40S and Perfekta for grain yield, and KG-52/3, Perfekta and Takovčanka for grain sedimentation was established. These cultivars achieved higher values than the overall average cultivar Perfekta for grain yield and KG-52/3 for sedimentation value. The obtained results in this research indicate that, in central Serbia where the soils are heterogeneous, with pronounced acidity and poorer fertility, an advantage should be given to varieties with high adaptability and stability of yield and quality such as the varieties Perfekta and KG-52/3. These varieties can be considered highly adapted and desirable for cultivation in central Serbia.

Abstract

During the last two decades, the production of watermelon in Serbia is based on the use of grafted seedlings. Grafting aims to increase the yield and maintain the quality of fruits, as well as resistance to stress caused by biotic and abiotic factors. The watermelon (*Citrullus lanatus* (Thunb.) Matsum and Nakai) cultivar Top Gun F1 was grafted onto Emphasis F1 and Strong Tosa F1 commercial rootstock hybrids and *Lagenaria siceraria* as simple rootstock accepted by many local farmers, for late open field growing conditions. Nongrafted and selfgrafted plants were used as control. The percentage of grafting in the seedling period ranged from 81% (Strong tosaF1 / Top Gun F1) to 91% (*Lagenaria siceraria* / Top GunF1). Grafted seedling plants had a higher height and thickness of the stem, as well as a larger leaf area compared to nongrafted and selfgrafted. It has been confirmed that grafting watermelons produce a larger number of larger fruits. The highest number of fruits per plant (2,2) was recorded in the variant *Lagenaria siceraria* / Top Gun F1, with an average weight of 6.510 g. Hybrid rootstocks contributed to a uniform number of fruits per plant 1,7-1,8 with an average weight of 7.450-7.700g. Stress caused by unfavorable climatic conditions and pest attacks affected the number of fruits per plant 0,9-1,1 of nongrafted and selfgrafted plants, with a weight of 3.200-3.910 g. Detrimental effects were not determinates in fruit quality such as fruit index, rind thickness and sensory properties (has been proven by the results of panel tasting) on grafted plants, but differences according to the rootstock being used were evident. Grafted plants improved plant growth and yield without any harmful effects on fruit quality.

Keywords: *watermelon, grafting, rootstocks, yield, quality*.

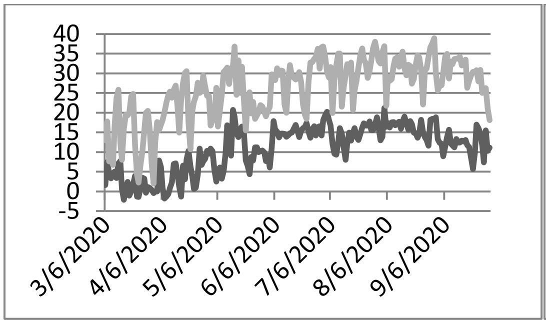
Introduction

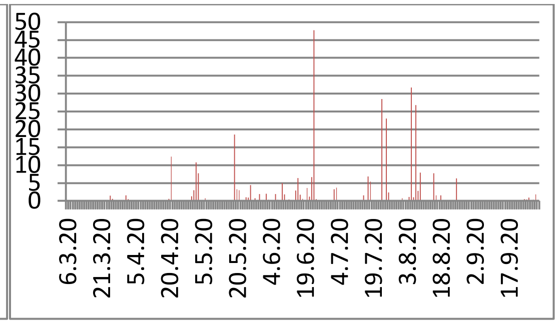
Grafting can be defined as the natural or deliberate fusion of plant parts so that vascular continuity is established between them (Pina and Errea, 2005) and the resulting genetically composite organism functions as a single plant (Mudge *et al*., 2009). By grafting vegetable species the problems caused by biotic and abiotic stress are overcome. Grafted watermelon has been reported to resist infection by pathogens, as well as nematodes (Lee *et al*., 2010). The root systems of grafted plants are stronger and more efficient in the uptake of water and nutrients, which indirectly improves yield (Miskovic *et al*., 2016). The use of rootstocks can enhance plant vigor through vigorous attainment of soil nutrients, avoidance of soil pathogens and tolerance of low soil temperatures, salinity and wet-soil conditions (Davis *et al*., 2008). However, rootstock/scion combinations affect the final size, yield and quality of fruits from grafted plants , both immediately postharvest and during prolonged storage (Falik and Ilic, 2014). The quality of grafted fruit must be equal to or better than that of nongrafted watermelon to ensure market acceptability (Colla *et al*., 2010). Grafting can enhance fruit quality of watermelon by increasing

the synthesis of endogenous hormones and the acquisition and transport of mineral nutrients (Lee *et al*., 2010; Wang *et al*., 2017) and also by altering secondary metabolites (Lee *et al*.,2010; Kakizaki *et al*., 2017). There are many conflicting reports on changes in fruit quality due to grafting and whether grafting effects are advantageous or deleterious. The differences in reported results may be attributable in part to different production methods and environments, type of rootstock/scion combinations used, and harvest date (Rouphael *et al*., 2010). Despite the challenges, grafting is becoming a common practice in several countries, such as Spain, Italy, Turkey, Greece, and Israel (Edelstein *et al.*, 2017).
The objectives of this study were to assess the survival rate and morphological characteristics of grafted and nongrafted seedlings of watermelon. After transplanting, plant growth, yield and quality of grafted watermelon and control (nongrafted and selfgrafted plants) were monitored and compared.

Material and methods

Production of a grafted, nongrafted and selfgrafted watermelon was conducted in randomized complete blocks design with three replications during 2020 in an experimental garden located in the village of Moravac near Aleksinac (21∘ 42 ′ E, 43∘ 30 ′ N, altitude 159 m) in the central area of Serbia. The watermelon (*Citrullus lanatus* (Thunb.) Matsum and Nakai) cultivar Top Gun F1 was grafted onto Emphasis F1 (*Lagenaria type*) and Strong Tosa F1 (interspecies type: *C. maxima X C. moschata*) commercial rootstock hybrids and *Lagenaria siceraria* as simple rootstock accepted by many local farmers. Nongrafted and selfgrafted plants were used as control. The cleft graft (CG) applied in our research, was the initial grafting method used for cucumber and watermelon (Ishibashi, 1959). The sowing of the rootstock was done in pots with a diameter of 10 cm, and the sowing of the scion in boxes, at the end of March 2020. Morphological characteristics of scion and rootstocks cotyledons, grafted and nongrafted seedling plants were recorded: plant mass (g/plant), root mass (g), leaf area by conture paper method (cm^2/plant), and the survival rate of grafted plants (%).
When plants developed true five-six leaves (6 weeks after sowing) they were transferred into the experimental field to soil with spacing between rows 240 cm and 120 cm in a row, with a plant density of 0,35 plants m^{-2}. Growing technology involved the primary soil preparation before planting and fertilization with formulation 12: 11: 24 + ME (Yara Mila Complex) applied through a regular supplemental feeding drip system and foliar application. Vegetative growth characters were recorded in samples of three plants randomly chosen from each plot as follows. The fruits were harvested after 70-80 days (depending on the rootstock) from transplanting and at harvest the following characteristics were evaluated: total yield (t/ha^{-1}), number of fruits/plant, average fruit weight (g)**.** Fruit characteristics were determined by measuring: fruit length (cm), fruit diameter (cm), index of fruit, fruit rind thickness (mm). Panel test was determined by panel testing flavor (sweet aroma, flesh color, texture, juiciness, sweet taste, fermented flavor, after taste) by 5 persons per replication: Scale system from 1 (week) to 10 (strong). Meteorological data from March to September 2020 were used from the local meteo-station in Moravac.





Graf.1Max and min. temperature (III-IX 2020) Graf.2 Rainfall (III-IX 2020)

The data were analyzed by analyses of variance (ANOVA) follow by Tukeyś HSD test, using the Statistica 6.1 software (Statsoft, Tulsa, OK, USA). All analyses were performed at a 95 % and 99% level of confidence ($p<0.05$; $p<0.01$).

Results and Discussion

One of the most important factors in the process of grafting is the correct choice of rootstock and scion, as a prerequisite for compatibility. Grafting compatibility is related to taxonomic affinity (Davis *et al*., 2008). The result of compatibility is the establishment of vascularization between the rootstock and the scion, and the formation of callus, so it is important to determine the moment when grafting is approached, especially in species that have hollow hypocotyls.

Tab. 1 Morphological characteristics of watermelon seedling plants

Cultivar	Rootstocks and scions ready for grafting			Rootstock/ Scion	Grafted, nongrafted, selfgrafted seedlings of watermelon (phase true 3-4 leaves)			
	Plant mass g	Root mass g	Leaf area cm²/plant		Survival rate (%)	Plant mass (g)	Root mass (g)	Leaf area cm²/plant
Emphasis F1	2,20	0,63	23,8	Emphasis/ Top gunF1	85	18,1	3,48	215,1
Strong tosa F1	2,84	0,75	28,5	S.tosa F1 /Top gunF1	81	18,7	3,18	244,3
Lagenaria siceraria	2,02	0,51	24,2	L.siceraria/ Top gunF1	91	19,4	4,60	240,1
Top gunF1	0,91	0,11	18,9	TopgunF1/ Top gun F1	82	7,72	0,78	114,3
-	-	-	-	Top gun F1	-	7,30	0,65	93,9
LSD 0,05	0,501	0,167	3,891			1,131	0,618	11,91
LSD 0,01	0,759	0,253	5,895			1,646	0,900	17,33

The too young plant is difficult to manipulate. Optimum seedling age varies for species and different grafting methods. The cleft graft (CG) method applied in our research and results indicate that the scion should be in the cotyledons phase up to 48 hours of age from the beginning of sprouting, and the rootstocks 60-96 hours, according to the vigor of the species, with a true leaf just conceived. Thus, hybrid Strong tosa F1 is most often included in grafting 2-3 days, and *L. siceraria* 4-5 days after sprouting. Uniformity in both germination and growth of the rootstock and scion are critical for grafting survival. Graft healing is dependent on hormonal

signaling originating in the cotyledons to successfully heal the wounded region (Daley and Hassell, 2014; Melnyk, 2017), therefore, traditional commercial methods of grafting watermelon depend on retaining at least one rootstocks cotyledon. The period of acclimatization was under the conditions of increased air humidity and moderate temperature (VV% 92-96%, daily temperature 23-28˚C) with shading of plants for five days. Turgor of the scion cotyledons indicates that vascularization has been established. Callus is formed 5-6 days after grafting and then the plant returns to natural microclimate. Similarly, Kubota *et al*. (2016), indicate that the success of callus bridge formation is reported to take 4–5 days under optimum temperatures.
The availability of seeds of the species *L. siceraria*, the high survival rate received during grafting and the influence on the increase of watermelon yield, make these rootstock very popular among the producers of grafted watermelon seedlings. In our study, the survival rate seedlings grafted on the rootstock of *L. siceraria* was 91%, 5-10% higher than compared to the commercial rootstock hybrids of Emphasis F1 (85%) and Strong tosa F1 (81%) (tab.1). The survival rate of grafted plants depends on compatibility between scion and rootstock, quality and age of seedlings, quality of the joined section, and post-grafting management (Hang *et al*. 2005). In contrast to solanaceous crops, it is rare to get 100% graft survival for watermelon, so it is recommended to graft up to 20% more plants than needed, depending on the grafting method and environmental factors (Miles *et al*., 2017). Watermelon seedlings grafted onto *L. siceraria* have the best morphological characteristics with significant differences compared to the plants grafted on commercial rootstocks hybrids. Control seedlings of watermelon have a significantly lower root mass, plant mass and leaf area compared to grafted plants. Đurovka *et al*. (2002) note that the average weight of grafted watermelon seedlings, depending on the rootstocks, is higher by 54.5-99.3% compared to nongrafted seedlings.
The grafting of watermelon onto different rootstocks increases plant growth. Data in tab.2, indicated that there were significant increments in plant vigor of the grafted plants compared to nongrafted and selfgrafted. Yetisir and Sari (2004) reported that out of 11 rootstocks tested on watermelon, all the grafted plants produced more biomass than control plants. Grafting watermelon positively affected plant vigor, height and disease control (El-Eslamboly, 2010; Alan *et al*., 2007) which is associated with the vigor and hormonal initiation of the root system.

Table 2 .Effects of the grafting on the vegetative growth characteristics of watermelon plants

Rootstock / Scion	Branch length to the first fruit (cm)	Stem diameter (cm)	Number of brunches	Number of leaves / plant
Emphasis/ Top gunF1	136,8	2,4	6,17	296
Strong tosa F1/ Top gunF1	214,2	2,7	6,82	360
L.siceraria/Top gunF1	89,5	2,5	6,34	310
TopgunF1/ Top gun F1	74,6	1,3	4,6	212
Top gun F1	82,3	1,2	4,4	194
LSD 0,05	32,05	0,693	0,837	64,74
LSD 0,01	46,64	0,541	2,508	94,20

Commercial rootstocks are vigorous and will quickly overtake the scion and therefore after receiving the grafted plants, it is necessary to monitor the appearance of lateral shoots of the rootstocks and remove them. Daley and Hassell (2014) apply fatty alcohol treatments for these purposes. Hagihara (2004) classified the species and cultivars of the rootstocks used in Japan on the basis of plant vigor. In general, 'Shin-tosa' rootstocks are more vigorous than the bottle gourd rootstock cultivars, which is confirmed by our research by comparing the rootstocks of Strong tosa F1 and *L. siceraria*. The total yield of watermelon grafted on *L. siceraria* was higher compared to the watermelon grafted on Emphasis F1, with statistically significant differences. However, the control watermelon plants formed a very significantly lower yield compared to the grafted plants, which is caused by climatic conditions. During May 2020, intense precipitation was recorded followed by hail that caused damage to plants, and June 2020 is recorded as the fifth rainiest in Serbia in relation to measurements in the last 70 years (RHMZ, 2020). Grafted plants regenerated more intensively in wet soil conditions, which resulted in significantly higher yields compared to the control.

Table 3. Effects of the grafting on total yield, fruits characteristics and quality of watermelon

Rootstock/ Scion	Total yield (t/ha^{-1})	Average mass fruit (g)	N° fruit/ plant	Fruit characteristics			Rind thickness (mm)	Panel test - flavor
				Length (cm)	Diameter (cm)	Index of fruit		
Emphasis F1/ Top gunF1	44,95	7.450	1,7	24,2	22,9	1,06	16,51	8,5
Strong tosaF1 /Top gun F1	49,01	7.700	1,8	24,7	23,6	1,03	17,10	7,06
L.siceraria/ Top gun F1	50,86	6.510	2,2	25,1	22,2	1,07	16,46	7,65
Top gun F1/ Top gun F1	15,65	3.910	1,1	18,7	18,3	1,02	15,90	7,3
Top gun F1	11,08	3.200	0,9	17,9	17,8	1,005	15,79	7,1
LSD 0,05	5,197	1253	0,618	2,016	2,387	0,0842	1,350	0,347
LSD 0,01	7,562	1824	0,9003	2,934	3,473	0,1225	1,964	0,505

In watermelon, two primary quality-related characteristics are fruit weight and flesh properties (Fredes *et al*., 2017). The positive effect of grafting on the average weight, number of fruits per plant and physical characteristics of the fruit is evident (tab.3). The exception is the fruit index, with no significant differences between variants and control. Rind thickness is significantly higher only in the fruits of watermelon grafted on Strong tosa F1 compared to nongrafted plants. Increasing the rind thickness in grafted plants affects the strength of the fruit and transportability. Quality fruits of control and plants grafted on hybrid Strong tosa F1 are balanced, thus achieving the basic postulation of grafting, but Panel tasting results indicate a significant to very significant improvement in taste in watermelon grafted on *L. siceraria* or Emphasis F1. Rootstocks influence the sensory properties of the fruit watermelon without detrimental effects on quality. Watermelon is a non-climacteric vegetable, so the moment of harvest is reflected in the quality. The traditional approach to assessing maturity may not apply to grafted plants. The harvesting of watermelon fruits grafted on *L. siceraria* and Emphasis F1 started about 7-10 days earlier compared to control or plants grafted on Stong tosa F1 (data not shown). Most literature relies on the assumption of synchronous ripening in grafted and nongrafted plants, potentially leading to confounding reports for fruit maturity and fruit quality resulting from grafting (Davi *et al*., 2020). Reduced quality may be a factor of improper (early) harvest timing (Soteriou *et al*., 2014). Simultaneous harvest of grafted and self-rooted plants assumes a synchronized maturation, which overlooks the effect of grafting on fruit ripening behavior (Davis *et al*., 2008). Future research should focus on this issue.

Conclusions

Grafted watermelon with a good rootstock/scion combination has better abiotic stress tolerance, higher yield and good quality. Grafting success depends on compatibility between scion and rootstock, quality and age of seedling, and post-grafting acclimatization. In our study, the survival rate of grafted seedlings was: 81% Strong tosa F1, 85% Emphasis F1 and 91% *L. siceraria*. Control watermelon seedlings have a significantly lower root mass, plant mass and leaf area compared to grafted seedlings. Grafted watermelon positively affected plant vigor. The grafted plants produced more biomass than control plants (nongrafted, selfgrafted). Grafting increased fruit size and the number of fruit per plant, and this causes higher yield than control. The fruits quality of grafted plants was equal to or better than control plants. Rootstocks affect the sensory properties of the fruit but without any harmful effects on quality.

GERMINATION OF *DIANTHUS SEROTINUS* SEED ORIGINATING FROM PLANTS PRODUCED BY MICROPROPAGATION

Marija MARKOVIĆ*, Vesna GOLUBOVIĆ-ĆURGUZ

University of Belgrade, Faculty of Forestry, Serbia
*Corresponding author: marija.markovic@sfb.bg.ac.rs

Abstract

Dianthus serotinus Waldst.& Kit. is important endemic, endangered and decorative species. It has a status of extremely endangered species in Serbia and it is under legal protection. *D. serotinus* can also be used as an ornamental, drought tolerant, low-maintenance species. To enable its *ex situ* and *in situ* conservation, it has been successfully propagated *in vitro*, in the Laboratory at the Faculty of Forestry in Belgrade. The obtained plants were acclimatized, flowered and produced seeds. The seed germination was tested immediately after collecting and after two years of storage. The effect of different disinfection methods on seed germination was also evaluated: treatment with 3.5% NaOCl solution for 15 minutes, treatment with *Allium sativum* L. extract containing bioactive allicin, and treatment with a fungicide Previcur (control). Immediately after collection, the seed germination (92.2 - 94.3%) and germination energy (90.0 – 91.1%) were high, and NaOCl and *A. sativum* extract had no effect on germination. However, after two years of storage, treatment with NaOCl significantly increased germination rate (90.0%) compared to control (81.1%), while *A. sativum* extract had an adverse effect (68.9%) on seed germination.

Keywords: *endangered plants, generative propagation, NaOCl, Previcur, allicin, Allium sativum.*

Introduction

Dianthus serotinus Waldst. et Kit. is a species included in category V (vulnerable taxa) of the IUCN Red List of endangered species. This endemic Pannonian species has the status of extremely endangered species in Serbia and it is under legal protection (Law on Environmental Protection, Rulebook on protected species, 2010). In Serbia, it grows in the area of Subotica - Horgoš Sands (Boža, 1999). *D. serotinus* is also an ornamental perennial species with long flowering period, scented white flowers, and bluish-green leaves. This drought tolerant species grows well on alcaline (pH 7.0 - 8.1) sandy soils with a low level of humus. With the aim to enable its *ex situ* and *in situ* conservation, *D. serotinus* has been successfully propagated using *in vitro* method (Marković *et al*., 2013, 2014a,b) and obtained microplants flowered and produced seeds.

Taking into account that *D. serotinus* is an endangered species, generative propagation is a convenient method for its *ex situ* conservation. In this way, propagation is simple and fast, and genetic diversity of obtained plants can be preserved. Thus, the seed obtained from microplants can be sown enabling further propagation and conservation of this species. Therefore, besides seed germination, the effects of storage length on seed germination should also be evaluated.

The use of pesticides is prohibited in the Subotica Sandlands protected area that includes the habitat of *D. serotinus* ("Official Gazette of RS", no. 127/2003) and hence propagation of *D.*

serotinus should be based on the principles of organic production, excluding the use of artificial pesticides. Lately, many research reporting the use of plant extracts with antibacterial and antifungal activities in plant production were published (Mbega *et al*., 2012; Bello and Sisterna, 2010; Rajendra *et al*., 2014; Sarfraz *et al*., 2020). A lot of researchers proved the inhibitory effect of *Allium sativum* L. extracts (containing bioactives allicin, thiosulfate and other constituents) on germination of spores of different species of fungi (*Penicillium* sp., *Aspergillus* sp., *Fusarium oxysporum*) that cause plant diseases (Irkin and Korukluoglu 2007; Ogbebor and Adekunle 2008; Portz *et al*., 2008; Perelló *et al*., 2013; Slusarenko *et al*., 2008; Okigbo *et al*., 2009; Nisa *et al*., 2011; Sarfraz *et al*., 2020; Borlinghaus *et al*., 2021). These studies were based on the need to point out the potential of the natural products that might be used to develop strategies in plant protection, especially for seeds treatments against seed decay or damping-off. The use of *A. sativum* extracts as a biopesticide has been promoted by many associations and organizations engaged in organic production, including Henry Doubleday Research Association (HDRA). Slusarenko *et al*. (2008) reported that *A. sativum* extracts can be used in pre-sowing disinfection of carrot seeds. Taking into account the recommendations and EU regulations related to organic production (Council Regulation 2092/91 on Organic Farming) and the positive effect of *A. sativum* extract on germination and further growth of seedlings of seeds infected with different fungi species (Slusarenko 2008; Perelló *et al*., 2013), we can consider that the *A. sativum* extract can be used as a pretreatment of *D. serotinus* seed. However, the question arose how the *A. sativum* extract may affect seed germination, and whether it could have inhibitory or stimulating effect.

Therefore, the aim of this research was to assess germination rate of *D. serotinus* seed immediately after collection and after two years of storage, as well as the effect of *A. sativum* extract on seed germination.

Material and methods

The seeds were collected from micropropagated plants produced in the Laboratory for tissue culture at the Faculty of Forestry in Belgrade. Part of the collected seeds was used for experiments immediately after collection and the remaining seeds were kept at room temperature, in dry conditions during 2 years. After 2 years of storage, the seeds were chilled for 4 weeks at the temperature of 4 - 5°C before setting the experiment.

The effect of different disinfection methods on seed germination was evaluated. First treatment included immersion of seed in a 3.5% NaOCl solution for 15 minutes. The seeds were rinsed three times for 2 minutes using sterile distilled water. The concentration of NaOCl and duration of treatment was set according to the method successfully used by Marković et al (2007) during establishing sterile *in vitro* culture from seed.

Second treatment consisted of soaking the seeds with water extract from *A. sativum* bulbs. The extract was made using 200 g bulbs that were chopped in a mortar, mixed with 200 ml of distilled water, homogenized for 5 minutes and then filtered through sterile gauze. This method of making *A. sativum* water extract was already reported by Nisa *et al*. (2011).

In the third treatment (control) the seeds were soaked in 1.5% (v/v) Previcur N fungicide solution for 5 minutes (Bayer AG Germany, active ingredient Propamocarb hydrochloride) according to method described by Baker *et al*. (2005) for testing seed germination.

After these disinfection treatments, the seeds were placed on the top of two layered filter paper in the petri dishes for germination. The seed testing was conducted according to the recommendations of the International Seed Testing Association (ISTA, 2010) for testing seed germination of the *D. plumarius* and *D. deltoides*, but a smaller amount of seeds was used. Humidity was controlled regularly by adding the distilled water if needed. Temperature was 20 - 26°C and germination was tested in long days conditions. First count (germination energy) was recorded on 4^{th} day and final count of germinated seeds was performed on 14^{th} day after placing seeds on germination.

Each treatment consisted of three replicates with 30 seeds. Obtained data were statistically analyzed and significance of differences between mean values was determined by analysis of variance (ANOVA, $p<0.5$) and the LSD (least significant difference) method. Prior to analysis, arcsin data transformation was performed.

Results and Discussion

The seed disinfection method did not influence germination of seed tested immediately after collection, the obtained differences were not statistically significant (Table 1) and all treatments had high germination rate (92.2 – 94.3%) and germination energy (90.0 – 91.1%). After two years of seed storage, germination energy was significantly reduced (60.0 – 75.6%), and germination rate was lower (68.9 – 90.0%). Change in germination rate after seed storage was studied for other *Dianthus* species. For example, Mikulik and Vinter (2002) examined germination of *Dianthus superbus* subsp. *superbus* immediately after collection, or after long-term storage at the temperature of 0°C. However, their results were probably influenced by storage temperature because germination energy (30%) and germination rate (80%) of seed tested after collection were lower than germination energy (32%) and germination (86%) of seed tested after 5 months of storage, but the germination rate was additionally reduced after two years (78%) and three years (71%) of storage.

In our research, the germination after two years of seed storage differed depending on disinfection method used. The highest germination rate was obtained after NaOCl treatment (90%), lower germination was achieved after Previcur treatment (81.1%) and the considerably lower germination was recorded after *Allium* extract treatment (68.9%). The influence of NaOCl on seed germination has already been reported for other plant species, because NaOCl is an oxidizing agent which may have a stimulatory effect on seed germination due to its influence on partial degradation of the seed coat and solubilization and oxidation of the inhibitors of seed germination (Marković *et al*., 2016; Lee *et al*., 2007). However, the effect of NaOCl on germination depends on its concentration and the length of treatment. For example, after 11 months of storage, the seed of *Sorghastrum nutans* were soaked in 5.25% NaOCl for 20 or 60 minutes, and germination was the lower after 60 minutes treatment (51%) compared to germination after 20 minutes treatment (53%) but in a control treatment (without NaOCl) only 47% of seeds germinated (Watkinsonand Pill, 1998). However, gibberellic acid (GA_3) had better effect on germination *S. nutans* (67%) and moreover Watkinson and Pill (1998) achieved the best results (71%) by soaking the *S. nutans* seed in NaOCl solution for 20 minutes, followed by GA_3 treatment.

Addition of NaOCl sometimes can have inhibitory effect on seed germination. For example, although treatment with 1% or 3% NaOCl for 5 or 40 minutes did not have a significant effect on germination of *Capsicum annuum* seed immediately after collection compared to a control, NaOCl showed inhibitory effect on germination of the seed stored at the room temperature for 10 months, and germination rate decreased with increased exposure to NaOCl solution (5, 10 or 20

minutes) (Khah and Passam, 1992). These findings are in a contrast to our results where NaOCl had a stimulating effect on the germination of seed after storage.
Beside having an effect on seed germination, NaOCl has also a fungicidal action (Macnish *et al.*, 2010; Sitara and Akhter, 2007) which is important for germination and seedlings survival (Mikulik *et al.*, 2002). The presence of pathogens on seed can affect seed germination, and for example the seed of *D. superbus* ssp. *superbus* infected with pathogens had a low germination rate (60%) compared to pathogen-free seed (84%), but germination rate of the infected seed increased considerably (88%) after NaOCl treatment (Mikulik *et al*., 2002).

Table 1. Germination of *D. serotinus* seed after different disinfection treatments

Storage length	Treatment	Germination energy (%)	Germination rate (%)
fresh seed	NaOCl	90.0^{d}	92.2^{cd}
fresh seed	*A. sativum*	87.8^{d}	93.3^{cd}
fresh seed	Previcur	91.1^{d}	94.3^{d}
2 years old seed	NaOCl	68.9^{bc}	90.0^{c}
2 years old seed	*A. sativum*	60.0^{a}	68.9^{a}
2 years old seed	Previcur	75.6^{c}	81.1^{b}

Values followed by different letters are significantly different at the $P<0.05$ level according to the LSD test

Although *A. sativum* extract did not have a significant effect on germination energy and germination rate of seeds that were sown immediately after collection, it had inhibitory effect on seed germination after two years of storage, because the obtained values were significantly lower than control treatment with Previcur (Table 1.). This indicates that *A. sativum* extract can be used in the disinfection of *D. serotinus* seeds for sowing immediately after collection, but it cannot be used as a pretreatment of the seed after long-term storage. However, it is necessary to conduct additional research to determine the effect of different concentrations of *A. sativum* extract on germination of *D. serotinus,* especially because allicin can induce necrosis if it is applied at higher doses (Borlinghaus *et al*., 2021).

Conclusions

After *D. serotinus* has been successfuly micropropagated, the obtained plants produced viable seed that can be used for further propagation of this species. The seed has high germination rate (above 90%) immediately after collection and the seed viability was preserved after 2 years of storage. However, to achieve high germination rate after 2 years of storage at the room temperature, the seeds should be chilled for 4 weeks at 4 - 5°C, following by immersion in a 3.5% NaOCl solution for 15 minutes. *A. sativum* extract can be used for disinfection of fresh seed, but it has inhibitory effect on germination of long-term stored seed.
Long-term seed storage at lower temperatures should be considered.

Abstract

Platanus × acerifolia is a widely planted ornamental tree, suitable for planting in cities, especially as a roadside tree because it is very tolerant of atmospheric pollution and root compaction. Despite producing large amounts of seeds, it is usually propagated by cuttings. However, the London plane produces a large amount of seeds and generative propagation is also possible, thus helping in a preservation of genetic variability which enables plane tree populations to adapt and to survive in heterogeneous environments in changing climate conditions. The aim of this study was to evaluate the effects of red and far-red light on seed germination, considering that seeds are small and possibly photoblastic. The seeds were collected in April and imbibed for 72 or 103 hours, followed by exposure to white light, red light, far-red light or their combinations before placing seeds on germination. The seeds in the control treatment were kept in dark. Despite expectations, obtained results show that London plane seeds are not photoblastic. Furthermore, the highest germination rate (41.0%) was obtained in a control treatment (seeds kept in dark). However, dark conditions did not promote germination because there was no significant difference in a germination rate among seeds exposed to white light, red light or far-red light.

Keywords: *London plane, photoblastic seed, germination, photosensitivity, far-red light.*

Introduction

Platanus × acerifolia (London plane) is large deciduous tree growing up to 40 m, which is widely planted in cities for its hardiness and ability to survive in harsh urban street and soil environments (Zion, 1994; Vukićević, 1996; Plotnik, 2000). The London plane is very tolerant of atmospheric pollution and it can endure root compaction when planted in tree row with a small space for root development (Dixon *et al*. 2013). It is also very decorative tree, with its large crown and changing colors of the bark (Plotnik, 2000). In Serbia, London plane is very popular urban roadside or parkland tree. Besides its ornamental use, the plane tree wood can be used in carpentry, for plywood production, in a paper industry, or it can be used to produce attractive veneers (Dixon *et al*., 2013).

London plane can be propagated by seeds or cuttings (Hartmann *et al*., 2014; Grbić, 2004). The cultivars are usually propagated by hardwood cutting, but softwood cuttings can also be used. Some cultivars (e.g. 'Bloodgood', 'Columbia', 'Liberty') can be propagate by grafting. Generative propagation is simple, but germination percentage is usually low. The seeds can overwinter in the seedballs on tree before collection. If the seeds are collected in autumn, then stratification at about 4°C is necessary.

The aim of this study is to investigate the possibility to use seed collected from elite trees growing in Belgrade for generative propagation of this species. In this way, propagation is fast and easy, and obtained plants will preserve genetic variability thus enabling to obtain plane trees adapted on local conditions, capable to survive in heterogeneous environments in changing climate conditions. Besides, *P.* × *acerifolia* seeds are very small, without endosperm which indicates that seeds can be photoblastic. However, there is no data available regarding photodormancy of the London plane seed. For this reason, we evaluated the effects of white, red and far-red light on seed germination in order to assess phytochrome regulated seed germination i.e. if the plane tree seeds are photoblastic or not.

Material and Methods

The seeds were collected from *P.* × *acerifolia* elite tree growing in park Kalemegdan, in April. *Upon bringing in* the Laboratory for seed testing at the Faculty of Forestry, University of Belgrade (Serbia), the seeds were stored in a dry and dark place few days before setting an experiment.
To test the effect of red and far-red light on germination, two types of filters and two types of lamps were used. Red light was obtained using a red plastic filter which was 3 mm thick and a fluorescent lamp (Philips 100w). Far-red light was obtained using a dark red plastic filter which was 4 mm thick and an incandescent lamp (Tesla 100w).
Before light treatments, the seeds were imbibed for 72 hours or 103 hours in distilled water. The seeds were exposed to red or far-red light for 5 minutes and put on germination in a dark conditions, at 25˚C. Two other light treatments included germination of seed in dark (24 h) or natural white light conditions (16h light / 8 h dark) (table 1).

Table 1. Germination treatments

	Treatment
R72	72 h imbibing + red light
R-FR72	72 h imbibing + red light + far-red light
R-FR-R72	72 h imbibing + red light + far-red light + red light
D72	72 h imbibing + 24 h dark
L72	72 h imbibing + 16h/8h white light
R103	103 h imbibing + red light
R-FR103	103 h imbibing + red light + far-red light
R-FR-R103	103 h imbibing + red light + far-red light + red light
D103	103 h imbibing + 24 h dark
L103	103 h imbibing + 16h/8h white light

The seeds (three replicates with 100 seeds per treatment) were placed on germination on the top of two layers of filter paper in the Petri dishes. The number of germinated seeds was recorded daily during the period of 21 days. After that, the number of remaining viable seeds that did not germinate was determined in order to calculate the real germination rate, as a percentage of sound (viable) seeds that germinate (Grbić et al., 2010). The germination energy was recorded on 7th day. Obtained data were statistically analysed using the program Statgraphics Plus, Ver 2.1.

Results and Discussion

The germination percentage was low in all treatments (Tables 2, 3) ranging mostly between 30% and 35%. This can be expected because low germination percentage of P. × acerifolia has already been reported, varying from 20-30% (Dixon et al., 2013) to 48% (Falleri and Pacella, 2011).
The light or dark conditions and treatments with a red and far-red light did not affect germination because there was no statistically significant difference among obtained values (Tables 2, 3). The highest germination rate (41%) was obtained in a dark conditions with seeds that imbibed for 72 h before germination. However, dark conditions did not promote germination because there was no significant difference in a germination rate among seeds exposed to white light, red light or far-red light. Moreover, germination of seeds in dark conditions after imbibing of 103 h was only 32%.

Table 2. Germination of 72 h imbibed seed

Treatment	Germination rate (%)	Germination energy (%)	Real germination rate (%)
R72	22.7[a]	18.7[a]	23.7[a]
R-FR72	23.3[a]	18.7[b]	24.1[a]
R-FR-R72	33.3[a]	24.0[a]	32.7[a]
D72	41.0[a]	23.0[a]	42.3[a]
L72	30.7[a]	21.0[a]	31.2[a]

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

Table 3. Germination of 103 h imbibed seed

Treatment	Germination rate (%)	Germination energy (%)	Real germination rate (%)
R103	28.3[a]	22.3[a]	28.9[a]
R-FR103	31.3[a]	26.0[a]	32.5[a]
R-FR-R103	32.0[a]	26.3[a]	33.8[a]
D103	32.0[a]	23.0[a]	32.3[a]
L103	33.7[a]	16.7[a]	34.5[a]

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

Comparing obtained germination rates between seed imbibed for 72 h and 103 h, it can be observed that germination rate was more uniform after 103 h, ranging from 28.3% to 33.7%, while germination rate after 72 h varied from 22.7% to 41.0%. This indicates that after 72 h seed probably did not imbibe enough water and hence the difference in germination, although it was not significant.
The real germination rate expressed as a percentage of full seeds that germinated was slightly higher than germination rate in all treatments, indicating that there were no many empty seeds in these samples. However, there are reports that full seeds can be dead and not able to germinate (Donald, 1985; Barnett and Dumroese, 2006). For this reason, Falleri and Pacella (2011) used IDS (incubation, drying, separation) technique which was developed on the principle that water imbibed by live seeds is lost at a slower rate than water imbibed by dead seeds when both are

subjected to uniform drying conditions, and they succeed to increase germination rate of *P.* × *acerifolia* from 48% (control) to 86% using petroleum ether as a separation medium.
Taking this into account there is a possibility that we could achieve better results by removing the dead seeds from the samples. However, it is also possible that germination rate and quality of seed was affected by seed source and that collecting seeds from other trees could give different results, especially because poor cross-pollination in isolated trees can cause a production of large numbers of empty seeds (Hartmann *et al*., 2014). For example, Hishyar and Gailan (2016) showed that seed collected from *P. orientalis* plants growing in different altitude exibited significant differences in germination rate (46.3% - 66.5%) and further seedlings growth.

Conclusions

The results obtained in this research showed that *P.* × *acerifolia* seeds don't respond to light treatments of white, red and far-rad light which indicate that phytochrome is not involved in regulation of germination i.e. seeds are not photoblastic. However, germination rate was low, ranging from 30 – 40% which can be caused by a large percentage of dead seeds in a samples or poor choice of mother trees. For this reason, different elite trees growing in Belgrade area should be examined as a seed source for further propagation of this species. Also, different techiques for removing dead seeds from seeds samples, including IDS method, should be examined.

Abstract

Buddleja davidii a vigorous shrub with an arching habit and honey-scented lilac to purple flowers, widely used as an ornamental plant. There are many varieties and cultivars of this species, and they are propagated vegetatively. However, it produces viable seed and it has been recorded as naturalized or even invasive species in many countries. For this reason, testing germination of the seeds collected from the plants growing in the Belgrade area in Serbia can help to evaluate their potential to spread by self-sowing. The seeds of summer lilac are positively photoblastic and the aim of this study was to investigate the effect of red and far-red pulse of 5 minutes on seed germination. The obtained results show that a reversible effect of red and far red light on seed germination is partially expressed. The highest germination rate was recorded after 5 minutes of red light pulse (29.3%), red light treatment followed by far-red light resulted in much lower germination (9.3%). However, treatment with far-red light followed by red light reversed the effect of far-red light, but germination percentage was lower, only 14.7%.

Keywords: *summer lilac, butterfly bush, photoblastic seed, photosensitivity, far-red light.*

Introduction

Buddleja davidii (summer lilac, butterfly bush) is a deciduous, fast growing, shrub native to China. It is widely grown as an ornamental drought tolerant plant. Summer lilac can reach height of 2 – 3 m, with a spread of 1 – 3 m, and it is popular garden plant because of its bushy habit, arching stems and lilac to purple fragrant flowers that blooms from late summer to late autumn, sometimes to first frost if overblown flowers are regularly removed (Vukićević, 1996). It thrives in the full sun, in medium moisture, well-drained soil and it is slightly salt tolerant. Butterfly bush is suitable for borders or mass planting, usually grown in parks, cottage gardens or butterfly gardens, because flowers are attractive to butterflies and bees). Besides, it is a popular fresh cut flower (Wasson, 2003). There are many varieties and cultivars of this species with white, pink, blue or reddish flowers, and they are propagated vegetatively by softwood or semi-hardwood cuttings (Vukićević, 1996; Wasson, 2003; Hartmann *et al*., 2014). Generative propagation is also possible, and seeds can be sown in spring without pretreatment, but plants are not genetically true by seed (Hartmann *et al*., 2014).
However, this species has escaped gardens and naturalized in the United States, Canada, New Zealand and in central Europe (Invasive Species Compendium, 2021). Summer lilac produces large number of small seeds that are easily distributed by wind, or by water. Considering that self-seeding is a cause of spreading, removal of spent flower clusters prior to formation of seed is recommended. However, summer lilac still has the potential for further expansion and it can invade and dominate disturbed natural areas. Since the seeds of summer lilac are positively

photoblastic (Tallent-Halsell and Watt, 2009; Thompson and Abbott, 2013), the aim of this study was to investigate the effect of red and far-red pulse of 5 minutes on seed germination.

Material and methods

Healthy, vigorous shrub growing in park-forest Kosutnjak (Belgrade, Serbia) was chosen as a seed source for this research. The seeds were collected in autumn, brought to the Laboratory for seed testing at the Faculty of Forestry, University of Belgrade (Serbia). The effect of 5 minutes exposures to red and far red light on seed germination was evaluated (Table 1). The control treatment was set in dark conditions. Three types of light filters were used. A fluorescent lamp (Philips 100w) with 3 mm thick red plastic filter was used to obtain a red light. An incandescent lamp (Tesla 100w) with 4 mm thick dark red plastic filter was used to obtain far-red light. Green fluorescent tube and a green plastic filter were used for handling the seed in dark conditions.
The seeds were imbibed for 72 hours at the temperature of 20°C before being exposed to light treatments. After light treatments the seeds were put in a germination chamber in dark conditions. The seeds in a control treatment were put in a germination chamber without any light pretreatment.

Table 1. Germination treatments

	Treatment
R	5 minutes red light
R-FR	5 minutes red light + 5 minutes far-red light
R-FR-R	5 min. red light + 5 min. far-red light + 5 min. red light
R-FR-R-FR	5 min. red light + 5 min. far-red light + 5 min. red light + 5 min. far-red light
D	24 h dark conditions

Three replicates with 75 seeds per treatment were placed on germination on the top of two layers of filter paper in the petri dishes. The seeds were examined daily. After 7 days, the number of germinated seeds was recorded (germination energy) and germinated seeds were counted daily during next 14 days. Last count was on 21st day after placing the seeds on germination. After that, the seeds were examined with the aim to determine the percentage of viable seeds which is needed to calculate the real germination rate, as a percentage of sound (viable) seeds that germinate (Grbić, 2003).
Obtained data were statistically analysed using the program Statgraphics Plus, Ver 2.1. The significance of differences between the means was calculated by the analysis of variance (ANOVA, $p < 0.05$) and the least significant difference (LSD) test.

Results and Discussion

The obtained results showed red light and far-red light treatments influenced seed germination significantly (Table 2). Also, our results confirmed that seeds of *B. davidii* are positively photoblastic because there were no germinated seeds in dark conditions. The highest germination rate was recorded after 5 minutes of red light pulse treatment (29.3%), and red light treatment followed by far-red light resulted in much lower germination (9.3%). However, red light treatment after far-red light reversed the effect of far-red light, and germination percentage was higher (14.7%) than after far-red treatment, but lower compared to seeds that were only treated with red light.

The 5 minutes pulse of red light was sufficient to induce germination, despite seeds being placed after this treatment in a germination in dark conditions. Tang *et al*., (2008) showed that duration of seed exposure to red light can influence germination rate and they obtained higher germination of *Chenopodium album* after 20 minutes of red light treatment compared to 1 or 2 minutes treatments. However, their research showed that the treatment with red light 3 times for 1 minutes at the intervals of 12 h was more effective than a single 20 minutes treatment with red light.

Table 2. Germination of seed exposed to different light pretreatments

Treatment	Germination rate (%)	Germination energy (%)	Real germination rate (%)
R	29.3[a]	21.3[a]	29.3[a]
R-FR	9.3[bc]	8.0[ab]	9.3[bc]
R-FR-R	14.7[b]	12.0[ab]	14.7[b]
R-FR-R-FR	8.0[bc]	4.0[b]	8.0[bc]
D	0.0[c]	0.0[b]	0.0[c]

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

Germination rate obtained in our research was low, not exceeding 29.3%. However, Ebeling *et al*., (2008) also obtained relatively low values (32-42%) by testing germination of seeds collected from 10 *populations of B. davidii in China and 10 populations in Germany. They germinated seeds under 12 h light / 12 h dark regime and under* alternating temperature from 10°C to 20°C. *There is a possibility that germination of B. davidii seeds in our research could be higher if the seeds were exposed to natural light. Also,* Tang *et al*., (2008) reported that there was significant interaction of temperature changes and red light treatments, and light treatments were more effective if temperature alternated between 25°C and 5°C than if the temperature were maintained at 25°C constantly. This indicates that germination of *B. davidii could be higher with different duration of red light pretreatments, or with change in a temperature regime during germination.*

Conclusions

The results presented in this research confirmed that B. davidii seeds are positively photoblastic. The treatments with red and far-red light affected significantly germination. Seeds did not germinate in the dark and also far-red treatment resulted in low germination rate. However, the red light treatment following a far-red light treatment reversed the effect of far-red light increasing germination rate. Taking into account that germination of B. davidii can be higher with seed exposed to natural light and kept in alternating temperature conditions, there is a possibility that this species can easily spread by seed in Serbia. For this reason, special attention should be paid on removal of spent flower clusters prior to formation of seeds and use of alternative non-invasive species instead of B. davidii is recommended.

Abstract

Paulownia fortunei is a fast-growing, ornamental deciduous tree with large, fragrant pink flowers that has recently become popular for growing in green areas in Serbia, as well as on plantations for timber production. Dragon tree paulownia tolerates a wide range of soils, including soils contaminated with heavy metals pollution and it endures urban conditions well. The elite trees of dragon tree paulownia growing in the Belgrade area, well adapted to local conditions, were selected as a source for production of planting material for urban coenoses and specific-purpose plantations of this species. The dragon tree paulownia can be propagated by seed or vegetatively by cuttings. It produces a light-sensitive seed that requires light to germinate. For this reason, the aim of this research was to evaluate the effects of a red and far-red light pulse of 5 minutes on seed germination. Obtained results showed that red light (R) pulse had a positive effect on germination compared to far-red (FR) light treatments and that effect of red light could be reversed by far-red light and vice versa. The germination was higher after red light treatment (R – 10.5%, R-FR-R – 29.0%) than after far-red treatment (R-FR – 1.0%, R-FR-R-FR – 0.3%). However, the best result (77.5%) was recorded with seeds that germinate in white light conditions, without R or FR treatments.

Keywords: *dragon tree paulownia, Fortune's empress tree, photoblastic seed, photosensitivity, far-red light.*

Introduction

Paulownia fortunei (dragontree, Fortune's empress tree) is a deciduous fast-growing tree native to China and Taiwan (Viet, 2001; Radošević and Vilotić, 2010). The heart-shaped leaves are large reaching length of 25 cm. In the spring, dragon tree produces numerous large purple tubular flowers and it has been used as an ornamental tree. It is a melliferous species (Shankar, Abrol, 2015). Besides, it is used in agroforestry for growing in plantations for wood production. Dragon tree has light timber of fine grain, quite resistant to insect attacks and it is suitable for wood based panels, paper production and utility furniture industries (musical instruments, boxes, chests, furniture, picture frames, toys, doors and windows) (Rafighi, Tabarsa, 2011; Navroodi, 2013). *P. fortunei* has been used in a traditional Chinese medicine for treatment of bronchitis, enteritis, hypertension, dysentery, and its flowers are also edible, used as an ingredient for making some local delicacies (Grosso, 2018).
Dragon tree paulownia tolerates a wide range of soils, including soils contaminated with heavy metals pollution and it is used for removing heavy metals in contaminated soils, to decrease air pollution and for reforestryzation (Wang *et al.*, 2009; Viet, 2001; Madejón *et al.*, 2015). *P. fortunei* also endures urban conditions well.

The dragon tree paulownia can be propagated by seed or vegetatively by cuttings (Stuepp *et al*., 2014, 2015). Successful micropropagation of *P. fortunei* has been also reported (Clapa *et al*., 2014; Chunchukov and Yancheva, 2015). However, generative propagation is simple, enabling preservation of the genetic variability which is important for obtaining large number of different genotypes for selection of individuals with enhanced features and adapted well to heterogeneous local environments. Hence, the elite trees of dragon tree paulownia growing in the Belgrade area, well adapted to local conditions, were selected as a seed source. Dragon tree produces a large amount of small, light-sensitive seed that requires light to germinate (Grubišić *et al*., 1985). The aim of this research was to evaluate the effects of a red and far-red light 5 minutes pulse on seed germination, and to determine possibility of using selected trees as a seed source for production of planting material for urban coenoses and specific-purpose plantations of this species.

Material and Methods

The seeds of *P. fortunei* were collected from trees growing in Belgrade, brought in the Laboratory for seed testing at the Faculty of Forestry, University of Belgrade (Serbia) and used for testing the effect of red and far-red light on germination.

Red light was obtained using 3 mm thick red plastic filter and a fluorescent lamp (Philips 100w). Far-red light was obtained using 4 mm thick dark red plastic filter and an incandescent lamp (Tesla 100w). Green fluorescent tube and a green plastic filter were used for handling the seed in dark conditions.

Before light treatments, the seeds were imbibed for 72 hours in distilled water, at the temperature of 20˚C. After imbibition, the seeds were exposed to red or far-red light treatment, 5 minutes each (Table 1) and put on germination in a dark conditions, at 25˚C. Two other light treatments included germination of seed in dark (24 h) or natural white light conditions (16h light / 8 h dark) (Table 1).

Table 1. Germination treatments

	Treatment
R	5 minutes red light
R-FR	5 minutes red light + 5 minutes far-red light
R-FR-R	5 min. red light + 5 min. far-red light + 5 min. red light
R-FR-R-FR	5 min. red light + 5 min. far-red light + 5 min. red light + 5 min. far-red light
D	24 h dark conditions
L	16h white light / 8 h dark conditions

The seeds (four replicates with 100 seeds per treatment) were placed on germination on the top of two layers of filter paper in the Petri dishes. The number of germinated seeds was recorded daily, first count was on 7th day (germination energy) and the number of germinated seeds was recorded during next 14 days. The last count was on 21st day after placing the seeds on germination. After that, the number of remaining viable seeds that did not germinate was determined in order to calculate the real germination rate, as a percentage of sound (viable) seeds that germinate (Grbić et al., 2010). Obtained data were statistically analysed using the program Statgraphics Plus, Ver 2.1. The significance of differences between the means was calculated by the analysis of variance (ANOVA, $p < 0.05$) and LSD (the least significant difference) test.

Results and Discussion

Results obtained in this research showed that red light and far-red light treatments influenced seed germination significantly and confirmed that seeds of *P. fortunei* are positively photoblastic (Table 2). The far-red treatments inhibited germination, and obtained germination rate was very low and the same as the germination of the seed kept in dark, up to 2.5%. However, although seed exposed to red light had higher germination rate, it was low (10.5% and 29%) compared to seed that germinated in white light conditions (77.5%). Grubišić *et al*. (1985) obtained positive effect of red light on germination of *P. fortunei* but only after 6 hours of exposure, which was in contrast to their results obtained with other *Paulownia* species. Namely, while testing *P. tomentosa* response to red light treatments only one minute of exposure to red light was enough to obtain satisfactory germination of *P. tomentosa* seed.

Table 2. Germination of *P. fortunei* seed after exposure to different light pretreatments

Treatment	Germination rate (%)	Germination energy (%)	Real germination rate (%)
R	10.5[c]	9.2[c]	10.5[c]
R-FR	1.0[d]	0.3[d]	1.0[d]
R-FR-R	29.0[b]	21.2[b]	29.0[b]
R-FR-R-FR	0.3[d]	0.3[d]	0.3[d]
D	2.5[d]	0.75[d]	2.5[d]
L	77.5[a]	69.3[a]	77.5[a]

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

The obtained germination rate (77.5%) in a white light conditions was satisfactory and collected seed can be used for *P. fortunei* production. Similarly, Viet (2001) reported that expected germination of *P. fortunei* is 70%, which is in accordance with results obtained in our research, but Viet (2001) also stated that germination of *P. fortunei* can be increased considerably (90 - 95%) if the seeds are sown in *in vitro* conditions. The higher germination rate *in vitro* than *ex vitro* has already been reported for other plant species (Marković and Popović, 2012). However, there are reports of higher germination rate of *P. fortunei* (89%) obtained in standard *ex vitro* conditions (Aliarab *et al*., 2018) indicating that a seed source, i.e. genotype of mother trees can also affect germination rate. Besides, Grubišić *et al*. (1985) showed that gibberellic acid (GA_3) can induce germination which was previously inhibited by a far-red light pulse. Hence, there is a possibility that GA_3 could also have a promoting effect on germination of *P. fortunei* seed which should be investigated additionally.

Conclusions

The results obtained in this research confirmed that *P. fortunei* seeds are positively photoblastic and that far-red pulse can inhibit germination. The germination can be restored after additional red light treatment, but it is still low compared to a germination of the seed kept in white light conditions. However, maximum germination obtained in this research was high (77.5%) indicating that the seeds collected from selected trees have high germination rate in white light conditions and that these trees can be used as a seed source for production of *P. fortunei*. However, additional research should be conducted, and effect of gibberellic acid should be tested with the aim to increase germination rate.

GERMINATION OF RUDBECKIA FULGIDA VAR. SULLIVANTII 'GOLDSTURM' SEED UNDER DIFFERENT TREATMENTS

Marija MARKOVIĆ*, Mihailo GRBIĆ, Dragana SKOČAJIĆ, Danijela ĐUNISIJEVIĆ-BOJOVIĆ, Marijana MILUTINOVIĆ

University of Belgrade, Faculty of Forestry, KnezaViseslava 1, 11030 Belgrade, Serbia
*Corresponding author: marija.markovic@sfb.bg.ac.rs

Abstract

Rudbeckia fulgida var. *sullivantii* 'Goldsturm' is a low-maintenance perennial species that produces numerous flower heads with golden-yellow rays and brownish-black center disks, from July to October. It can grow on different soils and can endure drought once established. It can also be used as a cut flower. It is often grown in green spaces in Serbia. Usually it is propagated vegetatively, by division or cuttings. Also, it produces a large amount of seed and generative propagation is possible, but plants do not come true from seed. However, the seed is small and it can easily be dispersed at long distances by wind, spreading this plant in surrounding natural habitats. For this reason, the aim of this study was to examine the germination of *Rudbeckia* 'Goldsturm' seeds and thus determine the probability of its naturalization. Treatments included pre-chilling for 5 days at 3°C, followed by the exposure to white light, far-red light, red light or their combinations, considering that seeds were small and possibly photoblastics. Although pre-chilling treatment was recommended for *R. fulgida* according to ISTA rules, our results showed that germination of seed in all treatments that included pre-chilling was very low (below 3%). The highest germination rate of 14% was obtained in a control treatment where seed was not pre-chilled and germination was performed in white light conditions. The seed kept in dark did not germinate. Obtained results indicate that *Rudbeckia* 'Goldsturm' have no potential to establish its population in natural habitats by seed dispersion, and it can be included in a Green list of non-invading alien taxa that can be grown in Serbia without a risk of becoming invasive.

Keywords: *Black-eyed Susan, far-red light, photoblastic seed, photosensitivity, germination.*

Introduction

Rudbeckia fulgida var. *sullivantii* 'Goldsturm' (Black-eyed Susan, gloriosa daisy, orange cone-flower) is a rhizomatous, clump-forming perennial plant which can reach a height of up to 60 cm. It produces numerous, large, daisy-like flowers with deep yellow rays and dark brownish-black center disks. Black-eyed Susan blooms during summer and autumn (till October). It can grow on different soils, but prefers average, moist, well-drained soils in full sun, although it tolerates light shade. Regular watering is preferred throughout the growing season, but it can endure drought once established (Kellum 2008). The cultivar 'Goldsturm' is worldwide popular low-maintenance perennial plant, often used in a perennial borders, cottage gardens, or as a cut flower. It is also grown in green spaces in Serbia.

Usually, orange cone-flower is propagated vegetatively, by division or cuttings. Also, plants slowly spread in the garden by rhizomes. However, *R. fulgida* produces a large amount of seed and generative propagation is also possible, even plants often re-seed naturally, but they do not come true from seed (Hartmann et al. 2014; Fay et al. 1994). *R. fulgida* is native in North

America and it is not recorded as an invasive plant in Europe (https://www.cabi.org). However, there is a possibility of its naturalization because the cypselae are small and they can easily be dispersed at long distances by wind, spreading this plant in surrounding natural habitats.
For this reason, the aim of this study was to examine the germination of *Rudbeckia* 'Goldsturm' seeds and thus determine the probability of its naturalization. According to ISTA (1985) prechilling and light are necessary for germination of *R. fulgida*, but according to Hartmann et al. (2014) prechilling is not needed. Also, small-seeded species often require light for germination and seeds are mostly photoblastic (Milberg et al. 2000; McDonald and Kwong 2005). Hence, the effect of red ligh and far-red light pulse was also investigated in this reseach.

Material and Methods

The seedheads were collected in a private garden in Belgrade in August and brought in the Laboratory for seed testing at the Faculty of Forestry, University of Belgrade (Serbia). Dimensions and weight of seedheads were measured as well as weight of achenes. These data were used for calculation of an *extraction factor (the weight of cleaned achenes per given weight of* seedheads, *expressed in percent),* number of achenes in 1 kg and *absolute weight of achenes (weight of 1000 achenes).* The achenes were stored in a dry and dark place before setting the experiment 3 months later, in November.
Two types of filters and three types of lamps were used to test the effect of red and far-red light on germination, Red light was obtained using a red plastic filter which was 3 mm thick and a fluorescent lamp (Philips 100w). Far-red light was obtained using a dark red plastic filter which was 4 mm thick and an incandescent lamp (Tesla 100w). White fluorescent lamp (Philips 100w) was used to obtain white light (control treatment).
The seeds (three replicates with 50 seeds each) were placed on germination on the top of two layers of filter paper in the petri dishes, after being exposed to the different pretreatments (Table 1). Part of the seed were prechilled at 3˚C *and then exposed to light treatments. Part of seeds were placed on germination without prechilling. Germination was conducted* at 25˚C, except two treatments where seeds were placed on germination at 3˚C.

	germination
R + FR + R	no prechilling, seeds kept in dark for 5 days at 25˚C, then exposed to 5 minutes of red light pulse + 5 minutes far-red light + 5 minutes red light, returned in dark for germination
P 7 + R	prechilling 7 days at 3˚C + 5 minutes of red light pulse, germination in dark at 25˚C
P 7 + R + FR	prechilling 7 days at 3˚C + 5 minutes of red light pulse + 5 minutes far-red light, germination in dark at 25˚C
P 7 + R + FR + R	prechilling 7 days at 3˚C + 5 minutes of red light pulse + 5 minutes far-red light + 5 minutes red light, germination in dark at 25˚C

The number of germinated seeds was recorded daily during the period of 21 day. After that, the seeds were cut in order to determine the percentage of viable seeds which is necessary to calculate the real germination rate, as a percentage of sound (viable) seeds that germinate (Grbić et al., 2010). The germination energy was recorded on *7th day*. Obtained data were statistically analysed using the program Statgraphics Plus, Ver 2.1. The significance of differences between the means was calculated by the analysis of variance (ANOVA, $p < 0.05$) and LSD (the least significant difference) test.

Results and Discussion

R. fulgida var. *sullivantii* 'Goldsturm' seedheads collected in this experiment were averagely 13.5 mm long and 13.4 mm wide. The *extraction factor was* 23.82%, 1 kg contains 945 358 achenes and *absolute weight of achenes is 1.05 g*.
Germination was low in all treatments, and the highest germination rate (14%) was obtained in a control treatment where seed was not pre-chilled and germination was performed in white light conditions (Table 2). The germination of the seeds that were prechilled 5 days at 3˚C and placed on germination at 25˚C in light (16/8h) was only 2.7% indicating that germination was inhibited by prechilling and that recommendations by ISTA (1985) for *R. fulgida* cannot be used for this cultivar. Chilling time of 5 or 7 days also did not affected germination.
The seed kept in dark did not germinate, and there were no significant difference in the germination of seeds exposed to any of treatments with red light and far-red light. Nevertheless, the length of exposure to red light and far-red light treatments can also affect germination and for some species positive effect of red light on germination can be achieved only after 6 hours or of exposure (Grubišić *et al*. 1985).
It can be noticed that real germination rate was also low (Table 2) because a large number of sound, viable seeds did not germinate. Furthermore, the germination energy was 0% in all treatments, which means that none of the seeds germinated in the first 7 days.

Table 2. Germination of *R. fulgida* var. *sullivantii* 'Goldsturm'

Treatment	Germination rate (%)	Germination energy (%)	Real germination rate (%)
CL	14.0[a]	0.0[a]	15.4[a]

Values followed by different letters are significantly different at the $P < 0.05$ level according to the LSD test

Low germination in our research can be explained with relatively low germination temperatures. Although temperature of 25˚C has been commonly used for testing seed germination of majority of plant species, and Hartmann et al. (2014) recommend temperature of 21 - 24˚C for *Rudbeckia* spp., Fay et al. (1993) showed that germination of *R. fulgida* can increase considerably with increasing germination temperature. They used *R. fulgida* seeds from different sources and in all samples there were no germinated seeds at the temperature of 18˚C, but germination was 16-41% (depending on seed source) with increasing temperature to 25˚C, reaching 83-90% at the temperature of 32˚C. Further increase of germination temperature caused decreasing of germination rate (Fay et al. 1993). Thus we can expect that germination of *R. fulgida* var. *sullivantii* 'Goldsturm' could be higher if the achenes were placed on germination at higher temperatures (28-32˚C). Fay et al. (1993) conducted their research in a laboratory conditions at the constant temperatures, while in the field conditions temperatures would be different depending on a time of day, dropping considerably during night. For this reason, we can expect that *R. fulgida* var. *sullivantii* 'Goldsturm' germination will not be high enough for its expanding and naturalization in Serbia. Thus we can preliminary include this cultivar in the Green list of non-invading alien taxa in Serbia. This list comprises non-native species that do not have a potential to become invasive, according to Dehnen-Schmutz (2011). However, additional research should be conducted in order to assess the germination rate of *R. fulgida* var. *sullivantii* 'Goldsturm' in field conditions, as well as survival of seedlings.

Conclusions

The germination rate of *R. fulgida* var. *sullivantii* 'Goldsturm' was low, not exceeding 14%. The light was necessary for germination and seeds kept in dark did not germinate. The treatments with 5 minutes of red and far-red light pulse had no effect on germination. Prechilled seeds did not germinate or the germination was very low, not exceeding 3% in all treatments. Obtained results indicate that *Rudbeckia* 'Goldsturm' have no potential to establish its population in natural habitats by seed dispersion, and thus it can be included in a Green list of non-invading alien taxa that can be grown in Serbia, but further research of germination of *Rudbeckia* 'Goldsturm' in the field conditions is recommended.

Abstract

The aim of this study was to observe effects of the sowing date on the relationships among morphological properties of maize ears. The trial was set up in Zemun Polje in 2019 and encompassed five sowing dates with the initial one on April 1, and then on every 10 days until May 10 (S1, S2, S3, S4, S5). Three inbred lines (L1, L2, L3) were used as a material. During sowing, seeds were classified according to their size into small (6.5-8.4 mm), large (8.5-11 mm) and the primary seed fraction (6.5-11 mm). The parameters for the following morphological ear traits were determined under laboratory conditions: ear weight, ear length, ear thickness, cob weight and the grain yield. Obtained results indicated the significant contribution of all factors in expression of observed traits, as well as the significance of the interactions. The inbred L1 was the most stable genotype for the ear weight and the cob weight. The ear length and the ear thickness varied the least in all genotypes. The initial sowing dates (S1 and S2) were the most important for the ear weight. The third sowing date was the most important for the ear length (19.81cm) and the ear thickness (5.94cm). The highest cob weight was recorded in plants sown on the fifth sowing date (S5). The LSD tests showed that the differences in the morphological traits of ears of different sowing dates were significant between S5 and the remaining four sowing dates ($p<0.05$). Various fractions used in sowing affected all traits.

Key words: *agroecological conditions, cob, trait variability.*

Introduction

Due to the increasingly frequent changes occurring in environmental conditions in local regions, a need to reconsider the suitability of conditions for crop production has arisen. The oscillation of soil and air temperatures and precipitation sums during the maize growing season affects the yield and the yield components. Intra-seasonal climate variability can affect crop production during all stages of the crop growing cycle: directly through the effects of temperature, water availability, radiation interception, and carbon fixation; indirectly by modulating nutrient availability and the occurrence of diseases and pests (Olesen et al., 2000, Ceglar et al., 2016). The sensitivity of the optimal crop growth and development to specific weather conditions depends on the crop and the growth stage (Cantelaube and Terres, 2005). The properties of the produced hybrid maize seed depend on many factors: genotypic combination of parental inbreds, synchronicity of flowering, duration of pollination, duration of grain filling, length of maturation, grain moisture content at harvest. During the expression of the stated factors, agroecological

conditions also change. The variability of these conditions can change the growth and development of maize (Chen et al., 2011; Asare et al., 2011; Zhou. et al.; 2016).
Although maize yield increased, there was a significant seasonal yield variation due to the variation of weather factors (Ray et al., 2015; Sun et al., 2016; Farmaha et al., 2016).
The aim of this study was to determine the significance of the sowing adapted to the conditions of local climatic regions on the formation of ear, morphological traits and grain yield of maize.

Material and Methods

Three maize inbred lines L1 (FAO 400) L2 (FAO 600) and L3 (FAO 600), developed at the Maize Research Institute, Zemun Polje (Belgrade, Serbia), were used in the study.
The one-year trial was set up according to the randomised block design in the location of Zemun Polje in 2019. Sowing was performed on five dates starting from April 1 to May 10, every 10 days (S1: April 1, S2: April 10, S3: April 20, S4: April 30, and May 10).
Seeds used in sowing were classified according to their size into three fractions by using sieves with mesh sizes of 8.5-11(mm) (F1); 6.5-8.4(mm) (F2); 6.5-11(mm) (F3). The elementary plot encompassed nine rows of one inbred, 3x3 rows of seeds of the equal size.
Ears were harvested by hand. Five ears per a row were taken for testing. Morphological traits: ear weight (EW), ear length (EL), ear thickness (ET), cob weight (CW) and grain yield (GY) were determined after harvest under the laboratory conditions using the method of arithmetic mean of measured values obtained by measuring instruments for weight, length, and width. The results were processed using descriptive statistics, mean values according to research variants. The effect of factors on trait variability was determined by the factorial analysis of parametric tests, ANOVA and LDS, using the statistical package SPSS 20.

Results and Discussion

According to results of the trial set up in 2019, S3 was the most favourable sowing date. The highest mean values of EL, ET and GY (22.803 g, 6.930 cm and 5.670 t ha^{-1}, respectively) were obtained in inbreds sown on this date. S2 was the most optimal sowing date for EW (149.797 g), while the largest cob percentage (18.750%) was in S4, which was the most unfavourable grain to cob ratio. The sowing date S5 did not favour the development of morphological traits. With regard to S5, all traits lagged in the development. The cob percentage was the only trait with the positive result (11.185%). This phenomenon can be explained by insufficiently filled grain due to unfavourable conditions during the grain filling, and therefore the seed to ear ratio was low. The sowing date, as a beginning of the production, determines the crop uniformity, first of all a stable yield, which depends on various (?) moisture, structure and temperature of the soil, method and dates of sowing and seed quality (Pommel et al., 2002). These changes limit the established cropping practices (Lobell et al., 2013; Cicchino et al., 2010; Mayer et al., 2014), due to which seeds from different sowing dates differ in quantitative and qualitative traits. The resulting differences among various sowing dates were significant between S5 and remaining dates for all traits (EW, EL, ET, GY, CW). The difference between S1 and S4, i.e. S1 and S3 was significant for the trait EW, i.e. ET, respectively (Table 1). Values of observed traits were uniform for sowing dates S1 and S2.

Maize is the plant that is most variable in terms of the seed shape and size. The importance of the seed size in sowing is presented in Table 2. The formation of morphological traits of seeds differed among seeds of various fractions that were used in sowing. Stress is one of the main reasons that can lead to a decrease in a germination rate and uniformity (Kranner et al., 2010), which is related to the composition of the seed material. The ears with the highest EW (131.831 g), EL (17.630 cm) and GY (4.912 tha^{-1}) were developed from seeds that had not been classified according to their size (F3) in sowing. This is a result of the highest number of seeds that were adapted to the conditions of reduced moisture, that were capable to emerge rapidly and to establish a uniform crop. The F1 fraction favoured ET (4.616 cm), but also the most unfavourable cob percentage (16.822%). The results show that the seed selection according to their size was an important aspect of the production. The differences among seeds of various sizes were significant. The ear weight (EW) significantly differed over all fractions, while grain yield (GY) significantly differed over F1 and F2. The cob weight (CW) was significantly lower in F2 seeds than in F1 and F3 seeds. The seed size did not significantly affect traits ET and EL (Table 3).

Table 2. Effect of seed fractions on the expression of seed morphological traits (EL-ear length, ET- ear thickness, GY-rain yield, CW-cob weight)

Dependent Variable	(I)	Mean Difference (I-J) (J) fraction F1	F2	F3	Mean values	
EW	F1		10.602*	-3.889	F1	127.942

	F2	-0.875		-0.530	F2	3.742
	F3	-0.345	0.530		F3	4.271
GY	F1		0.088	-0.407*	F1	4.504
	F2	-0.088		-0.495*	F2	4.416
	F3	0.407*	0.495*		F3	4.912
CW	F1		2.109*	0.087	F1	16.822
	F2	-2.109*		-2.022*	F2	14.713
	F3	-0.087	2.022*		F3	16.735

Three inbreds (L1, L2, L3) were used in the trial. The diversity in genetic potential resulted in the relationship to the application of different sowing dates (Figure 1). L1 had approximately the same values for EL and ET in all four sowing dates (S1→S4). Based on the variability of traits in relation to the sowing date, L1 was the most stable inbred, while L3 expressed the greatest variability. All three inbreds had the lowest values of EL, ET and EW in S5.

With regard to the seed size used in sowing, L1 differed from remaining two inbreds. The F2 seeds of this inbred were the most optimal for the formation of morphological traits. On the other hand, F3 seeds were the most optimal for L2 and L3 in 2019 sowing. The application of different side sizes in sowing depends on the precipitation sum and temperature conditions during sowing. The classification of seeds over fractions homogenises endosperm mass. Seeds with small endosperms are more susceptible and a dysfunction of reserve/storage substances occur (Styer and Cantliffe, 1983) adversely affecting seed vigour, but on the other hand, such seeds emerge faster due to insufficient rainfall.

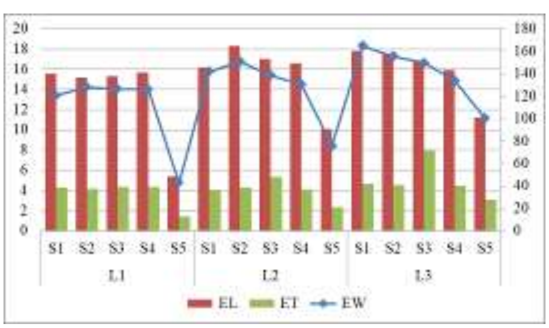

Figure 1. Effect of sowing dates on morphological traits (EW-ear weight, El-ear length, ET-ear thickness) over genotypes (L1, L2, L3)

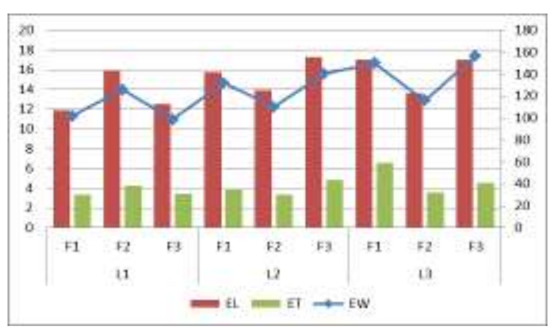

Figure 2 Effect of seed sizes on morphological traits (EW-ear weight, El-ear length, ET-ear thickness) over genotypes (L1, L2, L3)

The change of morphological traits and yield under the influence of observed factors (sowing date, genotype and seed fraction) was of the different level of significance. The ear weight (EW) and the cob weight (CW) significantly changed under the impacts of factors and their interactions. The action of both individual and combined factors was important for these traits. In contrast, ET changed the least in relation to factors. A significant change in this trait was observed with the change in sowing dates and the seed size x genotype interaction (FxG). The ear length (EL) is a trait that was also changed significantly under effects of sowing dates, genotypes and the interaction of all three factors (SxFxG). The highest effect of factors on the change of variance was on the cob weight (R = 0.818, Table 3).

Conclusions

According to presented results it can be concluded that all three factors (genotypes, sowing dates, seed fractions) significantly contribute to the quality of seed production. Producers decide on the application of appropriate technology based on traits of the genotype. In addition to genotypes, ecological conditions are also an important decisive factor in the choice of growing practices. The choice of the proper sowing date is one of the main prerequisites for successful production. Our results show that there were significant differences in the application of different sowing dates. The best conditions for the majority of the traits were achieved by the application of S3.
The seed size, as the third analysed factor, was important for the achieved results. The F3 seed resulted in the largest ear weight, longer ears, and in the end, this resulted in the highest grain yield. The successfulness of the seed material, which was of the widest range in size, is a consequence of the fact that the largest number of seeds had enough heat and moisture for germination and emergence.

Abstract

Stability of yield or of any other trait depends on the ability of a given cultivar to response to changes in the environment, which is also referred to as phenotypic plasticity. The analysis of a genotype × location interaction is necessary to obtain information on the stable performance of genotypes. This paper presents results of the genotype (G) main effect and the genotype by environment (GE) interaction, genotype plus genotype by environment interaction (G × GE) biplot analysis of a multi-environmental trial with eight maize hybrids of the FAO maturity group 600 and six different locations in Serbia conducted in 2018. The objective was to determine the effects of genotypes, six environments and their interactions on grain yield and to identify stable maize genotypes. The trial was set up in a randomised complete block design with three replications in each environment. The combined ANOVA indicated that the main effects of environments, genotypes and the genotype by environment interaction were highly significant. The G × GE effects were further partitioned using a GGE biplot model. In the FAO maturity group 600, the first mega-environment contained environments E6 (Požarevac), E5 (Pančevo) and E2 (Bečej) with a check G7 (ZP EXP1) producing the highest yield. The mega-environment contained environments E4 (Sremska Mitrovica) and E1 (Zemun Polje) with the most yielding hybrid ZPSC 606. Genotypes G8 (ZP EXP2) and G7 (ZP 707) are considered to be the "ideal" genotype in terms of performance and stability.

Key words: *AMMI stability value, GGE biplot, genotype, environment, maize.*

Abbreviations: AMMI (additive main effects and multiplicative interactions), E (environment), G (genotype), GE (genotype × environment), GEI (genotype × environment interaction), GGE (genotype and genotype × environment), MET (multi-environment trial), PCA (principal component analysis), IPCA (interaction principal component analysis).

Introduction

Global forecasts indicate that by 2025, maize will be the crop with the highest production in the world, and that the need for maize will double in the developing countries by 2050 (Rosegrant et al., 2008). Maize, together with wheat and rice, is the most important crop in global agricultural production. In terms of the total sown areas in the world, maize ranks second just behind wheat. The basic economic importance of maize results from the traits of the plant itself, diversity of the use and the production volume. In addition, maize is greatly important in terms of cropping practices, as the plant requires intensive growing conditions. Almost all parts of maize plants may be processed, which is exactly what gives maize a special economic significance.

The development of high-yielding and stable varieties and hybrids is the ultimate goal set in the majority of breeding programmes. The ideal maize genotype should have a high average yield together with a low degree of variation under different environmental conditions (Epinat-LeSignor et al., 2001). In addition to the variable environmental conditions, crop yields are greatly affected by genetic factors.

The yield is a multidimensional trait that encompasses several different properties affected by a number of factors. Maize yield depends on a genotype and its yielding and quality potential, agroecological conditions, levels of applied cropping practices. Certain genotypes express various performances when grown in many different environments. If a certain genotype shows good performance in one environment, it does not imply that it will express the same performances in other environments in which it is grown (Stevanović et al., 2012). Therefore, multi-environment trials are of a great importance for the majority of scientific breeding programmes. Multi-environment trials (METs) performed for the yield, involve testing of a larger number of genotypes in different environments and are trials most frequently carried out in agriculture (Huhn, 2000; Yan et al., 2000; Crossa et al., 2004;Yan and Tinker, 2006;Gauch, 2006;Čamdžija et.al.2011; Andrade et al., 2016).

Stability of yield or any other trait depends on the ability of a given cultivar to respond to the environmental changes, which is also referred to as phenotypic plasticity, Eberhart and Russell (1966). Moreover, stability is one of the most desirable traits of a genotype being introduced into production. However, activities of the identification, breeding and selection and the recommendation of superior genotypes are complex and limited by the genotype × location interaction that is inevitable in the multi-location environments (Asfaw et al., 2009).

The aim of this study was to determine effects of a genotype, environment, and their interaction on grain yield and to identify stable maize genotypes. Results of this and similar studies can potentially be a good basis for making recommendations in the future maize production in our country.

Material and methods

Plant material and the method of trial setting up

In 2018, the study was carried out in six different locations used by the Maize Research Institute, Zemun Polje (Table 1) and they were the first factor in this study. The locations were mainly in the lowlands of Serbia, which were intended for the successful cultivation of observed maize hybrids of the FAO maturity group 600.

Table 1. Various locations in which trials were performed in 2018

Location		Latitude	Longitude	Altitude (m)
E1	Zemun Polje	44°, 51′ N	20°,19′ E	83
E2	Bečej	45°, 36′ N	20°,02′ E	78
E3	Bajša	45°, 47′ N	19°,34′ E	101
E4	Sremska Mitrovica	44°, 58′ N	19°,37′ E	81
E5	Pančevo	44°, 53′ N	20°,41′ E	74
E6	Požarevac	44°, 37′ N	21°,09′ E	76

Maize hybrids of the FAO maturity group 600 are the basic plant material used in the study. Eight genotypes of the FAO maturity group 600, developed at the Maize Research Institute, Zemun Polje, were tested. The genotype G7 was a check in the FAO 600.
The three-replicate traits with 20 plants within each replicate were set up according to the randomised complete block design. Each genotype was sown in eight 5-m long rows. The row spacing was 0.75 m, thus the elementary plot size amounted to 30 m^2. The common maize growing practices were applied in the trial. Sowing and harvesting was done mechanically. Only four inner rows were harvested due to the border row effect, and the yield was determined in these four rows and then it was computed to one hectare. The genotypes (hybrids) were the second factor.

Table 2. Data on tested maize genotypes in multi-environment trials in 2018

Genotypes of the FAO maturity group 600	Hybrid designation
G1	ZP SC 6037
G2	ZP SC 6078
G3	ZP SC 6707
G4	ZPSC 6708
G5	ZPSC 6710
G6	ZPSC 606
G7 (check)	ZPSC EXP.
G8	ZPSC 666

Statistical data analysis

The assessment of differences among the analysed maize genotypes in six locations during one year as well as their interaction was performed by the analysis of variance for the factorial trial set up according to randomised block design. The additive main effects and multiplicative interaction (AMMI) model is characterised by the fact that it combines two methods: analysis of variance and the principal component analysis into the unique model with additive and multiplicative parameters. This characteristic of the AMMI model was applied in this assessment with the aim to separate the total phenotypic variance into additive (genetic) and non-additive (ecological) components, in order to assess the significance of the effect of the source of variation on the expression of traits. The last step in the AMMI analysis of stability is certainly the graphical presentation in the form of a biplot, which enables the perception of the dispersion of the observed genotypes, locations, treatments and their interaction. The horizontal x-axis of the AMMI1 biplot shows the main additive effects of a genotype, location, i.e. genotype, treatments, while the vertical y-axis shows the multiplicative effects of the genotype × environment interaction, and the genotype × treatment interaction, contained in the first two PC components.
In order to further and more accurate evaluate maize genotypes and locations, as well as the genotypes and the treatments, the GGE bioplot analysis according to Yan and Kang, 2003, (Gauch, 2013) was applied. The characteristic of the GGE biplot method is that, when studying yield stability, it does not separate but it jointly analyses the variability resulted from the effects of the genotype and the genotype × environment interaction. The statistical data analysis was performed using the computer statistical program GenStat 12th (GenStat, 2009).

Results and discussion

In recent years, GEI quantifications and studies on yield stability of several cereal crops have been performed. The different methods using non-parametic and paremetic statistics in the estimation of the stability of genotypes of cultivated crops are very important (Delić et al., 2009). The GEI analysis can be derived by using various methods, such as the stability analysis and additive main effects and multiplicative interaction (AMMI) model, principal component analysis or the linear regression analysis, analysis of variance (ANOVA) and the GGE biplot analysis. ANOVA explains only main effects and does not provide any information about individual genotypes and locations that are an integral part of the interaction. AMMI provides a large set of technical interpretations and uses a main component (autovector) to interpret cultivar performances by integrating the use of ANOVA and PCA. AMMI analyses combine additive components into a single model for main effects of a genotype and an environment, as well as multiplicative components for the interaction effect (Gauch, 2006).

Table 3. The average yield of maize grain yield (t ha^{-1}) of eight genotypes of FAO maturity group 600 (G1 → G8) tested in six locations (E1→ E6) in 2018

Genotype (G)	Tested locations (E)						Average E
	E1	E2	E3	E4	E5	E6	
G1	10.718	15.344	11.501	11.607	15.156	13.118	12.907
G2	10.710	16.033	10.206	9.478	15.187	13.952	12.594
G3	12.437	15.649	9.945	11.548	17.180	14.455	13.524
G4	13.360	14.695	11.017	13.238	15.650	14.965	13.820
G5	13.227	15.982	11.728	11.757	16.129	15.179	14.000
G6	14.195	15.830	11.037	12.512	16.832	14.701	14.184
G7	12.706	18.110	11.158	13.009	16.971	16.734	14.781
G8	13.913	16.022	11.301	11.782	16.833	14.115	13.994
Average G	12.658	15.958	10.986	11.866	16.242	14.652	13.726

The maize yield ranged between 10.986 t ha^{-1} and 16.242 t ha^{-1} over different environments or locations and between 12.594 t ha^{-1} and 14.781 t ha^{-1} over various genotypes (Table 3). The total average maize grain yield amounted to 13.726 t ha^{-1}. The raw data on the maize yield revealed that E5 (Pančevo), i.e. E3 (Bajša) was the most, i.e. least productive environment for all genotypes, respectively. On average, the genotypes G7 (check) and G2 (ZP 6078) were the most and the least productive, respectively.

ANOVA for the AMMI model of the maize grain yield (Table 4) points out that the effect of the location/environment (E), genotype (G) and their interactions (GEI) was very significant ($p<0.01$) in the investigation year (2018) (Table 2).

The environment or locations significantly affected the maize grain yield and this factor accounted for 70.6% of yield variability in 2018. The G effect on maize production was lower (8.09%), since that year was more favourable for maize cultivation. The AMMI1 analysis of variance showed that the effects of the source of variation, genotype, environment and GEI were important for the maize yield (Table 4).

This analysis of variance also showed that 72.5 %, 8.095% and 8.647% of the total SS were attributed to effects of environments, genotypes and GEI, respectively.

Table 4. Combined AMMI analysis of variance for the grain yield of observed maize genotypes of FAO 600

Source of variation	df	SS	MS	SS (%)	GxE explained (%)	Cumulative (%)
Total	143	795.6	5.56

Mean =13.726 t ha^{-1}						
Coefficient of variation (CV%)= 69						

***, ** and * significant at 0.1%, 1%, and 5%, respectively; ns = not significant (p > 0.05)

The large SS for the environment points out that locations were different with great differences in environments that caused the majority of variations in maize yields. In addition to the heterogeneity of the environments, or locations, significant differences were determined among genotypes.

Graphical analyses revealed phenotypic stability, genotypic behaviour of cultivars and performance-optimising environments. The AMMI model points out to the main effects of genotypes (G), environments (E) and their interactions (G×E). Furthermore, this model contributes to a better assessment of the cultivar, and based on that, recommendations for the selection of the test site (location). Analysed data based on the these models can be very useful for making better conclusions.

The GGE biplot analysis is another method that combines the genotype and the genotype under effects of environments in the evaluation of cultivars. The GGE model uses graphic axes and identifies superior genotypes in mega-environments. The mega-environment encompasses the groups of locations that consistently share the same genotypes tested. It also combines ANOVA and IPCA by partitioning the sum of squares of genotypes and the sum of squatters for the genotype × environment (G×E) interaction using the IPCA method. It is also used to present and assess genotypes in various environments (Gomes Machad et al., 2019).

The results showed the importance of testing and comparison of genotypes so that only the specific ones in terms of broad adaptability and stability and accordingly the location for which they are representative could be selected. Higher IPCA1 indicates a higher discriminatory ability of the environment (Yan et al., 2000; Gauch, 2006). This contributes to the determination of the discriminatory ability to improve partitioning through performances of different genotypes (Yan&Tinker, 2006; Yan, 2011). For instance, E6 (Požarevac) although the location with lower yields (only third in terms of average values), provided more information about tested genotypes than remaining locations. Thus, this study provides important information on the selection of the

best and ideal genotype or genotypes of the observed FAO maturity group 600 that are good for production in specific and widely adapted locations (Figures 1 and 2). Two mega-environments were revealed in the study of hybrids of FAO 600. The first group encompassed three locations (E5 - Pančevo, E6 - Požarevac and E2 - Bečej), while the second one consisted of two locations (E4 - Sremska Mitrovica and E1 - Zemun Polje). The G7 (check) and G3 (ZP 6707) are genotypes with the best performances. These genotypes are the most adapted to the mentioned environments (Figure 3).
With regard to "which-won-where", the hybrids with the best performances in the mega-environment or the sector were identified. The genotype G7 (Figure 3) was the hybrid with the best performance in the multi-location trial. At the same time, this genotype can be considered close to ideal in observed locations in 2018, including the assessment based on the GGE biplot with concentric circles (Figure 4). Furthermore, this was the best-ranked hybrid in all tested locations and among all genotypes (Figure 5). This fact provided researchers with the information, which hybrids should be recommended for the given and specific location, i.e. environment.

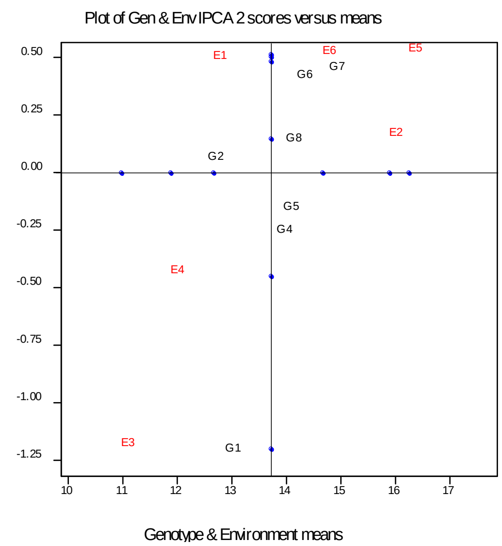

Figure 2. AMM1 biplot of grain yield (IPCA2) in 6 environments

.

GGE biplot analysis

Polygonal view of the mega-environment (which-won-where)

The important feature of the GGE biplot is that it predicts performances of hybrids by locations. In the mega-environment during the identification process, the farthest genotypes were linked together in the form of the polygon. Sectors, making visualisation of the mega-environment easy, were formed with lines vertical to the straight line segments of the polygon. Environments in one sector within which the best performing genotype was located could be considered a mega-environment for that genotype. Biplots in the Figure 3 are divided into five sectors. Genotypes belonging to the same sector with locations are better adapted to agroecological conditions of those locations. Two mega-environments are clearly observable: one consists of three locations

(E5, E6 and E2) and the other encompasses two locations (E4 and E1). Therefore, the best performing hybrids in each mega-environment are located at the top of the polygon. The genotype G7 (check) had best performances for the mega-environment consisting of three locations (E2, E5 and E6). The genotype G6 performed best in the mega-environment consisting of two locations (E4 and E1). The genotypes G8 and G4 best performed in the third location. These genotypes are most adapted to the stated environments.

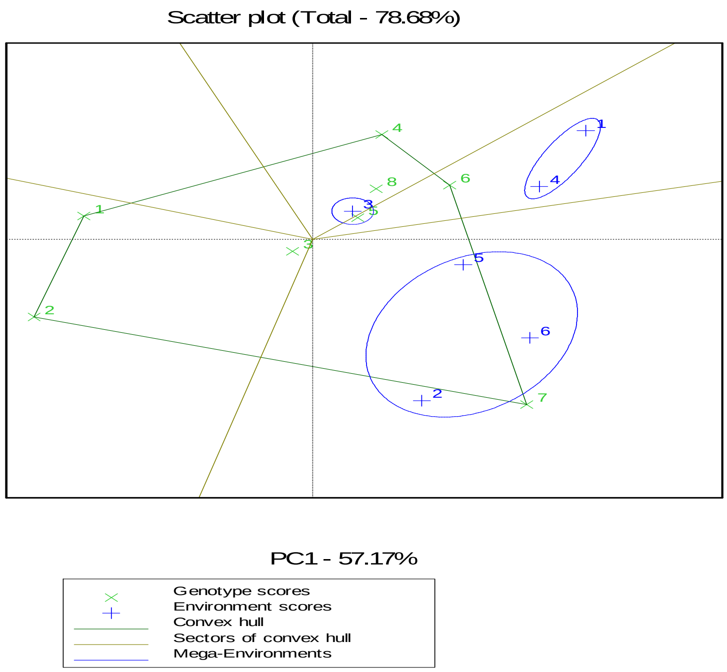

Figure 3. The "which-won-where" view of the GGE biplot

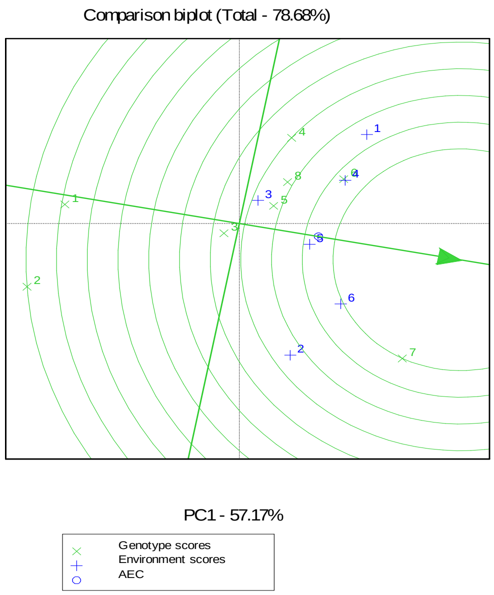
The ideal environment or a location is the one placed in the inner circle (Figure 4). Thus, E6 is considered the ideal environment or location. However, E3 and E2, being at the furthest circle from the centre of the concentric circles, are consider the least ideal environments.
The ideal genotype is the one in the centre or in the vicinity of concentric circles. According to the analysis, the genotype G7 is close to the ideal genotype, as shown by its position in the centre of the concentric circles.
The GGE biplot (Figure 5) presents the ranking of genotypes by yields and stability in locations. The line passing through the bioplot origin is called the average environment coordinate (AEC). Hybrids are ranked in the direction of a tester axis, while parallel lines help in the visualisation of the hybrid ranking.

The comparison biplot for genotypes based on concentric circles and the evaluation of efficiency of different genotypes in observed locations



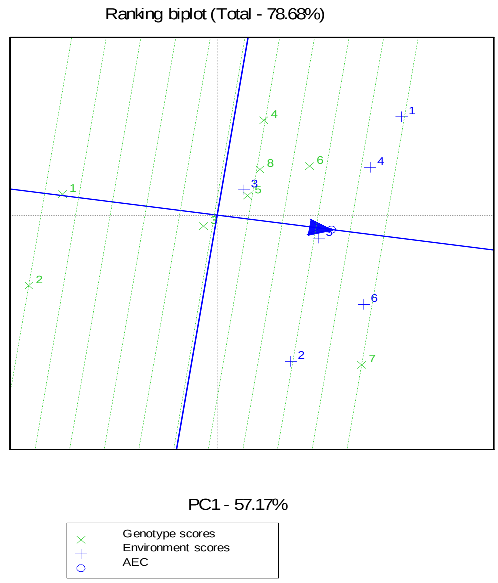


Figure 4. View of genotypes based on concentric circles

Figure 5. Ranking of environments based on the highest yielding genotype

In this example, the highest yield was determined in G7 in locations E6, E5 and E2. This genotype was followed by G6, G5, G8 and G4 in locations E1, E4 and E3, while genotypes G3, G1 and G2, having the lowest grain yield in 2018, were ranked last in all locations.

Table 5. Explanation of variations of two components PCI1 and PCI2

Models	Explanation of variations (%)	
	Hybrids of FAO maturity group 600	
	PCI1	PCI2
AMMI	45.23	25.44
GGE biplot	57.21	21.52

The GGE biplot also provided data that are important if the researcher has to make decisions and conclusions about specific correlations between locations and genotypes. The used AMMI and GGE biplot models were efficient in the observation of the genotype by environment (location) interaction. Satisfactory results were obtained by both methods - the difference was minimal, which only confirms the fact that these two models represent standards for data interpretation in this type of research, while interpretations of the GGE biplot graphics are considered the most reliable.

A comparative data analysis (Table 5) shows that the GGE biplot model was more efficient, especially in interpreting the variation of the first interaction axis, because it explained a greater variation on the first axis (57.21%), which was almost two thirds of the total variation unlike the AMMI model by which 45.23% were explained. Similar results have been obtained by other authors in the world and in our country (Rao et al., 2011; Mitrović et al., 2012).

Conclusion

Based on the detailed statistical analysis of results on the grain yield of eight maize genotypes of the FAO maturity group 600, obtained in trials in six locations in Serbia performed in 2018, the following can be concluded:

Grain yields of these hybrids were significantly affected by environments (or locations) (E), genotypes (G) and their interactions (G×E).

The contribution of the interaction of the environment (E), genotype (G) and the environment by genotype (G×E) interaction in the total variation of the hybrid grain yield amounted to approximately 72.52%, 8.09% and 9.64%, respectively, which was statistically very significant.

Effects of G × GE were further divided using the GGE biplot model.

The first mega-environment based on the GGE biplot contained locations E6 (Požarevac), E5 (Pančevo) and E2 (Bečej) with the genotype G7 (check), which had the highest yield of all genotypes of the FAO maturity group 600. The second mega-environment contained tow locations E4 (Sremska Mitrovica) and E1 (Zemun Polje), and the winning genotype was G6 (ZP 606). These genotypes were best adapted to these environments.

Based on the analysis, the genotype G7 (check) is the "ideal" genotype within FAO maturity group 600. This genotype is stable with a high mean value of the grain yield. This genotype was followed by genotypes G6 (ZP 606) and G8 (ZP 666) that were close to the ideal type on concentric circles. Then, these two genotypes were followed by genotypes G5 (ZP 6710) and G4 (ZP 6708). Based on their stability and yields these hybrids can be recommended immediately after the check.

Abstract

A two year field trial with ten promising native maize hybrids for grain production (Maize Research Institute Zemun Polje, Institute of Field and Vegetable Crops, Novi Sad), FAO maturty groups 300-600, was set up in the vicinity of Kragujevac (Lužnice site, 44 ° 06 ′ N, 20 ° 49 ′ S, 240 m a.s.l.), on brown forest soil type. The aim of this study was to recommend hybrids for specific agroecological conditions. In both years, sowing was performed at the end of April, of eight rows per elementary plot, at a row distance of 70 cm, and 18 to 25 cm within row, depending on recomended number of plants, in three replicates. During the experiment, standard agricultural measures were applied, excluding irrigation. Owing to a much larger amount and more favorable distribution of precipitation, especially in the critical developmental phases (tasseling - fertilization), the average grain yield of all maize hybrids in 2018 was almost three times higher than in 2017. The most noticeable reaction of hybrids to environmental factors was recorded in the hybrid NS 548 which, as one of the hybrids with the highest yield in 2017, in 2018 had a yield significantly lower than other hybrids. Hybrids ZP 560, ZP 606 and ZP 666 in both years belonged to the group of hybrids with the highest grain yield.

Keywords: *maize, hybrid, grain yield.*

Introduction

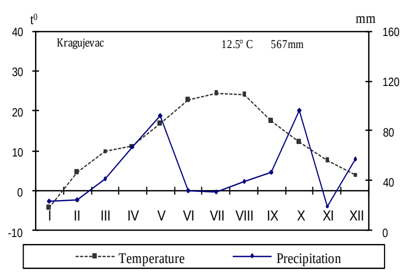
Maize, together with wheat, has the most important place in field production in the Republic of Serbia. In 2020, maize was sown on 996,527 ha, which is 3.6% more than in 2019, or 0.1% more than the ten-year average (2010–2019) (https://www.stat.gov.rs/sr-latn/oblasti/poljoprivreda-sumarstvo-i-ribarstvo/biljna-proizvodnja). Maize production in the Republic of Serbia is characterized by large variations in yield over the years. Insufficient precipitation and above-average air temperature during maize vegetation presents a major problem in its cultivation, both in Serbia and in the world, because in such conditions the potential for grain yield of high-yielding hybrids is not fully expressed (Kovačević et al., 2010; Markulj et al. 2010; Paunović et al. 2013, Pejić et al., 2020). A similar effect of weather conditions on maize yields is also in US Western Corn Belt (Shaw, 1988, Gaffney et al, 2015). Ummenhofer et al. (2015) indicate that historically high (low) yields in Iowa usually occur during years with an abnormally wet (dry) vegetation season. In the last 25 years, maize grain yield has increasingly depended on meteorological conditions during the growing season, which are very often characterized by the occurrence of "extreme climatic events" (Bekavac et al. 2010, Pavlov et al. 2011). One way to reach a compromise and satisfy the interests of both producers and breeders is to divide the area of cultivation of a crop into regions based on geographical, climatic and soil conditions that characterize them, and recommend hybrids for each region (Babić et al., 2013). The field experiment with 10 native maize hybrids for grain production, FAO maturity groups 300-600, was set up in the vicinity of Kragujevac for two years with the aim to recommend hybrids for specific environmental conditions.

Material and methods

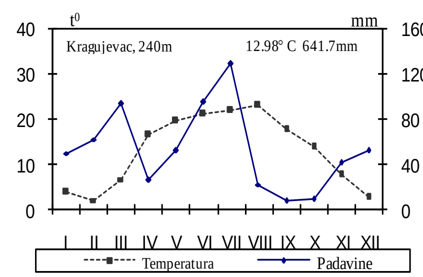
A field experiment with maize hybrids set up during 2017 and 2018 at the Lužnice site, municipality of Kragujevac (44 ° 06 ′ N, 20 ° 49 ′ S, 240 m a.s.l.), on brown forest soil type. Ten promising native maize hybrids of different FAO maturty groups (300-600) were selected: ZP 434, ZP 548, ZP 560, ZP 606, ZP 666 (Maize Research Institute Zemun Polje) NS 3022, NS 4051, NS 5051, NS 6030 and NS 6102 (Institute of Field and Vegetable Crops, Novi Sad). Sowing was performed in both years at the end of April. All hybrids were sown in three replicates of 8 rows per elementary plot, with the recommended number of plants, at a row distance of 70 cm, and 18 to 25 cm within row. In both years, along with primary tillage 20 t ha^{-1} of manure was incorporated; 400 kg ha^{-1} NPK (16: 16: 16) in pre-sowing preparation and 250 kg ha^{-1} KAN (27 % N) in top-dressing (phase 5-6 leaves) was added. During the vegetation, the crops were not irrigated. Harvesting was done manually at physiological maturity. After harvesting, the yield of cobs (60 plants) was measured from each plot and the grain yield ha^{-1} with 14% moisture was calculated. The obtained data were processed by the method of analysis of variance of two-factorial experiment (hybrid/year).

Meteorological conditions

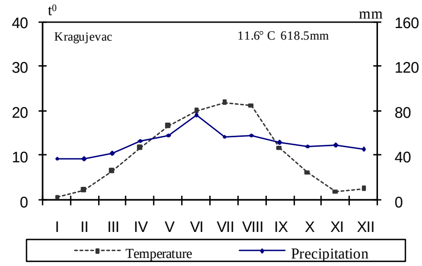
From April to September 2017, about 20% less precipitation than the multi-year average was recorded (Graph 1). The spring of 2017 (March - May) started with much higher temperatures than usual. Summer (June-August) was warmer and with less amount of precipitation (100.9 mm) compared to the multi-year average. Very warm weather continued in September, the last month of vegetation, when air temperatures were often around and above 30 ° C, with very little rainfall.



Graph 1. Climate diagram for Kragujevac in 2017



Graph 2. Climate diagram for Kragujevac in 2018



Graph 3. Climate diagram for Kragujevac in 1981-2010

In June and July 2018, in the phase of fertilisation and grain filling, a total of 224.9 mm of precipitation was recorded, while August and September were warm with a significantly lower amount of precipitation (29.5 mm) (Graph 2). The summer of 2018 (June - August) was warmer, with a higher amount of precipitation compared to the multi-year average (Graph 3).

Results and discussion

The maize vegetation period (April - October) in 2018 (Graph 2) was characterized by much higher amounts and a more favorable distribution of precipitation compared to 2017 (Graph 1), especially in the critical stages of maize development (tasseling - fertilization) so that the grain yield of all hybrids, on average, was almost three times higher (Table 1). The highest yield, on average for both years, was recorded in the hybrid ZP 560, significantly higher compared to other hybrids (Table 1). Hybrids ZP 606, ZP 666 and NS 4051 also had a significantly higher grain yield than other hybrids, while the lowest yield, significantly lower than others, was recorded in the hybrid ZP 548. Observed by years (Graph 4), a different reaction of hybrids to water supply is noticed (hybrid/year interaction). In 2017, the highest grain yields were recorded in hybrids NS 5051, followed by ZP 548 and NS 6102, while the lowest yield, significantly lower than others, was observed in hybrid NS 3022. The most noticeable reaction of hybrids to environmental factors was recorded in hybrid NS 548, which, as one of the hybrid with the highest yield in 2017, in 2018 had a yield significantly lower than other hybrids. In contrast, the hybrid NS 3022, with the lowest yield in 2017, in 2018 achieved grain yield at the same level, or even significantly higher than some hybrids belonging to later maturity groups (FAO 500 and 600).

Table 1. Grain yield (t ha^{-1}) of maize hybrids

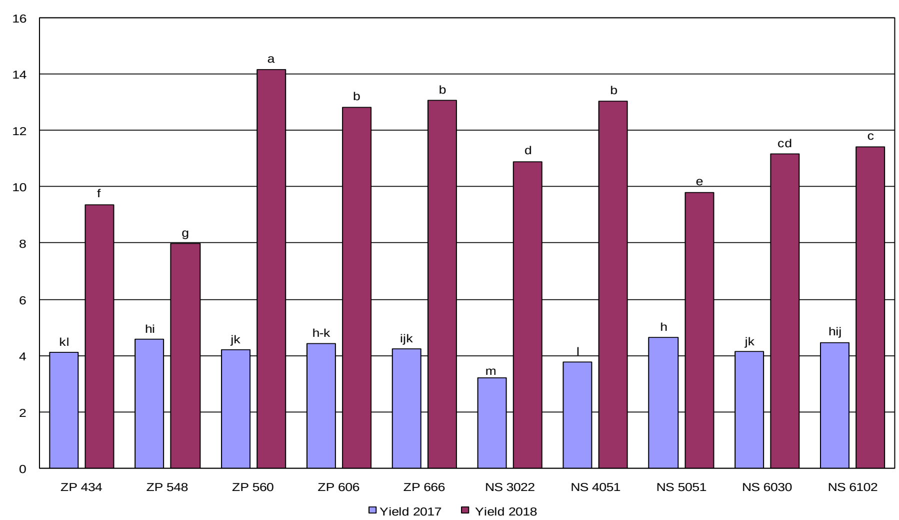
		Grain yield
Hybrid	ZP 434	6.73$^{f'''}$
(A)	ZP 548	6.27^{g}
	ZP 560	9.18^{a}
	ZP 606	8.63^{b}
	ZP 666	8.65^{b}
	NS 3022	7.08^{e}
	NS 4051	8.40^{b}
	NS 5051	7.22^{e}
	NS 6030	7.65^{d}

	NS 6102	7.95[c]
Years	2017	4.17[b]
(B)	2018	11.38[a]
ANOVA	Hybrid(A)	**
	Year (B)	**
	AxB	**

‴Means followed by different lowercase letters in columns for cultivars and years indicate significant differences according to LSD test ($P \leq 0.05$).

** F - test significant at the 99% level

Significantly higher grain yield compared to other hybrids in 2018, achieved the hybrid ZP 560, which in 2017 also belonged to the group of hybrids with the highest yield. In this regard, it should be also pointed out the hybrids ZP 606 and ZP 666, which in both years belonged to the group of hybrids with the highest grain yield. Weather conditions in the summer months (June, July and August) have a significant impact on maize grain yield (Boyer et al. 2013, Simić et al. 2018, Pejić et al. 2020). Filipović et al. (2015) state that the average annual yield reduction caused by drought, and related stress factors, in relation to the expected yields in the given conditions, ranges from 10% to 20%, even up to 50%. Drought periods in critical growth phases can negatively affect yield, even if soil moisture is not a limiting factor in other developmental stages (Roth et al., 2013)



Graph 4. Grain yield (t ha^{-1}) of maize hybrids in 2017 and 2018

Mean values marked with different lower case letters differ significantly at the level of $p = 0.05$ according to the LSD test.

Based on the results of macro-experiments with 15 maize hybrids at 30 different localities in the Republic of Serbia, Stojaković et al.(2010) state that hybrids from FAO 500 and 600 maturity groups had higher yield and lower grain moisture content than hybrids of FAO group 700, which suggests that, when selecting hybrids, the sum of temperatures is the determining factor. Growing drought-resistant maize hybrids and appropriate agronomic measures as components of improved technology could mitigate the effects of stress caused by adverse weather conditions (Kovačević et al. 2010, Simić et al. 2018).

Conclusion

Owing to a much larger amount and more favorable distribution of precipitation, especially in the critical developmental phases (tasseling - fertilization), the average grain yield of all maize hybrids in 2018 was almost three times higher than in 2017. The most noticeable reaction of hybrids to environmental factors was recorded in the hybrid NS 548, which, as one of the hybrids with the highest yield in 2017, in 2018 had a yield significantly lower than other hybrids. Hybrids ZP 560, ZP 606 and ZP 666 in both years belonged to the group of hybrids with the highest grain yield.

Abstract

In order to introduce proper use of new disease-fighting agents into a country, certain relevant principles, requirements and criteria prescribed by the Forest Stewardship Council (FSC) must be observed, primarily with respect to measures of assessment and mitigation of risks, the list of dangerous and highly dangerous pesticides with the possibility of alternative protection. One of the main goals of the research is adjustment of the protective measures to the FSC policy through selection of eco-toxicologically favourable fungicides. We study alternative protection on the occurrence of mass dieback in oak forests seedlings in Central Serbia (caused by *Microsphaera alphitoides* Griff. et Maubl.) with various dosages of AQ-10 biofungicide, which is a pelleted formulation of conidia of *Ampelomyces quisqualis* Ces. ex Schlechtend. Simultaneous testing has been conducted on the efficacy of a chemical sulphur-based preparation. The results of the research have demonstrated that AQ-10 biofungicide can be used as a part of integrated disease management programmes as an alternative. The best results in suppression of oak powdery mildew have been attained through use of sulphur SC in the concentration of 0.5%, while very satisfactory results have been obtained by use of AQ-10 biofungicide in the highest dosage of application (70 g/ha). The number of treatments has been proven to have no significant impact on increased efficacy of the bio-preparation, or in other words, it shows that besides the application dosage, the high efficacy of the bio-preparation depends primarily on proper timing of the application.

Keywords: *Alternative protection, Quercus robur, Central Serbia.*

Introduction

One of the most spread pathogens that endangers forest survival and process of sustainable forest management in Serbia is *Microsphaera alphitoides*, fungi that causes oak powdery mildew. Without appropriate protection measures taken, this disease can destroy all seedlings in nurseries, or can significantly reduce height increment due to the sprout death.

High numbers of pesticides being used on a regular basis seriously endanger human health and environment. The facts that 60000 chemicals are regularly used, and even 1000 new ones are produced every year, illustrate adequately the seriousness of the problem (Jankovic *et al*., 1981).

Development of modern, non-dangerous sustainable strategies such as usage of biopesticides, effective microorganisms or products of their metabolism (as the alternative to chemical, synthetic compounds), is caused by global demand for reduction of usage of pesticides that are considered harmful. Biofungicides have more specific influence on the target organism comparing to chemical compounds – they impact exclusively the target organism not causing toxic effects on environment and therefore increase biodiversity.

Materials and methods

For treatment we were using new biofungicide AQ-10 which contains spores of *Ampelomyces quisqualis* Ces. ex Schlechtend. – hyper-parasite that kills the fungi causing powdery mildew. This biofungicide has good efficacy, biological protection, it is not selective for specific breeds of *Microsphaera alphitoides*. Chemical preparation used during research was sulphur. Sulphur is the first fungicide that was successfully applied in powdery mildew control (in 1848) and after 150 years there is no sign of the pathogen's resistance. It acts both as prevention and as treatment and its efficacy is due to the external factors, temperature in the first place (it is inefficient on low temperatures and it is phytotoxic on high temperatures). Appearance and development of fungi are examined when first signs of disease are evident on control plots, that is, when the clear difference between control plots and plots treated with fungicide and biofungicide becomes evident. Experiments are designed according to the instructions of the Method PP 1/152 (2) (EPPO, 1997b), as a random block design with four replications, and are placed on two localities in Central Serbia during 2010. The size of a replication (plot) was 8 trees (1 x 3m), 25 m^2.

In the first experimental plot the investigations were carried out on the oak seedlings *Q. robur* L. of seed origin, aged 6 years. The seedlings were between 0.30 cm and 1.70 m in height (with the majority roughly 1.20 m tall). The seedlings were planted densely in rows approximately 60 m long (8 rows in total, an average of 6 seedlings per m^2), with about 40 cm space between the rows. On the second site, the experiments were conducted on oak seedlings *Q. robur* L. aged 6 years. The Pedunculate oak seedlings aged (2+0) were planted in 2006 on the total of 24 plots, in 4 blocks with 6 rows each.

<u>The assessment</u> of the secondary infection on leaves was performed on 100 leaves with four repetitions per each variant. The assessment scale of each leaf was as follows: 0 = no infection; 1 = very low infection; 2 = partial attack (scattered spots affected by powdery mildew); 3 = moderate to severe disease (up to half of the leaf surface is affected by powdery mildews); 4 = very severe disease (more than half of the leaf surface under the powdery mildew; edges of the leaves begin to crumple and dry up). Regarding the method of application and amount of water per unit surface, the fungicides were applied using the backstroke sprayer with the consumption of 1000 l/ha of water.

<u>Statistical analysis:</u>

The intensity of infection was performed according to methods EPPO, PP 1/69 (2): 100-102 and PP 1/152 (2): 37-51. Phytotoxicity was monitored according to method PP 1/135 (2): 31-36. The data were analyzed by statistical methods - the intensity of infection according to method Towsend and Heuberger (1943), efficacy according to Fleming and Retnakaran (1985), and method PP/181 (2): 52-58. The differences in the intensity of infection were determined through analysis of variance and LSD test.

Results and discussion

Results of testing the effects of the chemical and biological preparation on oak powdery mildew control, presented in tables 1 and 2, demonstrate that on both sites the chemical preparation had somewhat higher efficacy than the biopreparation. It is also apparent that the efficacy of the biopreparation on both sites increased with the increase of the active matter dosage.

Table 1**.** Efficacy of the preparation on control of causers of oak powdery mildew (site I)

Number of Variants	Fungicide	Concentration/Doses (%), g, l/ha	Infection (%)	**Efficacy** (%)	Standard (%)
1.	AQ-10	30 g	15.35 d	48.05	56.91
2.	AQ-10	50 g	7.15 bc	75.80	89.78
3.	AQ-10	70 g	6.15 abc	**79.19**	93.79
4.	Sulphur SC	0.5 %	4.60 a	**84.43**	100.00
5.	Untreated	-	19.90 b	0.00	0.00
lsd 005			5.36		
lsd 001			7.35		

Table 2**.** Efficacy of the preparation on control of causers of oak powdery mildew (site II)

Number of Variants	Fungicide	Concentration/Doses (%), g, l/ha	Infection (%)	**Efficacy** (%)	Standard (%)
1.	AQ-10	30 g	10.60 a	61.21	65.03
2.	AQ-10	50 g	12.42 a	54.53	57.93
3.	AQ-10	70 g	4.45 a	**83.71**	88.94
4.	Sulphur SC	0.5 %	1.61 a	**94.13**	100.00
5.	Untreated	-	27.33 b	0.00	0.00
lsd 005			10.34		
lsd 001			14.61		

Statistical processing of the obtained results has shown that the differences are significant in all tested variances as compared to the control variance. Based on the variance analysis of a random block system, the difference between mean repetitions was found to be statistically significant at the probability of 95%, since $F_0 > F_{0.05}$.

A statistically significant difference was also found between mean treatments at the probability of 99%, since $F_0 > F_{0.01}$. Between the mean values of the control and the variance AQ-10 (application dosage 50 g) and all other tested variances there is a statistically significant difference at the probability of 99%.

There is no statistically significant difference between the mean treatments of other variances and all other treatments, and the differences are incidental.

Application of comparative analysis Duncan test (Duncan, 1955) aimed at determination of significant differences resulted in identification of a homogenous group in which a statistically significant difference between the mean treatments was found at the probability of 99%, since $F_0 > F_{0.01}$.

No adverse effects of the biological and chemical preparations on the treated plants and other organisms were observed at the tested sites. Moreover, the chemical preparation had no adverse effects (phytotoxicity on plants), since the application was conducted according to the prescribed procedure and at the temperature below 28°C, which is the critical temperature in application of sulphur compounds.

In the reference literature, multiple authors have confirmed and proved in different climatic regions that the intensity of infection with powdery mildew on a variety of plant species is directly dependent on environmental conditions, primarily temperature and air humidity. The intensity of infection of Pedunculate oak seedlings with powdery mildew in the nursery was therefore examined in connection with temperature and air humidity, as shown in Table 4, for the period from 13 May through 24 June.

Table 3. Infection of Pedunculate oak seedlings with powdery mildew depending on outside temperature and air humidity

Date	Rh (%)	Temperature (^{0}C)	Infection (%)
13. May	100	21	51
19. May	97	11	10
25. May	90	23	33
03. June	95	17	63
10. June	91	28	41

For germination of spores, the relative air humidity need not be exceedingly high. The presence of the pathogen is thus distinct in dense plantings with poor air circulation and damp and dark places. The frequency of infection increases with the increase of relative humidity of up to 90%, but the infection does not occur when the leaf surface is wet, or when it rains. Rain showers wash off the leaf inoculum and reduce the intensity of infection since the pathogen is epiphytic, while prolonged and notable periods of high temperature favour the development of pathogens.

The presented Table 3 clearly shows that low and high air temperatures (11° and 30°C) had a direct impact on reduction of the infection, which in this period amounted to 10% and 32% out of the total number of tested seedlings. At a time when the air temperature was 11°C and the relative air humidity was extremely high at 97%, which does not favour the development of pathogens, hence this was the probable reason why the infection was three times lower than at the temperature of 30°C - at that time when air humidity was favourable for the pathogen and amounted to 94%.

Very high rate of infection on seedlings was observed at temperatures of 17° to 21°C at the relative air humidity from 85% to 100% (the infection in this period amounted to 51% to 63% of all the tested seedlings).

Table 3 clearly shows that the negative effect on the pathogen of one of these two factors (humidity and temperature) can be greatly mitigated by the positive influence of other factors. Thus, a very favourable temperature of 21°C for pathogen development directly reduced the negative effect of maximum air humidity of 100% and led to a high degree of infection of seedlings of 51%, which was also registered under very good conditions of 85% humidity and temperature of 21°C. The effect of slightly lower temperature than the optimal one for the development of pathogen (17°C) was hence probably mitigated by the corresponding relative humidity of 94%, and therefore the infection of seedlings in that period was maximal and reached 63%.

The comparative analysis of the effects of temperature and air humidity on the occurrence of secondary infections and spread of powdery mildew infection with the results obtained by other authors (Kothari and Verma, 1972; Whipps and Budge, 2000; Guzman-Plazola *et al.*, 2003) shows that high relative humidity reduces the intensity of infection, which can help in controlling this pathogen in the future.

Temperatures of 30°C and above are fatal for the development of pathogens. The growth of the fungus is thus significantly higher at 20°C than at 25°C. High levels of relative humidity (80-

90%) are favourable for pathogen development in the short term, but longer exposure to these conditions leads to a restricted infection. According to the research of Guzman-Plazola *et al.*, (2003), short daylight period (two or three exposures of at least 2 hours at high temperatures of 35°C) suppressed the development of the disease as much as 70-92%.
Results of testing the effects of the chemical preparation have shown the efficacy of 84.43% (site I) and 94.13% (site II). Compared to the chemical preparation, biopreparation AQ-10 has also demonstrated very high efficacy. Moreover, fewer treatments with the biopreparation (carried out in the nursery "Rogot", with the application of the highest dosage of the biopreparation – 70 g/ha) have shown similar efficacy as a larger number of treatments with the same dosage of the biopreparation (applied in 7-day intervals in the nursery "Barosevac", following numerous secondary infections), which amounted to 79.19 and 83.71% respectively.
In practice, this means that the number of treatments is not a deciding factor in achieving high efficacy of the biopreparation. If the treatment is carried out at the suitable time, fewer treatments will accomplish a very satisfactory level of efficacy. This is obviously quite significant from the economic point of view, and this experience may be applied in nurseries for control of powdery mildew through use of biopreparations.

Conclusion

The chemical preparation Sulphur SC is still efficient to a satisfactory degree, with the advantage that resistance of pathogen cannot occur during its application.
The bio-fungicide AQ-10 can be used as part of an integrated disease management program, as an alternative to reduce the use of standard fungicides for control of powdery mildew in oak nurseries. The best results in suppressing the oak powdery mildew were achieved in variances in which the biofungicide AQ-10 was applied in higher dosages (50 and 70 g/ha).
When AQ-10 is applied prior to disease infection, it may significantly reduce powdery mildew compared to the untreated variant. In view of the fact that biopreparation AQ-10 is non-toxic to humans and warm-blooded animals as opposed to the chemical preparation, has no negative effects on the environment, ensures long-term control and is favourably priced, it can be concluded that it should be introduced in control of oak powdery mildew in nurseries. Future scientific research should certainly focus on testing the effect of AQ-10 on powdery mildews of other major forest species.
Within the scope of repressive measures, development and introduction of alternative methods of forest protection against harmful organisms is carried out with the purpose to generate suitable alternative preparations and protection methods, so as to overcome the problem of exclusion of unwanted pesticides. It is therefore necessary to support the scientific institutions in conducting the research aimed at producing alternative methods and pesticides with less adverse effects on the environment and biodiversity in forest ecosystems.

Acknowledgement

The study was carried out within the Project TP- 31070: "The development of technological methods in forestry in order to attain optimal forest cover", financed by the Ministry of Science and Technological Development, Serbia.

Abstract

The modern lifestyle imposes the need to discover and introduce foodstuffs that have nutritional and medicinal value into the food chain. The genus *Allium* includes a great number of species. The most studied species are onion, garlic and leek, for which there is evidence of beneficial effects on human health. Investigation of other, rare grown species of this genus, offers the possibility of expanding the range of food to vegetable species with potentially enriched chemical composition. Bearing in mind that the antioxidant properties of food are an important parameterofits quality, this paper aimed to examine the content of hydroxycinnamic derivatives (HCAs), as natural antioxidants, in two *Allium* species - *A. schoenoprasum* (chives) and *A. nutans* (blue chives), grown under different foliar application of selenium - Se (0, 10, 20, 30 g per ha). The total HCAs content was determined by spectrophotometric method, measured the absorbance at 525 nm. The obtained results are expressed as mg equivalent of chlorogenic acid (CGAE) per g of fresh weight. HCAs was in range 0.18 to 0.39 mg/g CGAE for *A. schoenoprasum*, and from 0.18 to 0.94 mg/g CGAE for *A. nutans*. The presence of HCAs indicates the potential antioxidant activity of the investigated species and justifies further detailed research with the aim of identifying other bioactive components that manifest beneficial effects on human health.

Key words: *Allium nutans, Allium schoenoprasum, antioxidant properties, HCAs.*

Introduction

The genus *Allium* includes a great number of species, which are spread throughout the Northern hemisphere (*Khassanov*, 2018). The best examined species of this genus which also have the greatest economic and nutritional significance are onion (*Allium cepa*), garlic (*A. sativum*) and leek (*A. ampeloprasum*). Although interest of researchers in studying other *Allium* species is constantly increased, data on their morphological characteristics, cultivation technologies as well as more detailed phytochemical analyzes are still modest, especially in the domestic literature.
Researches have shown that alliums have a number of beneficial effects on the human health, which are associated with a high content of various bioactive compounds. *Zeng et al.* (2017) indicated that introducing alliums into the diet can reduce the risk for various cancers. The same authors suggested that alliums extracts and oils have cardioprotective, antibacterial, anti-inflammatory and antioxidant effects. *Wan et al.* (2019) also indicated that consumption of

alliums had a preventive effect on the occurrence of cancer of the organs of the digestive tract. There is also evidence that garlic show effect in reducing blood pressure, regulating lipid and glucose status, etc. Given that these pharmacological effects are generally associated with the use of garlic or onion, there is a need to test other, rare grown species belonging to this genus. In this way, it is possible to expanding the range of food onto vegetable species with a potentially enriched chemical composition. For this purposes, current research was conducted on the species *A. schoenoprasum* L. (chives) and *A. nutans* L. (blue chives), which are rarely grown in Serbia, mainly at backyards or hobby gardens.

A. schoenoprasum L. and *A. nutans* L. are perennial species whose leaves can be used either fresh or dried. They are differed in terms of morphological properties, while had taste similar to onions. The natural habitats of *A. schoenoprasum* are cold regions of Europe and Asia. *A. schoenoprasum* has small, thin, dark green, tubular leaves, 0.3 to 0.5 cm in diameter (Figure 1). *A. nutans* L. also originates from colder regions, and is a widespread species in Siberia and Tibet. Leaves of *A. nutans* are dark green, lanceolate shape, flattened, 0.5 to 2.5 cm in diameter (*Lazić et al.*, 1997) (Figure 2).

Figure 1. Appearance of *A. schoenoprasum* L.

Figure 2. Appearance of *A. nutans* L.

Organosulfur compounds and polyphenols are the main bioactive components in the *Allium* species which have been studied so far (*Putnik et al.*, 2019). Organosulfur compounds, in addition to giving a characteristic smell and taste to alliums, are also responsible for their biological activities. However, the highly-volatile and thermally-unstable nature of these compounds, according to *Kathori et al.* (2020) reduce their effects on human health. In more recent studies, the pharmacological effects of alliums has been attributed to polyphenols that are more stable than organosulfur compounds, as well as due to its proven antioxidant activity (*Tanase et al.,* 2019; *Lorenzo et al.,* 2021). Polyphenols represent a large class of secondary metabolites in plants and more than 8000 have been identified so far (*Pandey and Rizivi*, 2009; *Neveu et al.,* 2010). Their presence in food improves its quality, nutritional and healing properties (*Vlase et al.,* 2013). In addition to exhibited pharmacological effects, polyphenols are also recognized as biomolecules that play crucial role for many physiological processes in plants, such as growth, development, reproduction, response to stress conditions (*Tanase et al.,* 2019; *Šamec et al.,* 2021).

The main polyphenolic compounds in the genus *Allium* are: phenolic acids, flavonoids and lignans (Figure 3) (*Kathori et al.,* 2020).

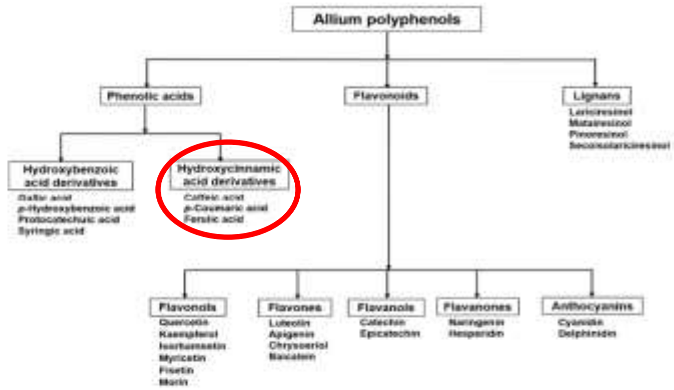

Figure 3. Polyphenolic compounds of the genus *Allium* (Source: *Kathori et al.*, 2020)

Hydroxycinnamic acid derivatives (HCAs) - caffeic, *p*-coumaric, ferulinic and sinapic acids are plant polyphenols from the group of phenolic acids and are defined as hydroxyl derivatives of cinnamic acid (*McCarthy et al.*, 2013). They are found in a large number of foods, including fruits, vegetables, cereals, spices and various beverages (tea, cocoa, wine, beer, coffee) (*El-Seddi et al.*, 2018; *Fási et al.,* 2019). It is assumed that of the total amount of polyphenolic compounds ingested with food, one third represents these acids (*Teixeira et al.*, 2013). The antioxidant properties of HCAs have been well described, especially in medical research. The role of HCAs in physiological processes in the human body is analogous to the role of polyphenols, so the literature emphasizes their potential ability to protect against cardiovascular disease, cancer, infectious diseases, as well as mitigate the adverse effects of chemotherapy (*El-Seddi et al.*, 2018). Considering the overall importance of polyphenols, but also HCAs as subgroups of polyphenolic compounds, various methods for determining their content have been developed. By using the standard Folin–Ciocalteu spectrophotometric method the total content of polyphenolic compounds can be obtained, which also including content of HCAs. Therefore, methods based on the specific quantification of HCA provide more reliable data on the presence of these derivatives, indicating the potential antioxidant effect of the tested samples. Literature data indicate that, although these acids were the subject of study back to the 1970s, during the recent years they are starting to gain an importance again and finding their place in scientific research. Given that the antioxidant properties of food are a valuable parameter of quality, and that mineral nutrition can affect the content of secondary metabolites in plants, the aim of this study was to determine the content of HCAs, as natural antioxidants, in the above mentioned rare *Allium* species from Serbia, grown under different foliar application of Se.

Material and methods

Production of *A. schoenoprasum* L. and *A. nutans* L. was carried out during two vegetation seasons, from October 2019 to September 2020, in open field conditions, at the location of Kovilovo, Palilula Municipality, Belgrade (Serbia). The experiment was conducted in three replicates. Selected species were grown under different foliar application of selenium fertilizer - sodium selenate (Na_2SeO_4), which was applied as a aqueous solution, in doses of 0 g, 10 g, 20 g and 30 g per ha, in the phase of intensive growth and development of plants (end of April).

In June, several samples (leaves) of fresh plant material were taken from plants grown under each treatment and each replicate, and were used to prepare a representative sample. The plant material was then cleaned from the ground and washed, chopped in an electric mill and used to

prepare extracts. Plant extracts were prepared by pouring 1 g of chopped samples with 20 ml of 80% methanol (MeOH). After that samples were intensively shacked for 2x90 min in plastic cuvettes protected from the light. Upon completion of the extraction, the precipitate was separated from the supernatant by centrifugation (4000 *g*). The supernatants were stored in a cool and dark place until they were analyzed. The determination of the total hydroxycinnamic acid derivatives (HCAs) content was evaluated using the spectrophotometric method as described by *Fraisse et al.* (2011), with some modification. The reacting mixture (RM) contained 0.2 ml of the plant extract, 0.4 ml of 0.4 M HCl, 0.4 ml of Arnow's reagent, 0.4 ml of 2.125 M NaOH solution and 0.6 ml of distilled water. The Arnow's reagent was prepared by dissolving 10 g of $NaNO_2$ and 10 g of Na_2MoO_4 in 100 ml of distilled water. The total volume of the RM was 2 ml. After preparation, the samples were left in the dark for 20 minutes, and then the absorbance of the obtained colored solutions was measured at 525 nm with a blank containing 0.2 ml of distilled water instead of plant extract. The content of HCAs derivatives was determined using a calibration curve with chlorogenic acid (CGA) as a standard. The obtained results are expressed as mg of CGA equivalents (CGAE) per kg of fresh weight.
For each sample, measurements were performed in three replicates, and the results were presented as the mean of three replicates ± standard deviation (SD).

Results and discussion

The obtained results showed that the selected species differ in terms of the content of HCAs. Also, within both species, there was a difference in the content of HCAs according to the examined Se treatments (Table 1). In *A. schoenoprasum*, the highest content of HDAs was found in plants treated with 10 g Se per ha, while the plants treated with the maximum concentration of Se (30 g per ha) had the lowest content. The lowest content of HDAs, in *A. nutans*, was observed in plants with application of Se at a concentration of 20 g per ha, while the highest content was recorded in untreated plants (Table 1).

Table 1. Content of HCAs in *A. nutans* and *A. schoenoprasum* according to different concentrations of foliar applied Se.

Se - treatment	***Allium SCHOENOPRASUM***	***Allium NUTANS***
	$\bar{X}$ (mg/g CGAE) ± SD	**$\bar{X}$ (mg/g CGAE) ± SD**
Control	0.25 ± 0.005	**0.94 ± 0.01**
10 g per ha	**0.38 ± 0.005**	0.19 ± 0.004
20 g per ha	0.23 ± 0.01	**0.18 ± 0.01**
30 g per ha	**0.19 ± 0.002**	0.19 ± 0.02

In this study, it was found that foliar application of Se does not affect on the increase in the content of HDAs in a clear and obvious way, compared to untreated samples. On the other hand, the research of *Vuković et al.* (data are not presented) showed that in other alliums, which are rare grown in our country, the presence of HDAs was not detected in either untreated or Se-treated plants. In contrast to these results, research conducted on basil (*Ocimum basilicum* L.) by *Skrypnik et al.* (2019) suggested that the application of Se, either foliar or by its addition to the nutrient solution, significantly increases the content of total polyphenols and HDAs. The same authors pointed out that the content of total flavonoids - compounds from the group of polyphenols, did not significantly differ between untreated and treated basil plants with selenium.

The observed differences between plant species and treatments can be explained by the still poorly investigated and understood influence of Se on the synthesis of secondary metabolites.

In general, the presence of HDAs indicates potential antioxidant capacity of *A. schoenoprasum* and *A. nutans*, and justifies further detailed research on these species in order to identify other bioactive components that have beneficial effects on human health.

Conclusion

Antioxidant properties are an important indicator of food quality. Previous research indicates that species of the genus *Allium* represent a rich source of bioactive molecules with potential antioxidant activity. Considering that the genus *Allium* has been consisted of about 1000 species of which a few have been examined in more details, numerous possibilities are provided for conducting both agronomic and phytochemical research. By introducing new plant species into production, but also by expanding the production of rare grown species of this genus, it can contribute to expanding the food range for vegetable species that, in addition to being nutritious, also have medicinal properties. The nutritional and medicinal properties of these species, could be further improved by the planned enrichment of alliums with microelements that are essential for human health, by implementing the process of biofortification, which is an increasingly popular agrotehnical measure in the world. Therefore, this research can be useful as a basis for more detailed studies of the process of biofortification over vegetable plants that are characterized by a potential therapeutic effect.

Abstract

Sowing of maize is a very important agro-technical intervention, bearing in mind that the omissions during sowing cannot be corrected later by other agro-technical measures. The quality of sowing maize, in addition to the quality of agro-technical works before sowing, also depends on the quality of work of sowing aggregates. Sowing aggregates for sowing maize must ensure the correct horizontal and vertical distribution of seeds because only the correct arrangement provides the plants with optimal vegetation space and the possibility to achieve high yields. A successful sowing unit, in addition to satisfactory quality of work, should also have high work productivity, i.e. achieved effects, because optimization is successful only with operational tests. The paper presents the results of testing the quality of work and performance indicators of units for sowing maize with different sowing mechanisms. The tests were performed in the agroecological conditions of central Serbia - Kragujevac area and included the assessment of the distribution of corn seeds along the length as well as the achieved effects concerning the projected depending on the defined parameters for mechanical sowing unit mechanism, under-pressurized sowing unit mechanism, and sowing unit with an over-pressurized mechanism. The obtained results show that the best longitudinal seed distribution was achieved when sowing maize with sowing mechanism type because the percentage of distances that were > 0.5 <1.5 of the theoretical grain spacing within the row was over 80% and the worst with mechanical sowing mechanism type A (mechanical) when these values were the lowest. The achieved effects concerning the projected ones varied in the range from 73.52% of the sowing unit type B to 83.41% as measured with the sowing unit type C. The increase in the speed of movement during sowing significantly affected the quality of the longitudinal distribution of corn seeds.

Keywords: *Seed drill, Quality, Longitudinal seed distribution, Performance.*

Introduction

Sowing is one of the most important operations in the production of maize because the omissions during sowing cannot be corrected later by other agro-technical measures. Proper horizontal and vertical seed placement allows for better germination and sprouting of maize and increased yields (Karayel *et al.*, 2002; 2006; Parish *et al.*, 2003). The introduction of "precision agriculture" enables a much better distribution of seeds by area and depth (Auernhammer, 2004; Meši *et al.*, 2008). Numerous field and laboratory methods have been developed to test and evaluate seeder performance (Navid *et al.*, 2011). Seeders that are traditionally used for sowing maize have the function of copying the terrain, but the height of seed ejection is conditioned by the construction of the sowing mechanism and the investor himself (Tao *et al.*, 2012). Sowing

quality is measured and calculated after crop emergence, bearing in mind that the composition of plants is the main factor of successful and profitable production (Raheman *et al.*, 2003). The value of the time utilization coefficient decreases with increasing working speed, which affects the reduction of labor productivity (Vičacki *et al.*, 2013). The highest percentage of obtained effects to the projected ones was recorded in variant S2 and amounted to 89.39%, and the lowest in variant S3, namely 71.34% (Barać *et al.*, 2006). The development and improvement of sowing mechanisms are conditioned by the requirements for a wider range of continuous dosing, increasing the performance of seeders and the precision of seed distribution of different sizes (Findura *et al.*, 2012). The quality of maize sowing is the most important factor influencing high and quality yield and is expressed as a percentage of the obtained sowing intervals according to ISO 7256/1 and 7256/2 (Bozdogan *et al.*, 2006; 2008; Turan *et al.*, 2015). At a sowing speed of 3.6 km h^{-1} seeder with a mechanical apparatus 68.5% of seeds were in the group of 0.5-1.5 required distance, at a speed of 4.3 km h^{-1} 65.3% of seeds, and at a speed of 5.4 km h^{-1} 62.4%. (Ivančan *et al.*, 2007). The same authors state that when sowing with a pressurized seed drill at a sowing speed of 3.6 km h^{-1}, 65.4% of seeds were in the group 0.5-1.5, at a speed of 4.3 km h^{-1} 63.2 % of seeds, and a speed of 5.4 km h^{-1} 61.0% of seeds. The share of realized gaps from 0.5 to 1.5 in the pressurized seed drill is higher concerning the pressurized seeder 81.43 to 88.57 to 68.89 to 77.78% (Turan *et al.*, 2011). The pressurized seeder obtained a very good quality of maize sowing, bearing in mind that in the group of 0.5-1.5 required spacing, there were 94.34 - 98.79% of plants (Banaj *et al.*, 2018).
The research is aimed to determine the effects of seeders with different sowing mechanisms when sowing maize and point out the advantages and disadvantages of the applied system in terms of quality of longitudinal seed distribution under different operating modes, with emphasis on reliability and quality of sowing aggregates under tested conditions.

Material and Methods

In the production conditions of central Serbia – at the vicinity of Kragujevac in Serbia during 2018/19 (44°07'15.9"N 20°50'04.3"E) tests of seeders with different sowing mechanisms were performed. The distribution of maize seeds by length and the achieved effects in relation to the projected ones depending on the defined parameters in four-row seeders: with mechanical sowing mechanism - Type A, seeder with underpressure sowing mechanism with - Type B- and seeder with overpressure mechanism - Type C Seeds of ZP 600 maize hybrids with a germination rate of 96% were used for sowing and met the basic requirements of seeds in terms of germination and dimensions (Vitazek *et al.,* 2005). The theoretical sowing distance was set differently and was for seed drill Type A 250 mm, Type B 245 mm, and Type C 240 mm. Based on the known theoretical sowing intervals, empty and double places are defined, where the double place in the case of sowing at a distance is less than 0.5 of the theoretical distance and the empty place in the case of sowing at a distance is greater than 1.5 than the theoretical distance. In the Type A seed drill, a seed plate 11 was installed, in the Type B seed drill the seed plate had 22 holes and a diameter of 190 mm, and in the Type C seed drill a sowing disc with 24 holes with a diameter of 250 mm. The required power for towing the tested seeders is 40 kW. The preparation of the land was done in a timely manner and included autumn plowing at 25 cm, while the pre-sowing preparation was done in the spring with a seed drill at a depth of 15 cm, so a well-scattered and crushed sowing layer was created. All seeders operated in similar conditions that were satisfactory, sowing was done at the end of April, and adjustments were made depending on the characteristics of the seeds. Tests and evaluation of the quality of work of seeders with different sowing mechanisms in maize sowing was performed according to ISO standards 7256/1 and 7256/2. The achieved effect was determined chronometrically, and all values during the test were read in 5 replicates. The experiment was performed in a completely random plan variant. The obtained results were processed using Microsoft Office Excel 2007.

Results and Discussion

Figures 1-3 illustrate the results of testing the longitudinal distribution of maize by the tested variants. The obtained results show that with the change of the defined parameters, the quality of the longitudinal distribution of maize seeds in sowing significantly changes. The results in Graph 1 indicates that the share of realized sowing distances in the group <0.5 of the theoretical distance obtained when sowing with a Type A seeder was in the range of 5.43 - 20.25%, working speed of 9.43 and 4.21 km h^{-1}, which are the largest measured values for all tested variants. The share of realized distances from 0.5 to 1.5 from the theoretical sowing with this type of seeder varied in the range of 54.32–78.53% (the lowest measured values of realized distances in this group according to all examined variants). When it comes to the share of open distances > 1.5 from the theoretical when sowing maize with this type of seeder, it is noticed that it was in the range of 4.03 - 39.81%, working speed of 4.21 and 9.43 km h $^{-1}$ (Figure 1).

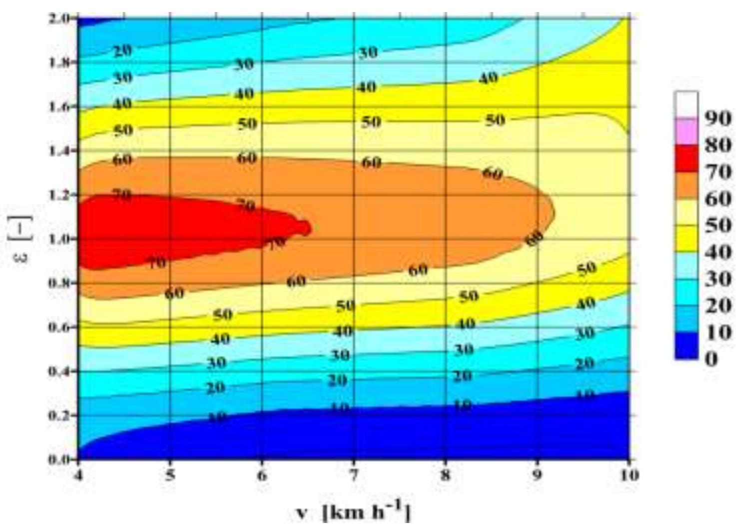

Figure 1. Obtained distance of maize along the length when sowing with seeders type A

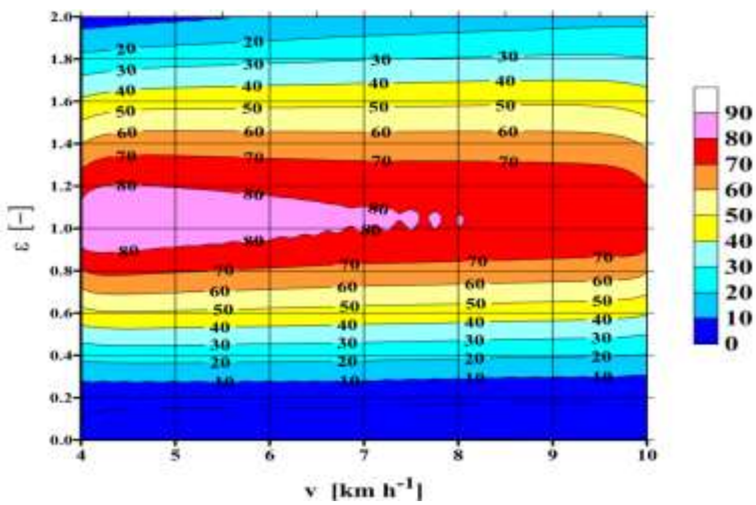

Figure 2. Obtained distance of maize along the length in sowing seeders Type B

The results in Graph 2 show that when sowing maize with a Type B seeder, the share of realized sowing intervals in the group <0.5 of the theoretical distance varied in the range of 3.99 - 8.72%, working speed of 9.83 and 4.47 km h^{-1}. The share of the obtained distances from 0.5 to 1.5 to the theoretically measured with the Type B seeder ranged from 74.35 to 88.67% (working speed from 9.83 or 4.47 km h^{-1}). The share in the group of realized distances >1.5 from the theoretical sowing with this seeder was in the range of 4.34 - 19.47%, the speed of movement was 4.47 or 9.83 km h^{-1} (Figure 2). Analyzing the results in Graph 3, it is noticed that when sowing with a Type C seeder, the smallest share of realized sowing intervals in the group <0.5 of the theoretical distance was measured and was in the range of 2.40 - 8.61% at an operating speed of 8.78 and 4.95 km h^{-1}. The share of realized intervals from 0.5 to 1.5 of the theoretical when sowing with this type of seeder varied in the range of 78.96 - 88.98% (the highest measured values of realized distances in this group according to all examined variants). The values of the share in the group of realized distances > 1.5 from the theoretical one were in the range of 3.24 - 16.63%, the speed of movement was 4.95 or 9.95 km h^{-1} (Figure 3).

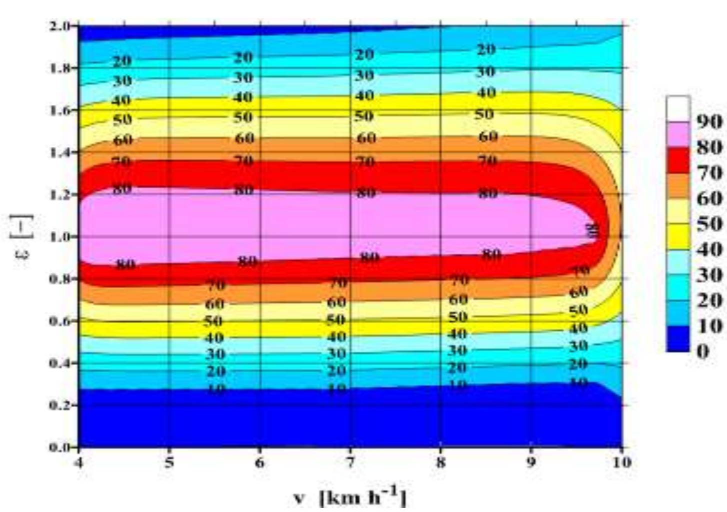

Figure 3. Obtained distance of maize along the length when sowing with seeders type C

The increase in working speed had a significant effect on the reduction of the quality of the longitudinal distribution of maize at sowing, bearing in mind that the share of realized distances from 0.5 to 1.5 concerning the theoretical distance decreased according to all examined variants. All three drills obtained a higher share of empty places concerning the double places, except in the case of the Type C seed drill, where the lowest values of 2.40% were measured .

The results we obtained in our research coincide with the statements of other authors (Auernhammer, 2004; Ivančan *et al.*, 2007; Bozdogan, 2008; Meši *et al.*, 2008; Findura *et al.*, 2012; Turan *et al.*, 2015; Banaj *et al.*, 2018).

The results in Graph 4 show that there is a significant impact of increasing the speed of movement on the values of the obtained effects because the values of the obtained effects increase with the increase of the speed of movement. According to all examined variants, smaller effects were obtained than projected. The lowest average values of the obtained effects concerning the projected ones were measured with the Type B seeder, namely 73.52% (0.77 ha h^{-1} concerning the projected ones 1.05 ha h^{-1}, working speed of 4.21 km h^{-1}), and the highest for the Type C seeder 83.41% (1.86 ha h^{-1} to the projected yield of 2.23 ha h^{-1}). With the Type A seeder, the obtained effects to the projected ones varied in the range from 74.45% (projected 0.94 and obtained 0.73 ha h^{-1}) to 82.65% (projected 2.11 obtained 1.74 ha h^{-1}) (Figure 4). Others came to similar results in their research (Barać *et al.*, 2006; Turan *et al.*, 2011; Findura *et al.*, 2012; Vičacki *et al.*, 2013).

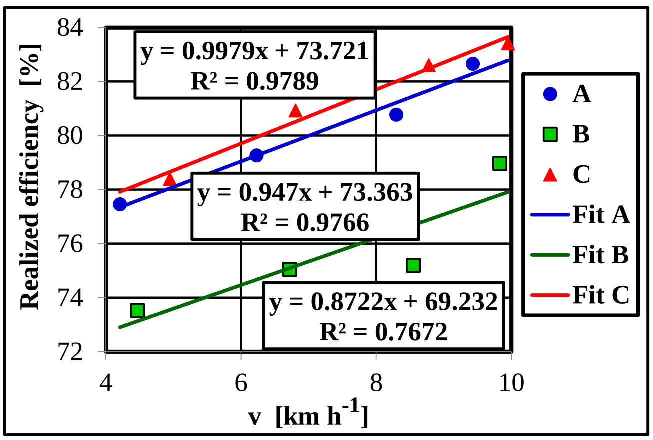

Figure 4. The obtained effects of tested seeders concerning the designed ones

Conclusions

Based on the obtained results, it can be concluded that the change of the defined parameters had a significant impact on the quality of the longitudinal distribution of maize seeds in sowing and the obtained effects concerning the projected ones. The smallest share of realized distances in the group <0.5 of the theoretical distance was measured when sowing corn with a Type C seeder and was 2.40%, and the largest with a Type A seeder - 20.25%. The highest values of the share of realized intervals from 0.5 to 1.5 from the theoretical one were measured when sowing corn with a Type C seeder, namely 88.98%, and the lowest when sowing corn with a Type A seeder, 54.32%. The lowest value of the share in the group of realized intervals >1.5 from the theoretical of 3.24% was measured when sowing with a Type C seeder, and the highest of 39.81%. in the case of a Type A seeder. With the increase of the working speed in all tested seeders, the quality of work deteriorated because the share of seed spacing in the longitudinal distribution decreased from 0.5 to 1.5 of the given spacing, and the share of corn blanks increased. All three tested seeders obtained a higher share of empty places to double places, except in the case of the Type C seeder, where the lowest values of 2.40% were measured. As the speed of movement increases, so do the values of the obtained effects in all variants. The lowest average values of the obtained effects to the projected ones were measured with the Type B seeder, namely 73.52%, and the highest with the Type C seeder, 83.41%. According to all examined variants, smaller effects were obtained than projected ones.

Abstract

Sour cherry is one of the most economically important temperate fruit species worldwide, which is widely used both fresh and processed. Due to the consumer demand for antioxidant-rich products, the development of new tart cherry selections with desirable quality characteristics is critical for the sustainability of cherry producers and processors. 'Leda' is a new sour cherry cultivar released from the sour cherry breeding program at the Institute PKB Agroekonomik. It was selected in mixed sour cherry orchard, from spontaneus seedlings population, and was recognized as cultivar in 2018 by the Serbian Ministry of Agriculture, Forestry and Water Management. The evaluation of this cultivar was done in comparison with the control cultivar 'Oblačinska' during a two-year period (2015 and 2017). Averagely, it bloomed a day or two after the control cultivar, while the ripening time was a day earlier than 'Oblačinska'. The productivity is higher than the standard cultivar. The attractive bright red coloured fruits are larger (3.8 g), compared to 'Oblačinska' (3.3 g), with shorter fruit stalk length (2.9 and 3.4 cm, respectively). It has rich, mild flavour, sweet-acidic and harmonic taste, having slightly higher value of soluble solids/total acidity ratio (10.4) compared to the standard cultivar (9.5). 'Leda' is highly resistant to economically important diseases and pests (*Monilinia laxa*, *Monilinia fructigena*, *Blumeriella jaapii*, *Wilsonomyces carpophilus* and *Rhagolethis cerasi)*. This cultivar could be used both for processing and fresh consumption.

Keywords: *Prunus cerasus, new realised cultivar, light red colour.*

Introduction

Sour cherry (*Prunus cerasus* L.), originated from around the Caspian Sea, is one of the most economically important temperate fruit species worldwide. It is one of the most popular fruits, which is widely used both fresh and processed. Sour cherries are excellent functional foods due to their high antioxidant capacity (Ferretti et al., 2010). Health benefits of cherries and their polyphenols against human diseases such as heart disease, cancers, diabetes are reviewed by Farretti et al. (2010). Also, there has been a great interest in sour cherry by-products due to the increasing production rate of sour cherry worldwide and the increasing efforts on seeking bioactive compounds from natural sources as functional food (Yilmaz et al., 2019).

Molecular analysis such as isozyme analysis, genomic in situ hybridization and karyotyping strongly suggests that *P. cerasus* is segmental allotetraploid obtained from natural hybridization between ground cherry (*Prunus fruticosa* L.) and sweet cherry (*Prunus avium* L.). (Hancock and Iezzoni, 1987; Santi and Lemoine, 1990; Beaver and Iezzoni, 1993; Schuster and Schreiber, 2000). Furthermore, it has also been established that majority of the chloroplast genome of sour cherry is likely inherited maternally from ground cherry, thus validating an inter-specific origin for sour cherry (Brettin et al., 2000). It is a small tree, or more often a deciduous bush, which suckers profusely from the root (Dirlewanger et al., 2007). Sour cherry growing is limited to a very small number of cultivars, mostly regional. In Central Europe the main sour cherry cultivar is the 'Schattenmorelle', a self-compatible and highly productive cultivar with dark red fruits and juice. In North America, 'Montmorency' – a self-compatible variety with bright red fruits and clear juice is the cultivar of choice. Among the other notable varieties, 'Pandy' (and its derivatives) are popular in Hungary and Romania, although it is self-sterile. In the structure of fruit growing in Republic of Serbia, sour cherry has an important place with 19,114 ha and the production of 101,568 tonnes (average for the period 2010-2019; FAOSTAT database, 2019). Together with raspberry, sour cherry represents the country's most important exporting fruit (Radičević et al., 2016). In assortment structure, different clones of 'Oblačinska' are predominant, accounting for 85% of the total crop along with spontaneously spread 'Cigančica' (Cerović and Radičević, 2008), while the rest make large fruit sour cherries, i.e. 'Rexelle', 'Heimanns Konservenweichsel', 'Kelleriis 14' and 'Šumadinka' (Milatović et al., 2015).

Regular yields and superior fruit quality are the two main objectives in sour cherry breeding programs. Besides that, improvement priorities include suitability for mechanical harvesting and processing, late flowering to avoid spring frost damage, round and small pit, resistance to *Blumeriella jaapii* and *Monilinia laxa*, self-compatibility, and a wide range of ripening dates (Iezzoni, 2008). Since the variability in sour cherry germplasm presents a wealthy source of diversity for breeders (Radičević et al., 2012), the vast majority of sour cherry breeding programs are in Europe. According to some estimates, there is about 500 sour cherry cultivars in the world. Sour cherries assortment is less dynamic compared to most other fruit species. Also the number of new cultivars that are developed worldwide is relatively small. In the last 30 years more than 200 new sour cherry cultivars have been released. About half of those were bred in Russia, followed by Ukraine, Poland, Romania, Hungary and Germany (Milatović and Nikolić, 2011). Breeding programs in Serbia so far have released ten sour cherry cultivars. 'Čačanski Rubin' ('Shasse Morello' × 'Köröser Weichsel') and 'Šumadinka' ('Köröser Weichsel' × 'Heimanns Konservenweichsel'), both from the Fruit Research Institute, Čačak, which were recognized in 1973 and 1984, respectively; 'Lara' ('Kelleriis 14' × 'Rexelle'), from Institute PKB Agroekonomik, Belgrade, which was recognized in 1993. 'Prima', selection from domesticated regional landrace of sour cherry, locally called 'Feketićka' was released in 2013; 'Lenka' is the first sour cherry cultivar from the breeding program at the Faculty of Agriculture, released in 2014. Cultivars 'Nevena' ('Köröser Weichsel' × 'Heimanns Konservenweichsel'), 'Iskra' ('Köröser Weichsel' × 'Heimanns Rubin') and 'Sofija' ('Čačanski rubin' × 'Heimanns Konservenweichsel') were released in 2015 from the sour cherry breeding program in the Fruit Research Institute, Čačak. 'Ivo 45' (clone of 'Oblačinska') released by Superior doo, and 'Leda' (spontaneous seedling) developed in the Institute PKB Agroekonomik were released in 2018. The main objective of sour cherry breeding program was to obtain new genotypes which would be well adapted to agro-ecological conditions of the Republic of Serbia., and which would produce typical dessert fruit or fruit for use by the food processing and frozen-food industries.

The aim of this study was to provide most important information on the new sour cherry cultivar 'Leda' developed in the Institute PKB Agroekonomik and to compare it with the control cultivar

'Oblačinska', with respect to tree characteristics, productivity, fruit characteristics and quality attributes, so as disease tolerance.

Materials and methods

Study of a new sour cherry cultivar 'Leda' was done at the Ljubić facility of the Fruit Research Institute, Čačak (43°53'N, 20°20'E, 220 m a.s.l.) near Čačak city in Serbia. The control cultivar for comparison was 'Oblačinska'. The experimental plot was planted in 2012. The rootstock was *Prunus avium* L. seedling and the tree spacing was 5×3 m. The experimental design was the randomized block with five trees. Study was carried out over a period of two years (2015 and 2017). The evaluations presented in this paper were carried out according to UPOV (2006). The flowering time of each individual tree was recorded visually, considered as the day when approximately 10-20% of the flowers were open (beginning), and when more than 90% of petals were dropped (end). Ripening time was recorded from date when more than 20% of fruits were for fresh consumption. Yield was determined by weighting all the fruits in the tree and was expressed in kg per tree. Fruit characteristics were measured on fruits harvested in full maturity stage. Fruit length, width and thickness were measured by caliper, while fruit stalk length was measured by a ruler. Fruit and stone weight were measured by scale. Mesocarp ratio was determined as a ratio between flesh weight and fruit weight. Soluble solids content was analyzed by using a digital refractometer Pocket PAL-1 (Atago, Japan). Titratable acidity was measured by neutralization to pH 7.0 with 0.1 N NaOH and expressed as percent of malic acid equivalent. Total and invert sugars contents were determined according to Luff-Schoorl method (Egan et al., 1981). Resistance of several tree organs to low temperatures and to economically important diseases and pests, such as *Monilinia laxa*, *Monilinia fructigena*, *Blumeriella jaapii* and *Rhagoletis cerasi* was done through field observation. For all traits mentioned a nine-score scale (from 1, representing very resistant, up to 9, representing very susceptible) was used.

Results and discussion

Phenological characteristics

The flowering time of 'Leda' was two days after 'Oblačinska' and lasted one day longer. Fruits ripen in the first decade of June, one day before a control (Table 1).

Table 1. Comparisons of phonological and tree characteristics, as well as field resistance between 'Leda' and 'Oblačinska' (average 2015 and 2017).

	'Leda'	'Oblačinska'
Flowering (start)	Apr-10	Apr-08
Flowering (end)	Apr-18	Apr-17
Flowering (duration)	9	10
Ripening (start)	Jun-09	Jun-10
Ripening (end)	Jun-16	Jun-17
Ripening (duration)	8	8
Tree habit	Spreading	upright
Tree vigor	Low	Low
Disease and pest resistance		

Monilia laxa	Resistant	Resistant
Monilia fructigena	Tolerant	Tolerant
Blumeriella jaapii	Resistant	Resistant
Rhagolethis cerasi	Resistant	Resistant

Tree, leaf and fruit

'Leda' is characterized by spreading tree habit and weak vigor. One-year-old shoot length of internode is short. Leaf blade color on the upper side is light green. Orange yellow nectaries are present. All fruit dimensions, goes in the favor of 'Oblačinska' which showed higher values. Contrary, the average fruit weight of 'Leda' was 3.8 g and it was slightly higher than in the control cultivar (Table 2, Figure 1). The data concerning fruit weight is somewhat lower than those reported by Fotirić-Akšić et al. (2016) and Radičević et al. (2010, 2018) for newly sour cherry cultivars originated from Serbia. According to the UPOV descriptor for sour cherry (2006) 'Leda' has a circular fruit. Fruit stalk length differs between 'Leda' and 'Oblačinska'. 'Leda' had a shorter fruit stalk of 4.53 cm, while in the control cultivar it was 3.63 cm. Altogether they are in the range reported by Perez-Sanchez et al. (2008). The stone was medium sized, with a share of ~7% in the fruit weight. Yield of cultivar 'Leda' was a 600 g higher than for the 'Oblačinska.

Table 2. Comparisons of fruit characteristics and yield between 'Leda' and 'Oblačinska' (average 2015 and 2017).

	'Leda'	'Oblačinska'
Fruit weight (g)	3.8	3.3
Fruit length (mm)	14.4	14.9
Fruit width (mm)	15.4	16.6
Fruit thickness (mm)	13.8	14.9
Stone weight (g)	0.28	0.33
Mesocarp ratio (%)	92.9	89.7
Stalk length (cm)	2.9	3.4
Fruit cracking (%)	Resistant	Resistant
Tree habit	Spreading	Upright
Tree vigor	Low	Low
Skin colour	Light red	Dark red
Juice colour	Colorless	Dark red
Yield (kg/tree)	3.03	2.43

Figure 1. Fruits of 'Leda' (left) and 'Oblačinska' (right).

Disease and Pest Reaction

Field examination (Table 1) showed that both 'Leda' and control cultivar exhibited high resistance of economically important fungal diseases and pest (*Monilinia laxa, Monilinia fructigena*, *Blumeriella jaapii* and *Rhagolethis cerasi*).

Fruit quality

Fruits of 'Leda' are characterized with a relatively high content of soluble solids, 16.95% in average (Table 3), which was higher than in 'Oblačinska' (15.55%). Also, 'Leda' showed slightly higher acid content (1.71%) compared to the control. Differences were also determined between soluble solids/total acids ratio, where 'Leda' (10.40) showed higher value than the control cultivar (9.49). The data on the chemical composition of fruits goes in the favor of 'Leda'. These results are lower than those reported in the literature (Fotirić-Akšić et al. 2016; Radičević et al., 2018) probably due to environmental factors.

Table 3. Comparisons of fruit quality between 'Leda' and 'Oblačinska' (average 2015 and 2017).

	'Leda'	'Oblačinska'
Soluble solids	16.95	15.55
Total acids	1.71	1.69
Soluble solids/Total acids	10.40	9.49
Total sugars	10.45	9.92
Inverted sugars	9.80	9.00
Sucrose	0.62	0.87

Conclusions

New Serbian sour cherry cultivar 'Leda', developed at the Institute PKB Agroekonomik, has attractive bright red coloured fruits with rich, mild flavour, sweet-acidic and harmonic taste, high productivity and resistance to economically important fungal diseases and pests. It surpasses the 'Oblačinska' cultivar in most traits studied. This cultivar could be used both for fresh consumption and processing. Given the consumer demand for antioxidant-rich products, the development of new tart cherry selections with desirable quality characteristics is critical for the sustainability of cherry producers and processors.

Abstract

Red clover (*Trifolium pratense* L.) is one of the most important and widespread leguminous forage species in temperate agriculture, which is characterized by a high yield of quality biomass. Actinomycetes produce antibiotics and vitamins that act favourably on physiological processes in plants. These microorganisms are present in the soil, however the application of selected microorganisms for seed inoculation leads to better results in crop production. The experiment was carried out in vegetation pots in semi-controlled conditions. This research consisted of investigating the effect of actinomycetes (*Streptomyces* sp.) application on the green mass per plants of 12 cultivars of red clover of different geographical origin: K-27, K-32, K-38, K-39, Una, Kolubara, Viglana, Manuela, Wilo, Repio, Diana and Longevo. The effect of inoculation was determined out at the onset of flowering. The results obtained showed that the application of microorganisms could affect plant mass yield. The highest value for green mass per plant was achieved in cv. K-39 using inoculum that contained *Streptomyces* sp. The application of actinomycetes had a positive effect in the most cultivars of red clover and there was a statistically significant difference between inoculated treatments and control, indicating the justification of the use of these microorganisms in plant production.

Keywords: *Red clover, Cultivar, Actinomycetes. Green mass.*

Introduction

Red clover (*Trifolium pratense* L.) is grown in Serbia in monoculture on 120.000 ha and it can successfully substitute alfalfa on soils of increased acidity in lowland and hilly regions. It is a very important perennial forage legume that is grown in various forms in agroecological conditions from subtropical to subpolar regions (Lugić *et al*., 2006). Its economical significance is based on high potential for production of biomass with high content of crude protein in biomass (Tomić *et al*., 2007) and red clover has quality and nutritive hay (Acikgoz, 2001). The chemical composition and quality of red clover forage depends on the stage of development, i.e. age of plants (Marković *et al*., 2011). It tolerates lower pH, less fertility and poorer drainage than alfalfa (Vasiljević *et al.*, 2005) and domestic populations are characterized by good resistance to drought and cold (Lakić and Vojin, 2010). Thank to developed root and intensive biological nitrogen fixation and favourable effect on soil, it is very important in crop rotation (Lugić *et al*., 2010).

Great importance of red clover is in the fact that it lives in symbiosis with *Rhizobium leguminosarium* bv. *trifoli* and it is beneficial to the agro-ecosystem two-fold; first through nodule transfer, and second through biomass decomposition (Wyngaarden *et al*., 2015). Next to rhizobia in the rhizosphere of red clover live numerous microorganisms. such as actinomycetes

(Andjelković *et al.,* 2014). Approximately 60 % of biologically active compounds used in agriculture are derived from the genus *Streptomyces* (Ilic *et al*. 2007). These genera have shown over time great potential in improving the future of agriculture (Olanrewaju and Babalola, 2019). Actinomycetes produce different type of growth factors like auxin and gibberellin substances, antibiotics and vitamins, which act favorably on the physiological processes of plants (Berg *et a*l., 2001; Kumar *et al.* 2010). Also, actinomycetes are known for their production of wide variety of enzymes which are important in order to degrade the cellulose, pectin and chitin and other substances in order to maintain the structure of soil (Priyadharsini and Dhanasekaran, 2015). These microorganisms are present, in higher or lesser abundance in the soil, buit the application of selected microorganisms for seed inoculation leads to can aid in increasing the potential of growth promotion in sustainable agriculture (Mitra *et al.,* 2019).
The aim of this study was to examine the influence of actinomycetes (*Streptomyces* sp.) on the green mass per plants of different cultivars of red clover.

Materials and methods

The experiment was set up in the semi-controlled conditions, in a greenhouse. For the purposes of research twelve commercial red clover cultivars were used: K-27, K-32, K-38, K-39 (Institute for forage crops, Kruševac, Serbia), Una and Kolubara (Institute of Field and Vegetable Crops, Novi Sad, Serbia), Viglana, Manuela (Research Institute of Plant Production in Piestany, Slovakia,) Wilo, Repio and Diana (US Dairy Forage Research Dairy Farm, Wisconsin, USA) and Longevo (Istituto Sperimentale per le Colture Foraggere, Lodi, Italy).
The inoculation was done using *Streptomyces* sp. (actinomycetes) concentration $7.8x10^{10}$ cells per ml were grown on the substrate by Krasiljnikov (Jarak and Djurić, 2006).
Red clover seed was sterilized with 0.2% solution of $HgCl_2$ and 70% ethanol, rinsed several times with sterile tap water and then immersed in the inoculum. After that, ten seeds of each cultivar from inoculum were planted in the 8 dm^3 volume vegetation pots filled with about 10 kg soil (five seeds per pot). Five milliliter of the inoculum was added to each pot. The experiment was conducted in ten repetitions, 10 plants per cultivar with inoculum. Also, ten plants per cultivar were without inoculation – control. Green mass per plant (g) was measured at the beginning of flowering.
The results were processed using the statistical package STATISTICA 8.0. The significance of the difference between the investigated treatments was determined by analysis of variance and LSD tests.

Results and Discussion

The results obtained showed that the application of actinomycetes thereof can affect on green mass per plant red clover. Thanks to use of inoculation with effective strains of microorganisms can intensify certain microbiological processes which can increase available nutrients for plants. The highest value for green mass per plant – 19.80 g was achieved in cv. K-39 using inoculum that contained *Streptomyces* sp, while the lowest value is recorded in cv. Longevo – 12.20 g (Tab.1).
The application of actinomycetes had a positive effect in the most cultivars of red clover and there was a statistically significant difference between inoculated treatments and control. Actinomycetes help the plant in the utilization of nutrient available in the soil for their growth, differentiation and used as a biocontrol agent against different pathogen (Persello-Cartieaux *et*

al., 2003). By usinginoculum of these microorganisms, Jarak *et al*. (2007) reported better germination and height and weight of red clover than recorded on the control variant. Application of the inoculation also gave positive effects on the length of red clover plants (Miličić and Jarak, 2008).
Horewer the response of plants three cultivars (K-32, Repo and Longevo) to inoculation was negative (Tab.1). Similar results were obtained by Andjelković *et al*. (2014). The authors reported that the application of individual cultures of *Streptomyces* sp. on alfalfa cv. Syntéza 1 has had a positive impact, but to cv. K-28 did not result in a statistically significant increase in green mass per plant compared to the control .The effect of inoculation depends on many factors: host plant activity, species, cultivar, strain and cell concentration of microorganisms in the inoculum (Walker *et al*. 2003; Bizos *et al.*, 2020). Each cultivar had a specific composition of root secretions, different conditions in the rhizosphere and specific interaction between microorganisms and the plant is formed (Andjelković *et al.*, 2020).

Table 1. The effect of inoculation by *Streptomyces* sp. on the green mass different cultivar red clover

Cultivar	Variant	Green mass per plant (g)
K-27	Control	13.10 ^{n}
	With inoculum	13.90 ^{l}
K-32	Control	16.70 ^{f}
	With inoculum	15.90 ^{h}
K-38	Control	17.37 ^{d}
	With inoculum	18.20 ^{b}
K-39	Control	18.30 ^{b}
	With inoculum	19.80 ^{a}
Una	Control	13.50 ^{m}
	With inoculum	13.93 ^{l}
Kolubara	Control	13.60 ^{m}
	With inoculum	14.30 ^{k}
Manuela	Control	16.30 ^{g}
	With inoculum	17.00 ^{e}
Viglana	Control	14.30 ^{k}
	With inoculum	14.80 ^{j}
Repio	Control	17.10 ^{d,e}
	With inoculum	16.30 ^{g}
Wilo	Control	17.30 ^{d}
	With inoculum	17.70 ^{c}
Diana	Control	14.30 ^{k}
	With inoculum	15.30 ^{i}
Longevo	Control	12.50 ^{o}
	With inoculum	12.20 ^{p}

Note: Mean values with the same superscript(s) are not significantly different according to Fisher's LSD test ($p<0.05$)

Conclusion

This study showed that the response of plants in the most cultivars of red clover to application of actinomycetes was positive. Only in three cultivars (K-32, Repo and Longevo) inoculation was negative effect on green mass per plant. The results suggest use of actinomycetes as effective biocontrol agent and should be considered a good way in the search for viable plant growth promoters for sustainable agriculture.

Abstract

Meadow fescue (*Festuca pratensis* Huds.) is one of the most important perennial grasses for animal feed production on grasslands. It is characterized by high and stabile yield potential and good biomass quality. The aim of this study was to determine genetic and phenotypic correlation coefficients of seven most important traits of two synthetic cultivars (Kruševački 21 and Pradel). Individual plants for hybridization, in order to obtain progeny by the method of Comstock and Robinson, were selected completely randomly. In order to examine the obtained progeny, the study was performed in an experimental field of the Institute for Forage Crops, in two replications. The experiment was set up according to the Nested Design I, with sets within the replications. In Kruševački 21, 60 full-sib progeny were studied in two sets, while in the Pradel a total of 39 full-sib progeny were studied. Within each full-sib progeny, 60 plants were analyzed. Statistically and high statistically relation was obtained between some traits and presented as genetic (r_g) and phenotypic (r_f) correlation coefficients. In cultivar K-21 very high statistically significant genetic correlation coefficients were determined between heading date and leaf length (r_g=0.873**), plant height and number of generative tillers per plant (r_g=0.893**) and dry matter yield in the first cut and annual dry matter yield (r_g=0.988**). In cultivar Pradel very high statistically significant relationship was obtained between heading date and plant height (r_g=0.978**), heading date and number of vegetative tillers per plant (r_g=0.926**) and annual dry matter yield with one side, and plant height (r_g=0.912**) and dry matter yield in the first cut (r_g=0.978**), on the other side.

Keywords: *meadow fescue, Nested Design I, genetic correlation coefficients, phenotypic correlation coefficients.*

Introduction

Meadow fescue (*Festuca pratensis* Huds.) as important perennial grass species, with high yield potential and biomass quality has great significance for animal feed production on grasslands and pastures. Meadow fescue is well adapted to continental climates where it can be an alternative to *Lolium perenne*, having in mind the fact that meadow fescue can be compared to species of the genus *Lolium* by quality and digestibility (Kölliker, 1998). Also, this species is of increasing importance in the northern regions (Casler and Santen, 2000). Meadow fescue is caenobiont of plant associations from the class *Molinio-Arrhenatheretae*, from lowlands to valleys in hilly areas (Vučković, 2004). It is mostly frequent in associations *Cynosuretum cristati*, *Festucetum pratensis* and anthropogenic association *Arrhenatheretum elatioris*. Meadow fescue is one of the most productive forage perennial grasses in extreme environmental conditions, like summer drought or winter hardiness. Also, meadow fescue is very tolerant to grazing; therefore pastures

where it dominates are long lasting. It can be grown as a pure crop, but more often in mixtures with other grasses and legumes.
Some forage grass characteristic (perennial species with anemophily mode of pollination, presence of high self-incompatibility and inbreeding depression) make breeding of this group of plants very difficult and complex. Basic condition for successful grass breeding process is the determination of genetic variability in breeding material. The existence of genetic variability in available breeding material allows success in breeding process. Variability within wild populations and cultivars of meadow fescue were documented for important agronomical traits, forage yield and forage quality traits (Babić, 2009; Babić et al., 2010; Babić et al., 2018).
The main goal in breeding program of any one forage grasses is to increase the dry matter yield, or maintain the yield through improving of other traits. The yield is very variable trait, influenced by a large number of genes, and also depends on the present agroecological conditions. Dry matter yield increase is part of all breeding schemes in perennial grasses, but small number of study consisted of improving the dry matter yield *per se* (Burton, 1982, Ceccarellii et al., 1980). Lot of breeding programs is aimed to improve different forage grasses traits which have high influence on DMY and showing high correlation coefficients with yield (Carlson, 1990; Babić et al., 2013). Determining in which way one trait affects another, makes it easier to determine criteria and predicts the course of breeding (Falconer and Mackay, 1996). In breeding process of one trait in the desired direction, the values of some other traits will change in size and direction in proportion to the size of the correlation coefficients between the given traits. The value of correlation coefficients depends on the frequency of genes in the studied collection (Falconer and Mackay, 1996), which means that the obtained correlation coefficients refer only to the studied collection in the given agroecological conditions.

Material and methods

The study was conducted in an experimental field of the Institute for Forage Crops Kruševac. Initial plant material were cultivars Kruševački 21 (K-21) from Serbia and Pradel from Switzerland. In the first phase of the research, 3000 plants per cultivar were sown in containers. At the beginning of tillering, individual plants were randomly selected and planted to obtain progeny according to the method of Comstock and Robinson (1948). The selection of full-sib families for the field experiment was carried out based on the obtained sufficient amount of seeds from hybridization (60 full-sib families were selected from the K-21 cultivar and 39 full-sib families from the Pradel cultivar). In order to examine the obtained full-sib families, the experiment was set up according to the Nested design I in two replications, with two sets within each replication. In K-21 were analyzed 60 full-sib families in total (30 full-sib families per set), while in the Pradel were studied 39 full-sib families (21 full-sib families within one set and 18 in the second set). Within each full-sib family, 60 plants were studied.
Genetic and phenotypic correlation coefficients were calculated based on the ratio of covariance and corresponding variances as follows:

$r_{g_{xy}}$ - Genetic correlation coefficient

$$r_{g_{xy}} = \frac{COV_{g_{xy}}}{\sqrt{\sigma^2_{g_x} \times \sigma^2_{g_y}}}$$

$r_{f_{xy}}$ - Phenotypic correlation coefficient

$$r_{f_{xy}} = \frac{COV_{f_{xy}}}{\sqrt{\sigma^2_{f_x} \times \sigma^2_{f_y}}}$$

Testing the significance of the correlation coefficient was performed by T-test using the ratio t=r/SEr for n-2 degrees of freedom (n is the number of analysed full-sib families).
The expected genetic gain from indirect selection (ΔGe) was also calculated as follows:

$$\Delta Ge = r_{gxy}\, k\, h_x\, h_y\, \sigma_{fx}$$

r_{gxy} - genetic correlation coefficient of trait x and trait y to which selection is performed
k - standardized selection differential (tabular value that depends on the selection pressure which in these studies was 1%)
h_x and h_y - square roots of heritability in the narrower sense of traits x and y
σ_{fx} - standard phenotypic deviation of trait x

Results and discussion

Table 1 shows the values of genetic and phenotypic correlation coefficients between the important traits for cultivar K-21 in the second productive year. In Table 2 presented values for these parameters for cultivar Pradel. Statistically significant and highly significant correlation coefficients were determined between some analyzed traits. In cultivar K-21 very high statistically significant genetic correlation coefficients were determined between heading date and leaf length (r_g=0.873**), plant height and number of generative tillers per plant (r_g=0.893**) and dry matter yield in the first cut and annual dry matter yield (r_g=0.988**).

In cultivar Pradel very high statistically significant relationship was obtained between heading date and plant height (r_g=0.978**) and heading date and number of vegetative tillers per plant (r_g=0.926**). Also, very high statistically significant genetic correlation coefficients were determined between plant height and leaf length (r_g=0.794**), dry matter yield in the first cut (r_g=0.875**) and annual dry matter yield (r_g=0.912**). Number of generative tillers per plant is highly correlated with leaf length (r_g=0.834**), number of vegetative tillers per plant (r_g=0.874**), dry matter yield in the fistr cut (r_g=0.771**) and annual dry matter yield (r_g=0.866**). Majidi et al. (2009) found strong correlations between plant height and dry matter yield (r_g=0.86**) and number of generative tillers and dry matter yield (r_g=0.58**) in half-sib families of tall fescue.

In cultivar K-21 statistically significant negative relationship was found between plant height and leaf length (r_g=-0.674*) and between heading date and number of generative tillers (r_g=-0.660*), while in Pradel negative genetic correlation coefficient was determined between leaf length and number of vegetative tillers (r_g=-0.830**). According to this results Babić et al. (2013) were found negative relationship between heading date and number of tillers per plant (r_g=-0.707).

HD - heading date, PH - plant height, LL - leaf length, NVTP - number of vegetative tillers per plant, NGTP - number of generative tillers per plant, DMY - dry matter yield per plant

In both studied cultivars, strong correlations were observed between dry matter yield in the first cut and annual dry matter yield (in K-21 r_g=0.988**; in Pradel r_g=0.978**). This is a consequence of the high share of dry matter yield in the first cut in the total annual yield, which ranged from 62.91% in K-21 to 87.34% in Pradel. A high share of yield in the first cut in the total annual yield of meadow fescue from 68.95 to 76.89% was recorded in the research of Babić et al. (2010). Also, Kanapeckas et al. (2005) and Lemežiene et al. (2004) reported that the share of dry matter yield in the first cut in the total yield of dry matter ranged from 52 to 55%.

Having in mind the previously calculated correlations between the most important agronomic traits, it is noticed that often by improving one, a negative response of the other trait is encountered. For this reason, the expected genetic gain from indirect selection was calculated, to determine what effect breeding of one trait has on other ordered traits.

Table 3. Expected genetic gain from indirect selection in K-21

Traits	HD	PH	LL	NVTP	NGTP	DMY I cut	Anual DMY
HD		0.02	2.23	0.59	-2.28	1.09	0.89

HD - heading date, PH - plant height, LL - leaf length, NVTP - number of vegetative tillers per plant, NGTP - number of generative tillers per plant, DMY - dry matter yield per plant

In K-21, achieving the expected genetic gain in plant height would lead to a decrease in the dry matter yield in the first cut and annual dry matter yield, but also the length of the leaves (Table 3). The obtained results are in accordance with the results obtained in Sokolović (2006). By breeding the meadow fescue in the direction of later maturity, the number of generative tillers per plant would be reduced. In Pradel, a positive effect was observed for most of the studied traits by improving other traits. Only the realization of the expected genetic gain at the heading date would lead to a decrease in the dry matter yield in the first cut. Also, an increase in leaf length would result in a decrease in the number of vegetative tillers per plant (Table 4).

Table 4. Expected genetic gain from indirect selection in Pradel

Conclusion

The most important trait, which requires the most attention in the process of breeding and creating new cultivars of meadow fescue for forage, as well as other perennial grasses, is dry matter yield. The results obtained in these studies suggest that indirect selection for dry matter yield is possible. In cultivar K-21, breeding on increased plant height affects obtaining genotypes with a larger number of generative tillers per plant, which leads to an increase in dry matter yield. In cultivar Pradel, breeding on increased plant height and number of generative tillers per plant, could lead to the creation of more productive genotypes. In both studied cultivars, K-21 and Pradel, a positive effect was observed for most of the studied traits by improving other traits.

RESEARCH OF HUMUS REPRESENTATION IN AGRICULTURAL LAND

Vladimir SABADOŠ*, Danijela ŽUNIĆ, Nataša PRODANOVIĆ

Agricultural Extension Service "Sombor", Serbia
*Corresponding author: agroso@mts.rs

Abstract

Humus is a stable form of organic matter in the soil, and at the same time it is most important form. Maintaining humus levels in the interval of 3-5% is the most important obligation of land users. However, the percentage of humus in soils has decreased in the last 20-30 years. Special emphasis should be placed on the harmfulness of burning crop residues on the plot for constant reduction of organic matter content and humus. As for the role of humus in the soil, its useful properties directly depend on which organic substances were the basis for it. In any case, it is a universal fertilizer suitable for different types of plants and soil. Moreover, it is permanently stored in the soil, it saturates it with useful elements. Humus and fertility - interconnected thing. In laboratory conditions, Agriculture Extension Service "Sombor" examined the humus content at two depths, of 0-30 cm and 30-60 cm, which consists of the oxidation of soil organic matter with 0.1N $KMnO_4$ solution. The average humus content in this study on agricultural land in the layer of 0-30 cm was 3.18%, while the maximum content was determined at the site near the settlement of Telečka and amounted to 5.94%. The land where this humus content was recorded belongs to the type of meadow black carbonate on a light plateau. The lowest humus content was recorded on saline near the settlement of Stanišić. At a depth of 30-60 cm, the humus content in the soil is significantly lower and averages 2.28%, which is 27.3% less than the content in the layer of 0-30 cm. The highest humus content in the layer of 30-60 cm was also in the sample from point 102 in the area of Telečka and was 5.12%. The lowest humus content at the examined depth of 30-60 cm was in the sample from point no. 46 which is located in the cadastral municipality of Kolut and amounted to 0.13%.

Keywords: humus, organic matter, oxidation, agricultural land.

Introduction

Humus is a dark, organic substance, formed by the humification of plants and animals. Humus is a high molecular weight organic compound in the soil formed as a product of partial decomposition of dead organic matter (plant and animal residues). Humus primarily has a very beneficial effect on soil structure. Heavy and compacted soils become looser and lighter by humanization, and thus other soil properties are improved, primarily water regime, airiness and heat (Živković,1972). In terms of chemical properties, humus contains all the necessary plant nutrients. Humus also has a beneficial effect on the biological properties of the soil by being a source of carbon necessary for the life and reproduction of microorganisms. Microorganisms dissolve organic matter and break it down into mineral ingredients that are used by plants for nutrition. During the decomposition of humus, CO_2 is created, which the plant needs for assimilation and which activates chemical compounds inaccessible to the plant in the soil. It follows that one should know the forms of humus and its quantity in the soil (Petrović N., Kastori, R, Rajčan, I. (1991).

Materials and Methods

In modern agriculture, all measures should be taken to promote the formation of mild humus and its increase in the soil. There are several methods for determining humus, and they are all based on the same principle - strong oxidants act on organic matter, which leads to the oxidation of carbon from humus. According to the humus content, soils are classified into the following groups. Very low humus soils contain up to 1% humus, low humus 1-3% humus, very humus 3-5% humus, very humus soils with 5-10% humus and very very humus soils containing more than 10% humus. Since there are several projects, and one biogas plant is under construction in the city of Sombor, there is a possibility of using the substrate after fermentation and biogas production, in order to use it to increase organic matter and thus the humus content in the soil. It should be emphasized that constant quality control of the produced substrate is necessary because it depends on the raw materials from which biogas is produced, and in addition to increasing the content of organic matter, it can also contain harmful substances that can negatively affect the quality of agricultural land. In this experiment, the amount of humus is determined by oxidizing the humus substance from the soil with a strong oxidant, $KMnO_4$ - the amount of humus present can be determined from the consumption of $KMnO_4$.

Laboratory procedure in PSS "Sombor": 1. Weigh 200-500 mg of air-dried soil on an analytical balance. If the soil is very humus, a smaller mass is weighed, and if it is less humus, a larger mass is weighed. 2. Transfer the soil completely to a larger Erlenmeyer flask (500 ml). Using a beaker, add 130 ml of distilled water and 20 ml of H_2SO_4 (previously diluted 1: 3 to 1 by volume of acid and 3 by volume of distilled water) to the flask. Then 50 ml of 0.1 N $KMnO_4$ solution are added with a burette. 3. Cook the contents of the zucchini by simmering for 10 minutes. A funnel should be placed on the opening of the flask to prevent a drop of the solution from splashing during cooking. Since the reduction of manganese from oxidation number +7 to number +2 is possible only in a strongly acidic solution, H_2SO_4 is added to the flask. If oxidation took place without H_2SO_4, manganese would be reduced only to the number +4. The oxygen released in this reaction oxidizes the organic matter in the humus to CO_2, which is released from the flask. The more humus in the soil, the higher the consumption of $KMnO_4$. 5.After the contents of the flask were boiled for 10 min, remove from the heat and immediately titrate the excess $KMnO_4$ using 0.1 N oxalic acid solution $H_2C_2O_4$, from the burette until decolorized. Since the decolorization reaction is slow, excess $H_2C_2O_4$ will be added to the flask, which is then re-titrated with 0.1 N $KMnO_4$ solution from the burette, until a pink color appears. This reaction is quite fast, so care must be taken when adding $KMnO_4$, as the contents of the flask will turn pink by adding just one extra drop of $KMnO_4$.

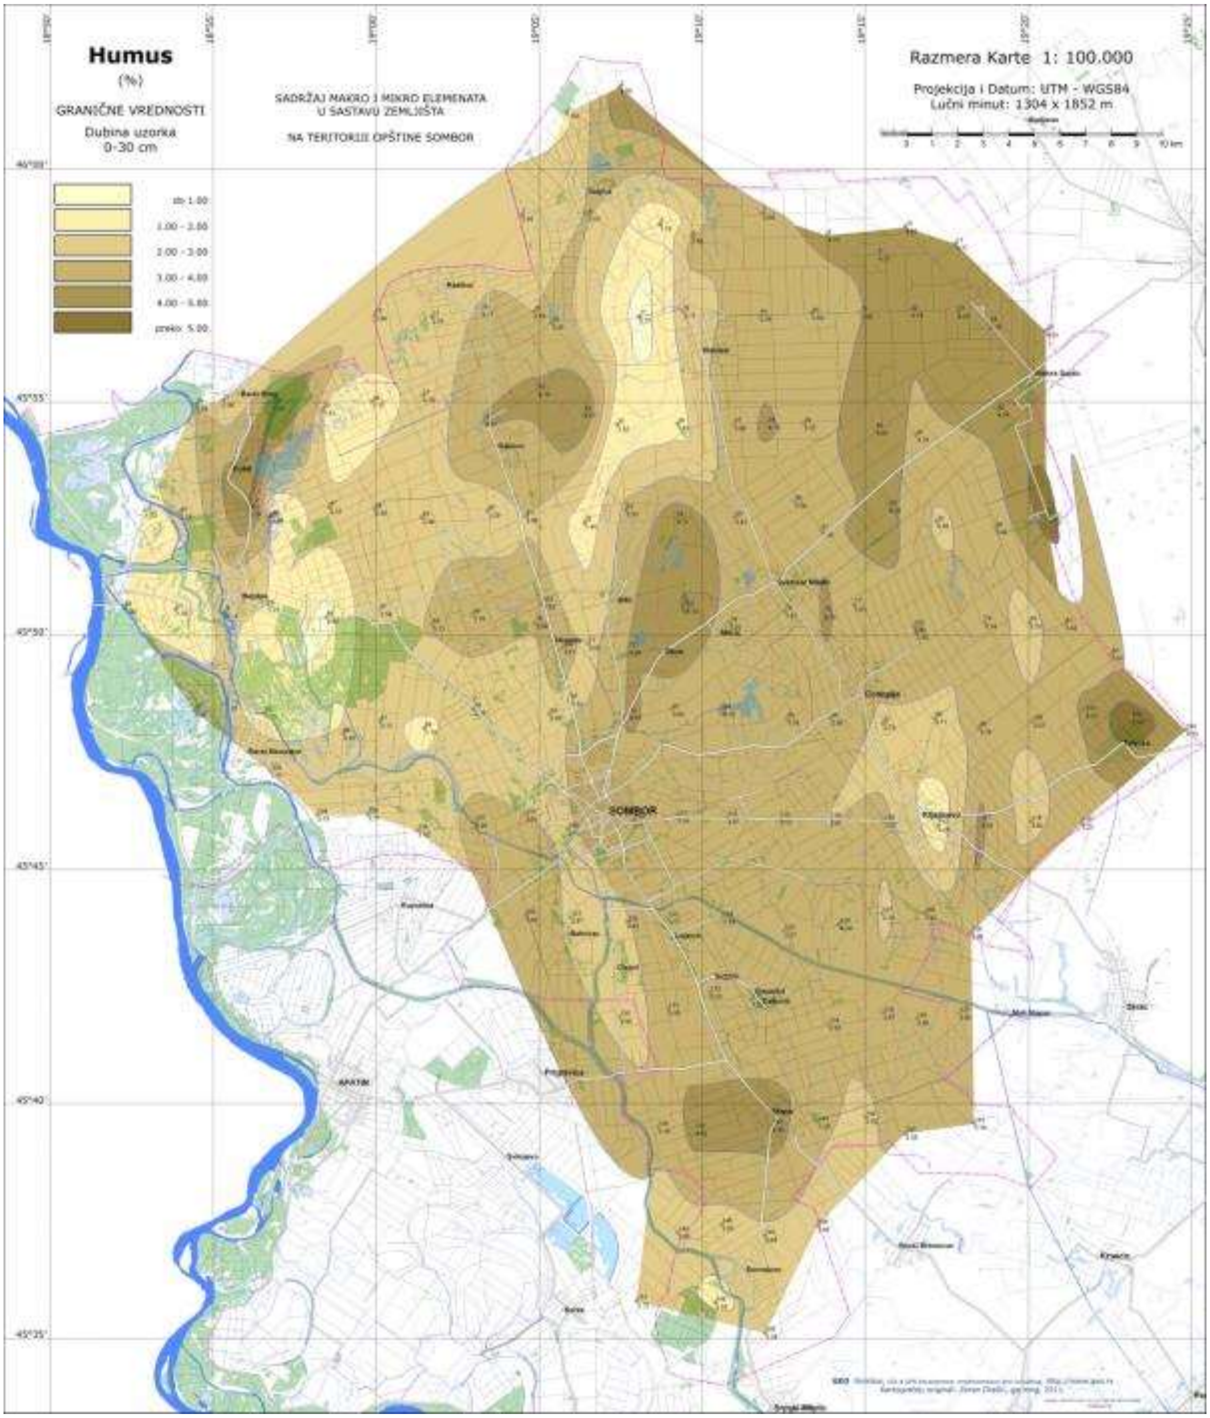
The humus content at a depth of 30-60 cm is significantly lower than the content in the soil layer of 0-30 cm. 75.52% of agricultural land in a layer of 30-60 cm has a lower humus content of 3%.

The content of humus in the soil, in addition to human influence, also depends on the type of agricultural land, and the following results can be stated: chernozem on a light plateau, part of the land in the "upper terrain" which includes cadastral municipalities Kljajićevo, Čonoplja, Svetozar Miletić, Stanišić and Riđica, has an average humus content in the layer of 0-30 cm, 3.73%, while in the layer of 30-60 cm, the humus content is 2.86%.

Photo 1.Transition from the upper to the lower terrain in the area of the inhabited place Svetozar Miletić

Results and Discussion

Meadow black carbonate on a light plateau, which includes areas on the "upper terrain" has a significant production capacity due to the content of humus and other production characteristics of the soil. In the case of meadow black soils, as well as chernozems on the loess plateau, the limiting factor of production capacities of these soils is the lack of soil moisture and low groundwater levels, and in dry years yields on the "upper terrain", ie on areas belonging to plateaus as part of the production area of the city of Sombor. The average humus content of this type is 3.03% in the soil layer of 0-30 cm, while the humus content in the soil layer of 30-60 cm is significantly lower and amounts to 2.32% according to these studies. On the type of soil (carbonate chernozem on the light terrace), which is located on the "lower ground", the humus content is average, 3.03% in the soil layer of 0-30. It is significantly lower in the soil layer of 30-60 cm and according to these studies is 2.32%. The type of agricultural land meadow black on the light terrace has an average humus content of 3.31% in the layer of 0-30 cm, and 2.50% in the layer of 30-60 cm. According to the manner of use of agricultural land, the highest average content of humus in the layer of 0-30 cm has orchards and arable land (3.30% and 3.23%), while the lowest average content of agricultural land that has been converted into landfills and it is 2 , 51%. At the second examined depth of 30-60 cm, the highest average humus content is in the lands used as gardens, and that is 2.67%. In this way of using agricultural land, the smallest difference in the average humus content is between the first and the second layer and it is 0.30%. The state-owned agricultural land of agricultural enterprises in restructuring has the highest humus content in both examined layers and it averages 3.82% in the layer of 0-30 cm, and 2.96% in the layer of 30-60 cm. It is the lowest in both examined layers with state land, which is rarely or never leased due to its weaker potential. Such lands can also be used primarily for grazing livestock, as well as for establishing artificial meadows, raising perennial orchards of fruits, vineyards, woody plants and alternative crops for the production of renewable energy sources. Such lands are also favorable for the cultivation of autochthonous plant species from the area of Sombor and Vojvodina, such as chamomile, dog rose, zova and other lesser-known species.



Map number 1: Values of humus content of agricultural land at a depth of 0-30 cm in the city of Sombor

Conclusion

Humus is not only a land, but also a community of living beings. Organic matter is the agricultural soil for many types of microbes and other microorganisms, which help the plant root absorb nutrients. The goal of every farmer is to increase the content of organic matter in the soil.This can be done by using compost, green manure, sowing annual forage crops, reduced or completely omitted cultivation, and afforestation. In an effort to meet the food needs of a growing population, more and more farmers are switching to intensive agriculture. Such a way of growing plants negatively affects the humus, intensifying the process of humus mineralization. Therefore, it is necessary to constantly add organic matter (organic fertilization) and maintain the optimal humus content in the soil by appropriate crop rotation and regulation of the soil reaction. These organic fertilizers can be livestock, chicken, horse or some other manure. Each crop has different requirements for organic fertilizer. The system instructs you, for more than 100 different crops, when to apply fertilizer and in what amount. Because humus is a product of the decomposition of organic matter, each time you add organic matter to the soil, the amount of humus will increase. It is a slow process, but if organic matter is added every year, the amount of humus will slowly increase.

Abstract

Melon is an annual, cross-pollinated species belonging to the family of *Cucurbitaceae*. Melon plants are usually monoecious: male and female flowers develop on one plant, but most commercial varieties and hybrids are andromonoecious, and on their plants develop male and hermaphrodite flowers. On melon plants, male flowers appear first, and then develop flowers with female reproductive organs. In this experiment, eight melon genotypes (parents), of which four were monoecious (Sesame, ED-3, ED-4, Pobeditel), and four andromonoecious (Chinese muskmelon, Anannas, Honey dew, A2-3lb), and their 20 hybrids (monoecious) were used. The experiment was conducted in Smederevska Palanka, during two vegetative seasons. Seven characteristics related to sex expression were observed. The aim was to determine the parents with the best general combining abilities (GCA) and to determine the heterosis in their hybrids for all seven observed traits. Negative heterosis for the trait period from sowing to the emergence of the first perfect/pistillate flower was recorded in 16 of 20 genotypes. A reduction of the period between the appearance of male (positive heterosis) and perfect/pistillate flowers on plants (negative heterosis) was found in 12 hybrid combinations. It was found that in as many as 17 hybrid combinations, the fruits ripen earlier than their parents. All eight observed parental genotypes showed significant GCA values for most of the observed traits. The results showed that the Sesame was the best general combiner, and represented a potential source of the desired alleles required for the melon breeding programs.

Keywords: *Cucumis melo L., monoecious, andromonoecious, hybrid, flowering.*

Introduction

Melon is an economically important, annual, cross-pollinated species belonging to the family of *Cucurbitaceae*. Melon (*Cucumis melo* L.) is the most diverse species of the genus *Cucumis*, and besides of a rich diversity of shapes and sizes of fruits, there is great variability in the morphology of the flower (Zhang et al., 2014).
Sexual reproduction is considered a turning point in the evolution of plant species (Rodriguez-Granados et al., 2016). Flower plays a major role in ensuring the continuation of the species in flowering plants. The flower, as a most important reproductive organ of the plant, is the least susceptible to changes under the influence of the external environment. The classification of flowering plants used today is, for this reason, based on parts of flowers or reproductive organs (Barret, 2010).
In order to increase the intensity of crossbreeding, plants have developed a number of different mechanisms to encourage sex determination, a process in which flowers become male or female.

In the majority of angiosperm species hermaphrodite flowers are formed on the plants, in which the male and female reproductive organs are formed within the same flower. Approximately 10% of angiosperm species develop unisexual flowers, flowers with only male or only female reproductive organs (Ming et al., 2011). Melon is especially interesting because of the biology of its flower. Three types of flowers can develop on melon plants: male - staminate, female - pistillate and hermaphrodite - perfect (Pitrat, 2008). Melon wild relatives are monoecious - male and female flowers are formed on the same plant, while about 70% of all commercial melon varieties and hybrids are andromonoecious - male and hermaphrodite flowers occurred on the same plant (Abdelmohsin and Pitrat, 2008). On melon plants, male flowers develop first, on the main stem, and on the first three nodes of side branches are formed flowers with female reproductive organs (Rodriguez-Granados et al., 2016).

Before choosing parental lines, it is very important to determine GCA and heterosis in the pre-breeding programs for all observed traits in all lines that are planned to be included in further hybridization (Olfati et al., 2012). General combining abilities for the observed characteristic are an important biometric parameter in determining the contribution of one parent to the positive or negative heterosis of his progeny (Fareghi et al., 2018). Heterosis is an agricultural phenomenon where, for some observed traits, hybrid genotypes demonstrated the phenotypic superiority compared to their parents (Yilmaz and Sari, 2012).

Many researches have studied and reported heterosis in melon for earliness (Abou Kamer et al., 2015; Choudhary et al., 2018), fruit yield (Abou Kamer et al., 2015; Selim, 2019), number of fruit per plant (Abou Kamer et al., 2015). Also, the combining ability for all this important traits in melon breeding programs was often determined by many researchers and breeders (Shashikumar et al., 2016). The aim of this study was to single out parental genotypes with the best general combining abilities, and to determine the heterosis of 20 hybrids for all seven observed traits.

Materials and methods

Four monoecious (Sesame, ED-3, ED-4, Pobeditel) and four andromonoecious (Chinese muskmelon, Anannas, Honey dew, A2-3lb) melon genotypes and their 20 hybrids were used as material in this study. Experiment was set up in Smederevska Palanka in Serbia (latitude 44°21'22.46"N, longitude 20°57'08.97"E, elevation 101 m), during two growing seasons (2011 and 2012). Melon plants were grown in clay pots (diameter 10 cm), and at the stage of 5-7 leaves they were transplanted to an open field. The trial was organized in three replications using complete randomized block design of 28 plots in one block (one plot for each genotype). Each plot consisted of 10 plants with a 150 cm distance between rows, and a 100 cm distance between plants. The soil type at this location is vertisol. Seven characteristics of sex expression in melon were monitored, measured and analyzed: total number of flowers per plant, number of pistillate/perfect flowers per plant, number of staminate flowers per plant, number of fruits per plant, period from sowing to the appearance of the first perfect/pistillate flower (in days), period from sowing to the appearance of the first staminate flower (in days), and period from sowing to full fruit ripening (in days). The aim of this study was to single out parental genotypes with the best general combining abilities, and to determine the heterosis of 20 hybrids for all seven observed traits.

Determination of general combination abilities was performed by the M x N hybridization method (Table 1).

3	F_{35}	F_{36}	F_{37}	F_{38}	Σ
4	F_{45}	F_{46}	F_{47}	F_{48}	Σ
$\mathbf{T_M}$	Σ	Σ	Σ	Σ	Σ

General average: $\boldsymbol{G_M = \frac{\sum T_M}{NxM}}$

For parents 1, 2, 3, 4: $\boldsymbol{GCA = \left(\frac{T_N}{M}\right) - G_M}$

For parents 5, 6, 7, 8: $\boldsymbol{GCA = \left(\frac{T_M}{N}\right) - G_M}$

To determinate heterosis in broader sense, the following formula was used:

$$\boldsymbol{H = F_1 - \left(\frac{(P_1 - P_2)}{2}\right)}$$

where F_1 is a mean value of F_1 generation, and P_1 a mean value of first parent, and P_2 a mean value of second parent. All the obtained results were statistically analyzed, using the Fisher's Least Significant Difference (LSD) test (Fisher, 1935).

Results and discussion

Based on the results for all 7 observed traits variety Sesame was single out as the best general combiner (Table 2).

Table 2. General combining ability for seven sex expression traits in melon

Genotype	Parent	A	B	C	D	E	F	G
Sesame	Mother	8.64	0.67	-0.67	-5.52	-1.91	-5.24	0.43

$lsd_{0.01}$		0.62	0.14	0.14	0.74	0.73	4.11	0.21

A – Total number of flowers per plant, **B** - number of pistillate/perfect flowers per plant, **C** - number of staminate flowers per plant, **D** - period from sowing to the appearance of the first perfect/pistillate flower (in days), **E** - period from sowing to the appearance of the first staminate flower (in days), **F** - period from sowing to full fruit ripening (in days), **G** - number of fruits per plant

For five of seven traits genotype ED-4 was singled out as the worst combiner with all negative GCA values. Beside Sesame, A2-3lb was excellent general combiner for trait number of pistillate/perfect flowers per plant, with a high significant value of GCA. Earliness is one of the important traits in melon breeding programs (Glala et al., 2010). Melon growers prefer high-yielding hybrids that will be placed on the market at a time when supply of market is still low and price is high (Duradundi et al., 2018). In order to produce early melon hybrids, it is necessary that pistillate or perfect flowers on mother plants and male flowers on father plants occurred as early as possible. As the best general combinators for this trait were single out the monoecious genotype Sesame and the andromonoecious genotype Anannas, and it may be recommended to cross these varieties in order to produce an early-growing hybrid. It was concluded that the best general combiner for breeding late-maturing hybrids is the variety Honey dew. For the trait number of fruits per plant, based on the results of GCA, best general combiner was Sesame, while genotypes ED-3 and ED-4 were single out as bad general combiner for this trait (Table 2). The estimates and direction of GCA for earliness, number of flowers with female reproductive organs, number of fruits per plant are similar with those obtained by Duradundi et al. (2018), and Shajari et al. (2021).

Table 3. Heterosis for seven sex expression traits in melon

1 – Sesame, **2 –** ED-3, **3 –** ED-4, **4 –** Pobeditel, **5 –** Chinese muskmelon, **6 –** Anannas, **7 –** Honey dew, **8 –** A2-3lb
A – Total number of flowers per plant, **B** - number of pistillate/perfect flowers per plant, **C** - number of staminate flowers per plant, **D** - period from sowing to the appearance of the first perfect/pistillate flower (in days), **E** - period from sowing to the appearance of the first staminate flower (in days), **F** - period from sowing to full fruit ripening (in days), **G** - number of fruits per plant

On melon plants, male flowers are formed first, and then flowers with female reproductive organs. The more uniform time of their formation on the plant, the greater the possibility that fertilization and fruit formation will occur. Negative value of heterosis for the trait period from sowing to the appearance of the first perfect/pistillate flower represents decreasing of this period of F_1 generation compared to their parents, and was observed in 16 hybrids. Negative values of heterosis for the trait period from sowing to the appearance of the first perfect/pistillate flower and positive values of heterosis for the trait period from sowing to the appearance of the first staminate flower were recorded in 12 genotypes (Table 3). In these genotypes, an earlier appearance of flower with female reproductive organs and a later appearance of male flowers was occurred, compared to their parents, that is, a shortening of the period between the first male and the first pistillate/perfect flower on the plant. These results are similar with those obtained by (Yilmaz and Sari, 2012; Choudhary et al., 2018). Earliness is complex but important trait in melons. This trait is correlated with number of days to first female and first male flower, number of nodes to first female flower, days to first harvest, and negative values of heterosis for these traits are desirable (Duradundi et al., 2018). Seventeen of the twenty hybrids had a negative heterosis value for trait period from sowing to full fruit ripening (Table 3). The hybrid combinations Sesame x ED-3, ED-4 x Fiat, and ED-4 x A2-3lb were the only ones whose fruits matured later as compared to their parents. Regarding the trait number of pistillate/perfect flowers per plant, positive heterosis was recorded in 14 of 20 melon genotypes (Table 3). For this trait, the highest positive value of heterosis was observed in the combination ED-3 x Anannas, and the highest negative value of heterosis was observed in the ED-4 x Chinese muskmelon combination. On the plants of ED-4 x Chinese muskmelon were detected the largest decrease in the formation of flowers with female reproductive organs, and the highest increase in the formation of male flowers, compared to the parents.

Conclusion

Some of the primary objectives in melon breeding programs include earliness, high female reproductive organs flower to male flower ratio, high number of fruits per plant, high fruit yield per plant, etc. Hybrids often demonstrate superiority of some economically important traits compared to their parents (heterosis). All eight observed parental genotypes showed significant GCA values for most of the observed traits. From 8 studied genotypes monoecious variety Sesame, used in experiment as mother line, was single out with best combining abilities for all 7 observed traits. This genotype represented a potential source of the desired alleles required for the melon breeding programs. Combination of monoecious variety Sesame (mother) and andromonoecious variety Anannas (father) may be recommended for future production of an early-growing hybrid. A reduction of the period between the appearance of male (positive heterosis) and perfect/pistillate flowers on plants (negative heterosis) was found in 12 hybrid combinations. These results are of great importance for organization of further steps in melon breeding programs in our country.

Acknowledgement

Research was conducted with the support of the Ministry of education, science and technological development of the Republic of Serbia (Grant number: 451-03-9/2020-14/200216).

Abstract

The examination of the effects of sustainable growing systems on the grain yield of winter wheat was conducted at the research and study field "Radmilovac" of Faculty of Agriculture (44°45' N, 20°35' E Serbia, 130 m above mean see level). Investigations was conducted in 2016/17 and 2017/18 on the luvic chernozem soil type, in completely randomized blocks. In intergrated growing system (IGS), based on low inputs, tillage was performed using a chisel plough at 25 cm with ≥30% of maize crop residues retaining on the soil surface and the pre-sowing tillage using a disc harrow and a harrow, basic fertilization in autumn with 600 kg ha^{-1} NPK and top dressing in spring with 60, 120 kg ha^{-1} N and control treatment, without top dressing. Two common winter wheat cultivars (*Triticum aestivum* ssp. *vulgare*) Ilina and Zvezdana grew in this growing system. Statistical analysis confirmed that year, variety and top dressing had a significantly greater impact on grain yield and year and top dressing on weight of 1000 grains. Interaction of year*cultivar and year*top dressing had a significant effect on investigation parameters. More favorable meteorological conditions in the first year led to obtaining statistically significantly higher grain yields (5885.56:5585.56 kg ha^{-1}). A higher yield per unit area was found in the Ilina variety (6012.22 kg ha^{-1}) compared to the Zvezdana variety (5458.89 kg ha^{-1}). With increasing N dose in top dressing, the weight of 1000 grains and the grain yield of winter wheat increased in both tested varieties (5437.5; 5704.17; 6065.00 kg ha^{-1}). An integrated cultivation system on heavier soils has less positive effects than on soils with more favorable characteristics, especially in the higher dose of N.

Key words: *integrated management, winter wheat, grain yield, top dressing.*

Introduction

Wheat (*Triticum aestivum* L.) is one of the most significant cultivated species and the staple food for more than 50% of the global population (Rizwan et al., 2016) and special attention must be paid to the farming system of this species. Integrated farming system is sustainability and it combine the best practices from organic and conventional systems have potential to reduce negative environmental impacts while maintaining yield levels. Special attention in this growing system is paid to soil tillage, selection of genotypes, fertilization and application of chemical protection means. The main trend in tillage for winter wheat growing the past 3-4 decades has been the introduction and increased use of pot-powered harrows for secondary tillage. A comprehensive survey of soil characteristics in many countries winter wheat fields showed that the use of rotary harrows significantly affects soil structure. At present, new technologies for the

cultivation of grain crops based on the use of minimum tillage are becoming more widespread (Korchagin and Chudanov, 2002).
With different reductions in soil tillage in our country, there are numerous results that are related, mainly, to better soils such as chernozem, but also to something more difficult such as eutric cambisol. According to some results, with the application of herbicides and special planters on chernozem, intensive production of wheat without plowing and pre-sowing preparation is possible (Konstantinović, 1997), while on heavier soils the advantage is mainly related to soil moisture preservation and soil protection from erosion. Compared to the conventional one, the conservation system of tillage achieved lower grain yields of winter wheat (25–35%), spring barley (5.72–51.85%), maize (24.90–24.62%) and soybeans (34.95–39.41%) as stated by Kovačević et al. (2020). Conservation technologies are more rational, however, since they give lower biomass yields than the conventional system, there is a need to examine their economic efficiency from the energy and soil protection point from degradation. Insisted conservation tillage systems are far more rational, but since they have resulted in slightly lower yields, there is a need to test their economic efficiency based on the ratio of additional energy input and the degree of soil conservation in each individual case. The introduction of a system of conservation tillage in the future must be in line with changes, both in crop rotation and in plant breeding (Momirović et al., 2021).
In addition to soil tillage systems, the optimal application of fertilizers is an important factor for obtaining high yield and high quality products. Tillage system and level of nitrogen fertilization in top dressing, as well as interaction between these two factors have important influence on grain yield of winter wheat (Dolijanović et al., 2019). Among the elements of mineral nutrition, nitrogen has the most important role in forming the yield (Litke et al., 2018), quality and utilizable value of the wheat grain (Blandino et al., 2016).
The objective of this study was to evaluate an effect of conservation tillage system and level of nitrogen top dressing on 1000 grain weight and grain yield of winter wheat in agroecological condition in Belgrade (Radmilovac research field).

Material and methods

Study site

The field experiment was conducted at the research field "Radmilovac" of Faculty of Agriculture ($44^o45'$ N, $20^o35'$ E Serbia, 130 m above mean see level). Since 1990 up to now, this experimental field has witnessed decades-long examinations of the impact of conventional, integrated and organic growing systems crop properties. The soil type is a luvic chernozem.

Experimental design

A three-factor field experiment (year, top dressing and variety) was designed as a randomised block with three replications, with the elementary plot of 6 m^2. The crop rotation was included four crops (maize → winter wheat → spring barley + red clover → red clover). In intergrated cropping system (ICS), based on low-inputs, tillage was performed using a chisel plough at 25 cm with ≥30% of maize crop residues retaining on the soil surface and the pre-sowing tillage, using a disc harrow and a harrow, basic fertilization in autumn with 600 kg ha^{-1} NPK and top dressing in spring with 0, 60 and 120 kg ha^{-1} N. Two common winter wheat cultivars 'Ilina' and 'Zvezdana' were used with 550 seeds m^{-2}. Cv. 'Ilina' is an excellent winter hardiness cultivar of medium-late maturity, which belongs to the B1 quality group. Cv. 'Zvezdana' is a very good winter hardiness cultivar of medium early maturity, which belongs belongs to the A1 - A2 quality group. Both varieties are very resistant to *Erysiphe graminis* DC. and well-resistant to

Puccinia striiformisf. sp. *tritici* (Pst). All used varieties are winter resistant and morphologically very similar, produced in the same seed company (Institute of Field and Vegetable Crops, Novi Sad, Serbia).

Sowing was conducted on October 22th and 25th, 2016 and 2017 and harvest was done on July 03rd, and June 28th. For weed control in the studied cropping systems used the preparation Maton (2,4D) for treating from the middle of tillering to the beginning of jointing (stages 25-30 of the BBCH scale) in the amount of 0.5 l ha^{-1}.

Statistical analysis

Sampling of wheat grains was performed in June, at the stage of full maturity and measuring 1000 grain weight and grain yield. The data were statistically processed using statistical package, IBM SPSS Statistics Version 25 (ANOVA). The level of significance was set at $P < 0.05$.

Results and discussion

The long-term mean precipitation in this area is on average 531.2 mm and the mean annual temperature is 10.3°C. However, in the research years (2016/17 and 2017/18), significant differences in meteorological conditions could be noticed, particularly regarding precipitation (Table 1). The annual precipitation in the first year was lower than the long-term average, with the extreme values in December (as low as 2.6 mm). Smaller amounts of precipitation were recorded in January, February, March and June compared to long-term averages. In this year, the average air temperature was also lower than the long-term average by 0.5°C. Higher temperature deviations from the long-term average were registered in October, November, December, January, February and May. On the other hand, significantly higher temperatures than the long-term average were recorded in June (+ 2.4°C). In the second year, precipitation was on level long-term average with more favourable precipitation schedule by months. The average months and annual temperatures were very higher than first year investigation (Table 1). In general, in terms of meteorological conditions, the second year of investigation was less favourable, primarily due to higher precipitation in June and higher air temperatures during April and May, which affected the 1000 grain weight and grain yield, especially in the Zvezdana variety.

Table 1. Mean monthly air temperatures and precipitation sums from October to June in Belgrade

Months	Temperature (°C)			Precipitation (mm)		
	2016/17	2017/18	1991-2016	2016/17	2017/18	1991-2016
October	11.1	13.9	13.3	76.8	65.9	56.2
November	7.7	8.4	8.4	71.8	41.2	46.6
December	0.9	5.1	3.1	2.6	45.2	53.9
January	-3.3	5.3	2.3	23.4	39.3	52.8
February	5.4	2.3	3.8	23.5	58.1	48.6
March	11.5	6.9	8.2	27	64.8	54.1
April	12.7	18.2	13.8	51.8	39.7	48.2
May	18.4	21.5	18.1	86.1	56.2	84.0

Average/Sum	9.9	11.5	10.3	416	532	531.2

The results of the study of the influence of the observed factors on the weight of 1000 grains and the grain yield of winter wheat are shown in Table 2. The weight of 1000 grains was statistically significantly influenced by the year of investigating and the level of top dressing (individual factors), and interaction of all investigation factors. The grain yield of the examined winter wheat cultivars changed statistically significantly under the influence of all examined individual factors, as well as under the influence of the year * variety interaction (Table 2).

When we look at the obtained yield of winter wheat by years, it can be seen that the lower yields were obtained in 2017/18, which was with more unfavorable meteorological conditions. By growing the Zvezdana variety, lower grain yields and a weight of 1000 grains were achieved in relation to the Ilina variety. The absolute highest grain yields in both cultivars were recorded in conservation cultivation technology with protective treatment and intensive top-dressing of 120 kg ha^{-1} nitrogen (6597 and 6080 kg ha^{-1}). When it comes to the interaction between the year and top-dressing, it is interesting that with the increased amount of nitrogen in top-dressing, the negative effects of weaker meteorological conditions can be eliminated.

The results show that top-dressing in the first and second year of investigating, with the amount of 60 kg ha^{-1} nitrogen in the cultivar Ilina increased the yield by 6.5 and 4.6%, and with 120 kg ha^{-1} by 11.5 and 11.3% compared to the control. The increases in the variety Zvezdana were smaller, ie they were 1.7 and 6.7% for the dose of 60, respectively 9.0 and 14.5% for the second dose of nitrogen compared to the control. The relatively smaller increase in yield observed by the years of testing is the result of the weak effect of nitrogen in the first year of testing, primarily caused by bad meteorological conditions. However, the small difference between the two fertilization levels examined suggests that the Ilina and Zvezdana cultivars we used in these studies were cultivars with relatively lower nitrogen requirements. This fact recommends them as suitable for rational cultivation technologies based on reduced investments. It should be noted that increased nitrogen doses in top dressing are most justified in intensive winter wheat gay systems, especially in the case of intensive varieties (high input) (Kovačević et al., 2009).

Table 2. Yield and 1000-grain weight of the studied wheat cultivars in integrated cropping systems

Top dressing (kg ha^{-1} N) (C)	Variety (B)/ Year (A)	1000-grain weight (g) 2016/17	1000-grain weight (g) 2017/18	Yield kg ha^{-1} 2016/17	Yield kg ha^{-1} 2017/18

Conclusions

Based on the results of examining the impact of important agro-technical measures as elements of growing technology based on the basic postulates of sustainable agriculture on the weight of 1000 grains and the grain yield of winter wheat, it can be concluded:
The examined parameters had higher values in the first, meteorologically more favorable, year of investigating. Top dressing with a higher dose of nitrogen was more efficient than the rational dose in both years. The choice of variety is extremely important for rational (low-input) technology of growing winter wheat. The chosen degree of reduction in soil tillage, mineral nutrition and protection corresponded to the selected varieties, which showed increased adaptability to reduced tillage conditions, achieving optimal grain yields and a more modest mineral diet.

Abstract

Research was performed in vineyard of "Radovanović" winery, Serbia. Experimental vineyard is located at altitude of 220 meters, GPS coordinates N 44º 25' 47"and E 21º 02' 14". Row spacing is 2.4 m and 0.9 m between vines in row. The inter-row space was sown with a following grass-legume mixture: 60% *Festuca rubra,* 30% *Lolium perenne* and 10% *Trifolium repens*. Experiment with grass-legume mixture was set with two factors, fertilization with two nitrogen fertilizers (AN and KAN) and rates of 0, 50 and 100 kg N ha^{-1}. The yield of fresh and dry biomass and visual assessment of grass quality under influence of nitrogen fertilization were monitored. For soil fertility analysis samples were collected from 3 depths: 0-30, 30-60 and 80-100 cm. The most important grapes and berries structural indicators, sugar and total acids content in must were determined. The aim of the research is to determine influence of grass inter-row cover maintained according to criteria of optimal turf management, on structural indicators and quality of grapes. Results show that soil pH generally increases with depth, concentrations of organic C, total N and available P_2O_5 and K_2O decrease with depth. Grass groundcover and fertilization have a clear influence on examined soil fertility parameters. Sugar content in must varied from 17.6–25.2%. Large variations were found for bunch weight (103-259 g), epicarp weight from 100 berries (2.23-9.62 g) and average seeds number from 100 berries (110-177).

Keywords: *wine grape, soil, grass cover, structural indicators, grape quality.*

Introduction

The promotion of the environmental sustainability in viticulture requires increasing knowledge in all the issues related to vineyard ecosystems; as well as the need to reconsider management techniques for plants and their hosts, for soil and topsoil, paying an increasing attention to actions aiming at safeguarding the structure and fertility of the cultivation sites. The degradation of soil quality may lead to serious problems for wine production, and a cultural damage as soil is unanimously considered a key component of the terroir (Marques et al., 2010). Among strategies to increase environmental sustainability in vineyards, cover cropping with grasses has been recognized as an effective practice to promote soil conservation and protection (erosion control, aggregate stabilization, soil porosity enhancement) (Keesstra et al., 2018). Perennial cover crops offer a wide range of agronomic and environmental benefits to agroecosystems. Recent studies on intercropping in vineyards have shown that in some situations, water stress may not be greater than that prevailing in bare soil vineyards (Celette et al., 2008). Also, Celette et al. (2005) found that grape vine predawn leaf water potential and stomatal conductance did not differ significantly in vines where weeds were controlled in each inter-row by applying glyphosate during the growth period or sown with tall fescue (*Lolium arundinaceum* Schreb/Darbysh.). Despite this, the authors have highlighted, in the plants managed by covering a lower length of the canes and a lower number of leaves, suggesting that vine and tall fescue were competing for nutritional resources. Ingels et al. (2005) underlined that with an adequate distance between the row and the cover crop, the short time effects of grass cover on the vineyard performance are negligible. Moorlat and Jacquet report that grass covering afect decrease in the number of vine roots in the upper soil layers interrow and increase amount of organic matter, N, K_2O and pH. On cover soils temperature is higer, soil erosion is reduced (Napoli et al., 2017), water use is higer, primarly in spring, vine vigor and shoot lenght, must acidity it is reduce and did not affect grape yield. Total phenol content in berry skin can be incrisead. Absolute and relative percent of individual components of bunch (berries and stem) and berries (skin, mesocarp and seeds) is important in assessing grape quality as processing materials for wine. On average, 100 kg of grapes contain 3-5% of stem and 95-97% berries, while berry composition include 8-11% of skin, 2-4% of seeds and 85-95% of mesocarp (Marković et al., 2017). Values of mechanical composition of grapes and berries parameters can vary under influence of temperature, insolation, microclimate in grapevine trunk (Keller, 2020), but also under application of different agrotechnical and ampelotechnical measures like irrigation, fertilization, grassing, defoliation etc. (Cataldo et al., 2021). This paper is intended to provide useful indications on sustainable management for vineyards growing in southeastern Europe at Balkan peninsula. Our objectives were to analyze the effects of grass intercrops on grapevines quality.

Material and Methods

Research was performed in vegetation season 2020, in vineyard of "Radovanović" winery, Serbia on Cabernet auvignon cv, clones VCR 169 and 191. Experimental vineyard is located at altitude of 220 m, GPS coordinates N 44º 25' 47"and E 21º 02' 14". Row spacing is 2.4 m and 0.9 m between vines in row. Vineyards is characterized training system with height of 90 cm on which is Guyot pruning used. All experimental vines were uniformly pruned where was left spur with two buds and one arc with eight buds. For the analysis of basic fertility, soil samples were collected with a drill from depths: 0-30, 30-60 and 80-100 cm. Using standard agrochemical methods it was determined: pH, (both actual pH_{H2O} and exchangeable pH_{KCl}), total organic carbon, total nitrogen content, available phosphorus (P_2O_5) and potassium (K_2O). The effect of different rates (N1- 0 kg N/ha; N2 - 50 kg N/ha; N3- 100 kg) of applied nitrogen fertilizers (AN and KAN) on sown grass-legume mixture: 60%, *Festuca rubra* 30% *Lolium perenne* and 10% *Trifolium repens* was investigated. The trial was set up in a random block design with plot size 10 m^2 in three replications. The grass cover in clone 169 was cut once, while cover in clone 191 was cut two times, and fresh, dry biomass and visual assessment of grass quality under influence of nitrogen fertilization were monitored. Visual assessment was monitored by scale from 1 (bad conditions, weak cover) to 10 (complete cover, compact sod). Data were analyzed were analyzed through analysis of variance and LSD test, in order to recognize significant effects of fertilization treatments. Analysis of collected grape samples was done at laboratory of Faculty of Agriculture University of Belgrade. Berries were harvested at full maturity (fenolic maturity). Mechanical analysis of grape bunches and berries was done by Prostoserdov (1946) and Markovic and Przić (2015). Bunches were measured for their weight, length and width, and rachis (pedicel) from each berry was carefully cut off with scissors so that as little mesocarp as possible was left on stem. Number of berries per bunch was also determined and berry mass per bunch and mass of stems were measured on analytical balance. From each variety 100 berries were selected for purpose of mechanical analysis and after measuring mass of berries, berry skin and seeds were separated. Mass of seeds and skin of 100 berries was measured on analytical balance, and number of seeds in 100 berries was determined by counting. Other parameters were obtained by computation. Ripening parameters are shown through content of accumulated sugar in grape juice-must, total acids content and pH. Sugar content was determined by physicochemical methods using Oeshle mostwage, values were calculated using Dujardin-Salleron tables. The total acid content was determined by titration with n/4 NaOH and pH using pH-meter.

Results and Discussion

The surface (0-30 cm) and subsurface layer of the soil (30-60 cm deep) is acidic, while at a depth of 80-100 cm it is neutral to alkaline (Table 1). In relation to soils under other cultivated crops and natural stands, the difference between the measured values of pH (so-called ΔpH) in the surface layer is very large. According to the content of total organic carbon, the surface layer of the soil is weakly in humus, the subsurface is very weakly to slightly, while the layer at a depth of 80-100 cm is very weakly in humus. The nitrogen content in the soil under the vineyard is generally low, while in the available P_2O_5 this soil is poor. In available K_2O, the land under the vineyard is generally well supplied.

Table 1. Agrochemical properties of soils

Treatment (kg N/ha)	Depth (cm)	pH in H_2O	pH in 1M KCl	Total organic C (%)	Total N (%)	Available (mg/100 g)	
						P_2O_5	K_2O
0	0-30	6.98	4.87	0.589	0.054	1.82	19.76
	30-60	6.48	4.78	0.954	0.069	2.19	24.62

	30-60	6.58	4.78	0.966	0.117	2.57	21.32
	80-100	8.51	7.39	0.361	0.043	6.21	21.29

The observations showed that the grass covers were different in examined vineyards. The grass cover in clone 169 was poor which resulted in one cutting (beginning of May), while another grass cover (in clone 191) was more productive, compact, generally in better condition (table 2). Fresh and dry matter yield was much better under clone 191, without effect of applied amount or fertilizer type, similar to results Krga et al. (2015) without effect of nitrogen application on dry matter yield in sown legume grass mixture. The visual assessment of grass cover followed yield and turf under clone 191 was in much better conditions then turf under clone 169. Both clones (169 and 191) had the highest values of bunch length and width in treatment with a concentration of 50 for AN and KAN. Clone 191 had lower cluster mass with the lowest value of this parameter determined for KAN 50 (103 g) and AN control (129 g). Clone 169 had higher values of cluster mass, with treatment AN 50 (259 g) and KAN control (225 g).

*Maximum values; $^{\oplus}$minimum values.

The same trend of variation was determined for average number of berries in the bunch, weight of stem and the weight of all berries in bunch. Mechanical composition of grape and berry represents ampelographic and technological characteristic of each variety. This elements significantly affect technological properties of cluster and eventually physical and chemical properties of wine (Blackford et al., 2021). Through these indicators can be made conclusion about oenological potential of variety or clone, bearing in mind that these elements are important for synthesis and accumulation of polyphenols (Pržić, 2015). A higher percent of berry epidermis was recorded for clone 169 in control treatment of fertilization with KAN (7.63%), while slightly lower values were found in treatment with AN. The lowest value of percent of berry epidermis was determined for AN 50 (4.28%). Clone 191 had higher values for all three KAN treatments for % of mesocarp in berry, while in all three AN treatments had the highest values of % seeds in the berry.In treatment with AN 100 for clone 191, the highest values of berry indicator (91.6) were determined, while for the AN treatment 50 for clone 169, was determined the lowest value of this indicator (70.6). Sugar content in must varied from 17.6–23.2% (AN 100) and 20.8–25.2% (KAN 100). According to total acids content expressed as tartaric acid, clone 191 figure in treatment of fertilization with KAN. Acording to Marković et al. (2017) and Keller (2020), acid content varies widely, which leads to the conclusion that acid content was influenced by treatment fertilization with KAN (treatments with 50 and 100). In AN treatments was found a lower content of total acids expressed as tartaric. This variation trend was founded for both clones. Clone 169 had lower pH must values in all AN and KAN fertilization treatments.
Gontier et al. (2011), in an experiment carried out in three field cases, comparing chemical weeding with natural grass and sown grass, observed reduction of vigor and yield, fall in nitrogen content of the must and increase in sugar and polyphenolic content using cover crops. However, those effects were not the same on all the experimental fields (water reserve of the soil, variety) and on all the studied treatments (species sown). Muscas et al. (2016) report that legume mixture reduces bunch weight, whereas grass mixture affect lower bunch weight and number. Also, grass mixture increase sugar content, content of anthocyanina and other ploypheno ls, whereas legume mixture reduce content of this components. Marques et al. (2020) report that that cover crop reduce vine vigor, does not affect yield and increase grape quality present throe total anthocyanins content.

Conclusions

Based on the research results, it can be concluded that the vineyard inter-row grass cover gave different yields of fresh and dry biomass, as well as grass quality was different in clones. The applied of different levels of mixture fertilization did not significantly affect the cover in individual clones. On the other hand, the parameters of the mechanical grape composition depended on clone, but also on the levels and types of applied nutrients to mixture in the inter-row distance. Namely, in clone 169, by applying 50 kg of AN on the mixture, the largest width, length and weight of the bunch, the largest number and weight of berries are achieved. Chemical characteristics of grapes depend on clone and fertilization. Sugar content is higher in clone 169, while the acid content is highest in clone 191.

Abstract

For the last few decades, the most crucial goal in strawberry cultivation has been to extend the harvest season. Day-neutral varieties are increasingly being used to extend the season. The study aimed to determine the fruiting patterns of some day-neutral and short-day strawberry cultivars grown in open field (OF) and greenhouse conditions (GH). Frigo plants of some day-neutral ('Monterey', 'Albion', 'Sweet Ann', 'San Andreas') and short-day ('Benicia', 'Fortuna', 'Rubygem', 'Festival', 'Camarosa', 'Amiga') strawberry cultivars were planted on 7-8th July 2014 on raised beds covered with silver-grey polyethylene mulch in plastic greenhouse and open field in Samsun, Black Sea Region, Turkey. In OF condition, harvest commenced in May and terminated in October. Day-neutral (DN) cultivars extended the harvest season up to October, two months longer than short-day cultivars. On the contrary to GH, there was no harvest of any variety in April in OF. In OF conditions, intensive harvest periods were May and June for all cultivars. In OF, all cultivars continued fruiting in July and August, but yield of day-neutral cultivars were higher; however, yield of short-day (SD) cultivars 'Fortuna', 'Rubygem' and 'Festival' were also remarkable. Generally, yields were not obtained from short-day cultivars in September in OF. In GH conditions, harvest commenced in April and continued until September with day-neutral and some short day cultivars 'Festival', 'Fortuna' and 'Rubygem' with insufficient yields, none of the cultivars had fruit in October. In GH, the intensive harvest period was May for almost all cultivars. However, Aril was intensive harvest time for 'Benicia', June for 'Festival' and 'Rubygem', April and June for 'Fortuna'. In general, there were no apparent differences between short-day and day-neutral varieties in terms of fruiting patterns in GH, however in June and July, it was noted that short-day cultivars had higher yield than day-neutral. Yield decreased gradually from the beginning of July to the end of August in all cultivars in GH.

Introduction

Changing production systems, reduced chemical control options, and rising demand for summer-fall strawberries and high-quality strawberries drove strawberry breeding efforts to develop some cultivars to meet these diverse needs (Hokanson and Finn, 2000; Baruzzi and Faedi, 2002; Gu et al., 2017). It was found that high tunnels offer many advantages, including environmental modification, season extension, higher yields, quality improvement, crop protection from severe weather, and the ability to achieve premium prices compared to open field production (Carey et al., 2011). Growers are very interested in high tunnel berry production. Where land is expensive or limited and inclement weather makes production risky, growers are certainly aware of the value of the protected crop (Demchak and Hanson, 2011). The fruit yield (weight, average size and number) of june-bearing strawberry cultivars grown in the high tunnel was higher compared to the open field production system (Kadir et al., 2006). In open-field production systems, there are several studies highlighting the importance of environment for growing strawberry successfully. Temperatures above 29 °C encourage excessive crown development, which will potentially reduce overall plant growth, subsequent fruit size and fruit weight (Hellman and Travis, 1988; Kumakura and Shishido, 1994; Wang and Camp, 2000; Masaru et al., 2016). The strawberry industry in Turkey achieved an expansion and is progressing steadily. Turkey is the 4th largest strawberry production after China, USA and Mexico (FAO, 2019). Main production is provided from southern regions. In the coastal regions of Black Sea, where the weather is relatively cool in summer, cultivar adaptation experiments performed recently have had very promising results with cultivars producing fresh fruits in summer months (Kandemir, 2016; Mısır, 2016). Cultivar selection is one of the key factors to ensure success in strawberry production and selected cultivars should be able for fruiting in early or late season. Short-day cultivars have long been popular in many parts of the world (Pritts and Handley, 1998; Black et al., 2002), but these cultivars prevent growers from participating in the commercial strawberry market except for the short fruiting period of 4 to 6 weeks each year (Pritts and Handley, 1998). Day-neutral strawberry cultivars are less affected by day length and typically continue to flower as long as temperatures remain between 4-26 ºC, resulting in a substantially longer fruiting period compared with short-day plants (Pritts and Handley, 1998; Rowley et al., 2010). Furthermore, day-neutral plants produce ripe fruit 10 weeks after planting, not the following year as with short-day plants (Pritts and Handley, 1998), reducing the period of crop management before financial return (Bornt et al., 1998). The objectives of this study were to determine fruiting patterns of different strawberry cultivars grown in greenhouse and open field conditions and to assess their potential for early and summer-fall season strawberry production.

Material and Methods

The experiment was carried out during 2014-2015 in the greenhouses (GH) and open field (OF) production systems in the experimental area of Agriculture Faculty at Ondokuz Mayis University, Black Sea coastal area, Samsun, Turkey. Elevation at research station is 115 m; the soil was clayey with a soil pH of 6.96 and organic matter 2.29 % in open field and sandy with a soil pH of 7.41 and organic matter 5.43 % in greenhouse. The experiment was arranged as a completely randomized plots design with four replications and 20 plants per plot. Greenhouses sized 6x20x3 m and covered with 1 cm thick polycarbonate were used. To avoid from high temperature over 26 ˚C in greenhouses, passive top and side ventilation as well as shade cloth with 50% light transmittance were used. On 7-8 July 2014, strawberry plants of day-neutral ('Albion', 'Monterey', 'San Andreas', 'Sweet Ann') and short-day cultivars ('Camarosa', 'Amiga', 'Rubygem', 'Fortuna',' Festival') were planted on raised beds (0.70 m wide, 0.40 m high) covered with silver-grey polyethylene mulch. Each bed had two rows of staggered plants with a distance of 0.3 m between the rows and the plants. In each crop environment (greenhouse and open field), single drip lines per bed was used for irrigation. During the soil preparation, manure (0.5 t/ha) was applied to soil. Fertilization and pest control were achieved following current crop recommendations. The monitoring of the air temperature was carried out in each experimental area with data logger (Kistock KH 200), registering the information hourly. The blossomed flowers after planting were continuously removed until autumn. During harvest period, fruit was collected from each plot, two times per week. Monthly yields were calculated by dividing number of plants of fruit amount obtained each month.

Results and Discussion

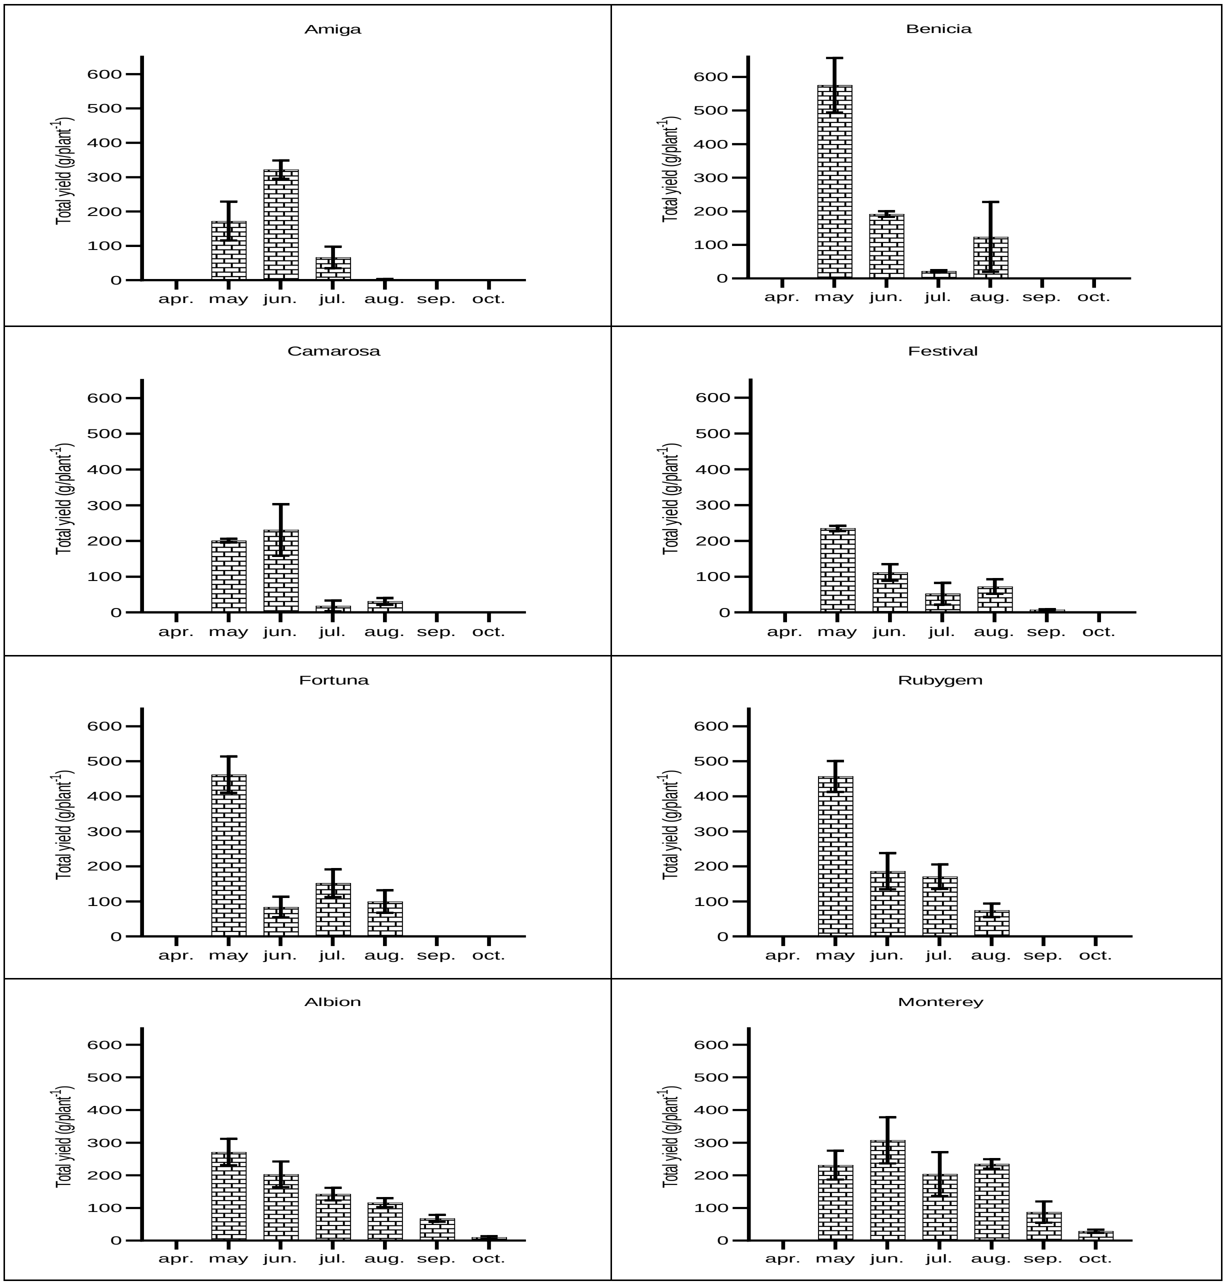
Open Field

In the open field condition, depending on the SD and DN strawberry variety, the harvest continued about 5-6 months from early May to early October. On the contrary to GH, there was no harvest of any variety in OF in April. There was also no harvest after August for all SD cultivars, except for the 1% yield in September at 'Festival' (Figure 1, Table 1). Finally SD cultivars performed 4 months of harvest period except 'Amiga' and 'Festival' (3 and 5 month, respectively), which is contrary to that SD cultivars producing fruit for several weeks in early summer (Solomon et al., 2001; Hoover et al., 2014). The cool summer temperatures in the Black Sea Region seem to have resulted in longer flowering and fruiting in the SD varieties, with the average temperatures during the 2015 harvest season being 16.2, 21.1, 24.7 and 24.4 ºC in May, June, July and August, respectively. Although the intensive harvest period of the SD varieties as general was May and June, as specifically intensive harvest time for 'Benicia' (68%), 'Festival' (48%), 'Fortuna' (58%) and 'Rubygem' (51%) was May, and for 'Amiga' (58%) was June (Figure 1, Table 1). These findings indicate that 'Benicia', 'Festival', 'Fortuna' and 'Rubygem' are early and 'Amiga' is late variety. Kandemir et al. (2019) confirmed this indication in their study. SD cultivars continued harvest season in July and August, however a remarkable yields were obtained from 'Fortuna', 'Rubygem', 'Festival' (totaly 31, 29, 28%) (Table 1).

Table 1. Monthly distribution of yield in strawberry cultivars grown under open field and greenhouse conditions (%).

	Open Field						Greenhouses					
Cultivar	May	Jun.	Jul.	Aug.	Sep.	Oct.	Apr.	May	Jun.	Jul.	Aug.	Sep.
Amiga	30	58	11	1	-	-	13	48	27	10	2	-
Benicia	68	22	2	8	-	-	48	38	9	5	-	-
Camarosa	42	47	4	7	-	-	15	40	29	13	3	-
Festival	48	23	12	16	1	-	17	31	30	16	5	1
Fortuna	58	11	19	12	-	-	26	25	30	15	3	1
Rubygem	51	20	20	9	-	-	17	31	34	14	3	1
Albion	33	25	18	14	8	1	26	35	22	11	4	2
Monterey	21	28	19	20	8	4	17	42	20	13	7	1
San Andreas	35	28	14	15	8	-	29	38	19	11	2	1
Sweet Ann	13	42	17	22	4	2	9	54	17	17	2	1

No yield was obtained from SD cultivars in September, except very insignificant yield of 'Festival' (1%).Harvest period was longer about 2 month in DN cultivars ('Albion', 'Monterey', 'San Andreas' and 'Sweet Ann') than in SD cultivars (Figure 1). In addition, while the intensive harvest period of 'Albion', 'San Andreas', 'Monterey' DN cultivars was May and June (totaly 58, 63 and 49%, respectively), main harvest period for 'Sweet Ann' was June. This suggests that 'Sweet Ann' is a late-flowering cultivar. Kandemir et al. (2019) found that 'Sweet Ann' is the latest variety among ten SD and DN examined varieties. The yields in July and August of all DN cultivars (totally 32% for 'Albion', 39% for 'Monterey', 29% for 'San Andreas', 39% for 'Sweet Ann') were significantly higher compared to SD varieties. Yield sharply declined in September in all DN cultivars, 'San Andreas' terminated harvest period in the end of September. A negligible yield were recorded in October from 'Albion', 'Monterey' and 'Sweet Ann'.



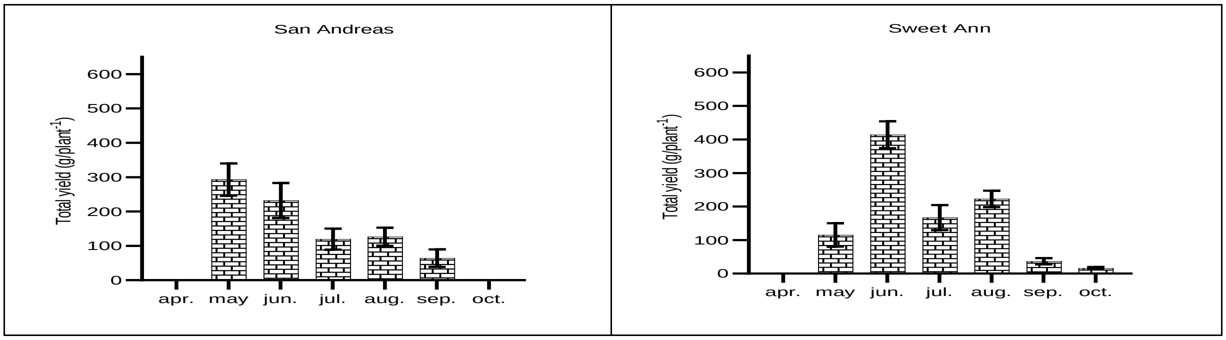


Figure 1. Effect of cultivar on monthly yield under open field conditions during 2014-15 cropping season. Vertical lines through data points are standard errors.

DN cultivars bear fruit in a short period of 3-4 months, they are suitable for summer and autumn fruit production in areas having cool summers (Galletta and Bringhurst, 1990). In mild climate, it was reported that DN cultivars 'Albion' and 'San Andreas' produced fruit up to 2.42 and 3.29 kg/plant, respectively, in a 6-month harvest from April to October in Korea (Ruan et al., 2011). Reitmeier and Nonnecke (1991) reported that DN strawberries have potential to produce fruit throughout growing season, which increases the harvesting periods, potential to increase yields, and income to the producer as it provides the opportunity to grasp off-season price.

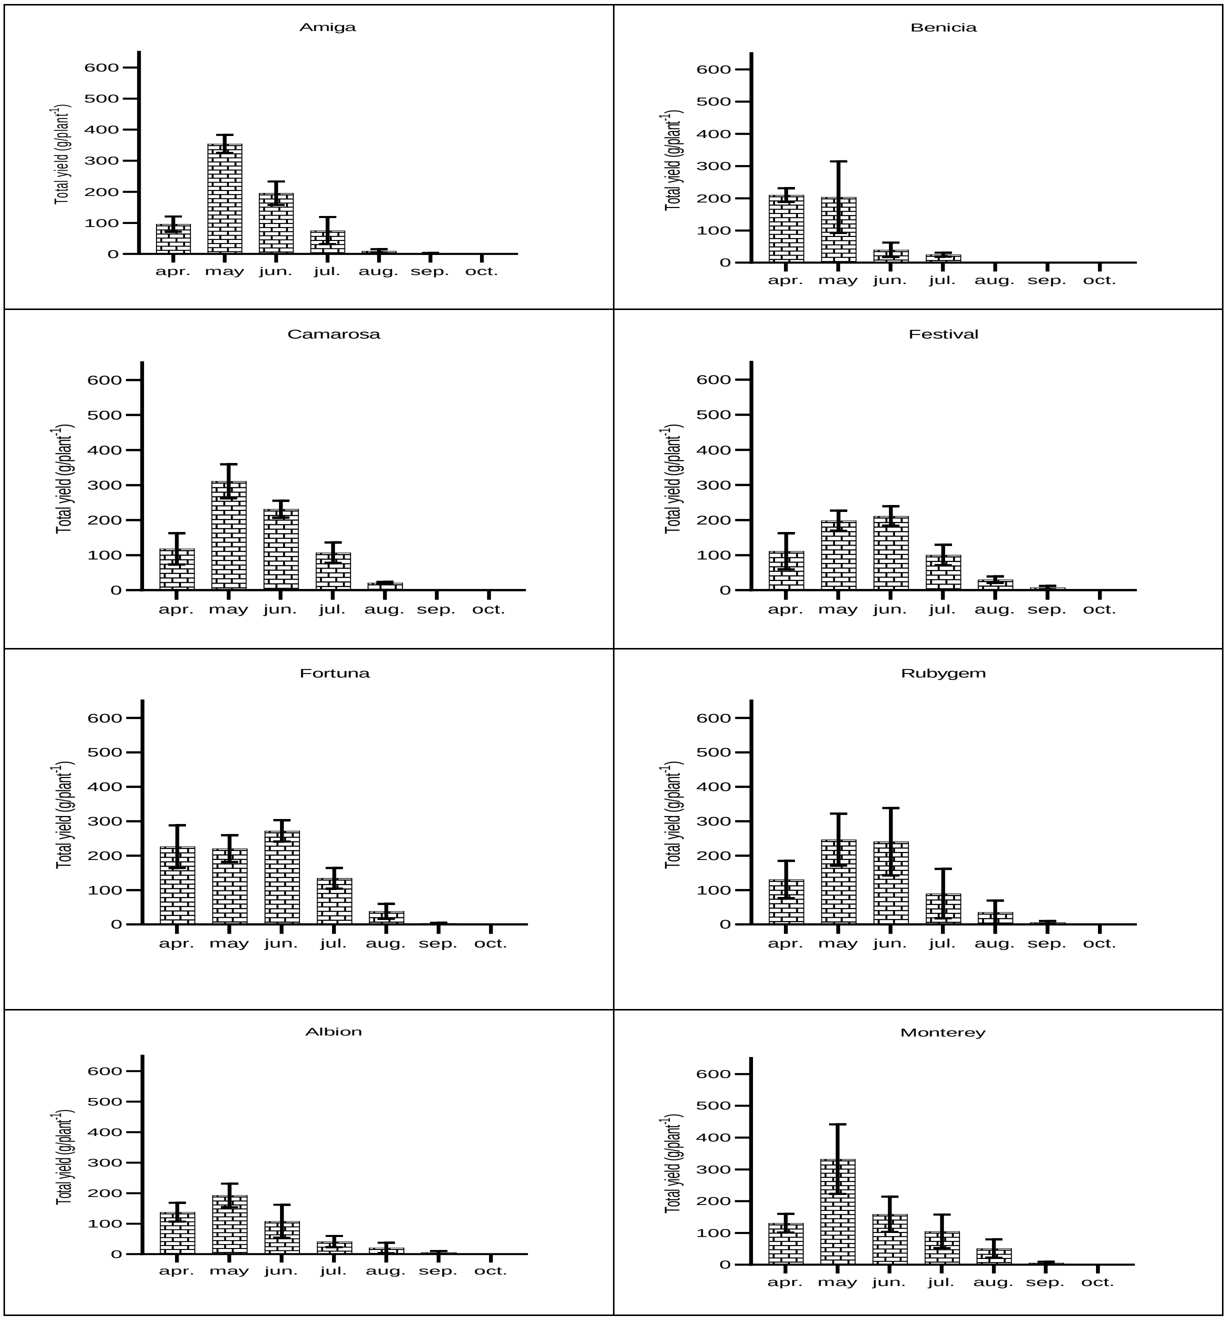
Greenhouse

During the early spring, warm temperatures in GH provided early plant growth, flowering and fruit production of all strawberry cultivars. During the spring, temperatures were 11.0, 12.6, 16.1, 20.5 °C in GH, 8.5, 8.7, 9.9, 16.2 °C in OF, respectively for February, March, April and May. As a result, the harvest in GH started one month earlier than in OF, at the beginning of April. Kadir et al. (2006) found that high tunnel strawberries were 5 weeks earlier than field grown strawberries in Kansas. Many researchers reported earliness of strawberry varieties grown in greenhouse conditions (Önal, 2000; Gündüz and Özdemir, 2003; Öztürk and Demirsoy, 2004; Gündüz and Özdemir, 2008; Crespo, 2010; Rowley et al., 2010; Gündüz and Özdemir, 2012; Kandemir et al., 2019).

Depending on the variety, harvest in GH commenced in April and lasted about 5-6 months through September. The intensive harvest period of almost all cultivars was May, however specifically intensive harvest time was April (48%) and May (38%) for very early cultivar 'Benicia'; May (31, 31%) and June (30, 34%) for 'Festival' and 'Rubygem', respectively; April (26%), May (25%) and June (30%) for 'Fortuna' (Table 1, Figure 2). In April, 'Sweet Ann' and 'Amiga', the late varieties, produced the lowest yields, while the yields of other varieties in April were sufficient. Kandemir et al. (2019) reported the latest harvest dates for this two cultivar among ten strawberry cultivars in GH condition. Late harvest explains their low yields in April in our study. Also, it is noteworthy that remarkable yields in June and July were obtained from SD cultivars except 'Benicia', compared to DN cultivars 'Monterey', 'Albion', 'Sweet Ann' and 'San Andreas'.

Considering all cultivars, SD and DN, their yields decreased except 'Sweet Ann' in July. Yields of 'Sweet Ann' in June and July were identical. 'Benicia' terminated the harvest period in July. Compared to the OF, harvest in GH terminated early in 'Benicia', likely due to its peculiarity that it is an early variety. In the GH, yields also were low in Benicia due to severe black root rot (Kandemir, 2016). In August, most of cultivars considerably decreased yield, simultaneously

'Amiga' and 'Camarosa' terminated harvest period. All DN varieties extended the harvest period into September, however, their yields were insufficient. Also low yields were obtained from SD cultivars 'Festival', 'Fortuna' and 'Rubygem' in September. In GH, unlike in OF, none of the examined cultivars had fruit in October.



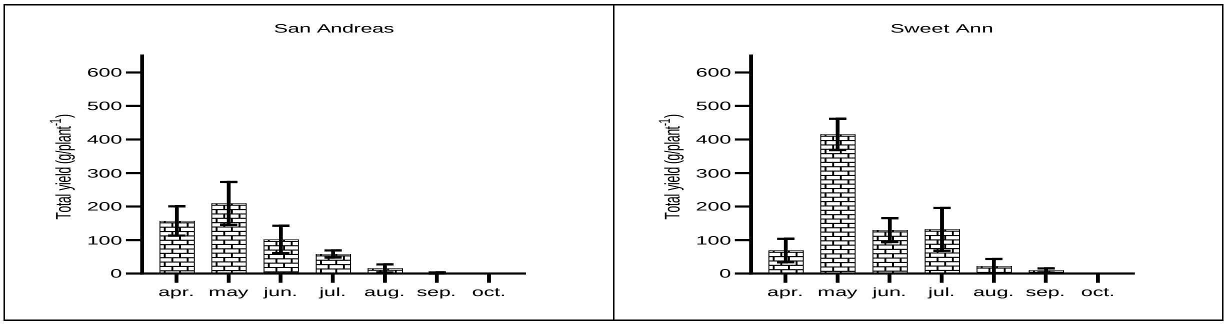


Figure 2. Effect of cultivar on monthly yield under greenhouse conditions during 2014-15 cropping season. Vertical lines through data points are standard errors.

Conclusions

The length of the strawberry harvest season has gained importance in recent years. Turkey has just encountered the demand for locally produced off-season strawberries. In this regard, inner regions with high altitude and Northern areas seem promising. However, using proper DN and SD strawberry cultivars is a key factor to extend the harvest season and obtain performance of high-yield in northern parts of the country where growing conditions are more challenging. In our study harvests commenced in April (GC) and May (OF), continued until September (GH) and October (OF) respectively, mainly with DN cultivars. However, in both growing conditions 'Festival', 'Rubygem', and 'Fortuna' appeared to be suitable SD varieties for extending the harvest season. This result is explained by fact that in Black Sea Region weather conditions are ideal for harvest period extension (early and out-season) with DN and some SD cultivars in combination with GH conditions. Average temperatures below 26 ºC in summer in Black Sea Region seem to encourage flowering and fruiting in DN and SD varieties in summer.

THE EFFECT OF CLIMATE CHANGE AND THE INFORMATION SOURCES USED IN THE ENTERPRISES PRODUCING SUNFLOWERSEED

Aysun YENER ÖGÜR*, Muzaffer KAYGUSUZ, Şiyar BİLİK, Murat ALP

Selcuk University, Faculty of Agriculture, Department of Agricultural Economics, Konya, Turkey
*Corresponding author: aysunyener@selcuk.edu.tr

Abstract

Sunflower, a member of the Asteraceae family; It is one of the world's strategic products. In the world, oilseed production is of great importance due to the economic value it creates. For this reason, it is very important for countries that the seed sunflower is affected by climate change. The increasing impact of climate change on agricultural production has a wealth of literature focusing on the potential value of weather and climate information to help farmers prepare and respond to these impacts. However, while the impact of climate change on the agricultural sector is growing, there is no clear de facto practice to reduce this impact. In this study, the effect of climate change and the information sources used on climate change in the enterprises producing Sunflower seed were examined. The sample volume was calculated as 62 with a 99% Confidence Interval and 10% error margin for the stratified sampling method, which was one of the simple random sampling methods. The effect of climate change on sunflower production was investigated. As a climate change effect, 1st group enterprises showed drought (4.54), 2nd group enterprises showed insufficient precipitation (441) and 3rd group enterprises showed drought (4.65). The information source used on climate change is the internet (4.36). The internet, agricultural engineers, pesticide dealers, leading farmers, visual and written media should be used to raise awareness about climate change for businesses producing seed sunflowers.

Keywords: *Sunflower, Climate Change, İnformation Sources.*

Introduction

Oilseed production is of great importance due to the economic value it creates (Acaravcı and Ergüven, 2015). Oilseeds, which are the raw material of the vegetable oil sector, are also the raw material of many different sectors (Gürkan et al., 2016). Oilseed meal, which has a very high protein content, is also preferred in animal nutrition (İlkdoğan 2008). Vegetable oils are strategic products that are used extensively in the food, energy, and chemical sectors (Taşkaya Top and Uçum, 2012). For this reason, it is very important that seed sunflower production is affected by climate change. The effects of climate change on agriculture are likely due to many other subtle changes, possibly from the effects of increased CO2 on plant growth, warmer and drier conditions, changes in wind speed, insect and plant disease pressures, and altered interactions between crops components. agro-ecosystems (Smith & Almaraz, 2004); however, effects that cause crop yield losses have often been overlooked (Lim et al., 2004, Scherm, 2004). The increase in CO2 and other greenhouse gases has had serious effects on global climate systems (Koocheki et al., 2006). It is likely to cause a number of new environmental changes, predominantly through anthropogenic activities (Allen, 1990; IPCC 2001; McMichael, 2001, Centritto & Loreto 2005). Increasing CO2 and thus temperature are likely to affect all aspects of plant growth, development, and function differently depending on plant species and geographic location (Centritto & Loreto, 2005). The increasing impact of climate change on agricultural production has generated rich literature focusing on the potential value of weather and climate information to help farmers prepare and respond to these impacts (Solis and Letson, 2013). In this context, calls have been made for a stronger extension role to support climate change adaptation in all areas, particularly in the agriculture sector (Brugger and Crimmins, 2014). But while the impact of climate change science on agriculture is growing and becoming more robust (Hatfield et al. 2014), the evidence for the actual application of extension studies to readiness and adaptation is low (Prokopy et al., 2013; Haigh et al., 2015; Lemos et al., 2014). In this context, organizations that act as intermediaries between climate-related information producers and users have an important role in raising awareness of climate change (Lemos et al., 2012; Prokopy et al., 2015). For this reason, the effect of climate change and the information sources used on climate change in enterprises producing seed sunflowers were examined in this study.

Material and Method

The main material of the study; The original data collected through a questionnaire from the enterprises producing sunflowers in the Çumra district of Konya province in Turkey, which was selected as the research region, constitutes the year 2020. In addition, previous research on the subject and the data of the relevant institutions and organizations were also used. In the research, the Stratified Random Sampling Method, which is one of the simple random sampling methods, was used in order to increase the accuracy of the data collected from the enterprises and to ensure adequate representation of different parts of the population. (Yamane, 1967; Güneş and Arıkan, 1988). Layer widths are grouped as 0-20 decare, 21-60 decare, 61 decare, and above. Sample volume was calculated as 62 at 99% Confidence Interval, with 10% margin of error, according to the Neyman Method. (Yamane, 1967).

$$n = \frac{\sum(Nh.Sh)^2}{N^2.D^2 + \sum Nh.(Sh)^2}$$

$$D^2 = (\frac{d}{t})^2$$

n: Number of samples,
N: Total unit number belonging to the sampling frame,
Nh: Number of enterprises in layer h,
Sh: Standard deviation of layer h,
d: Allowable margin of error from the population average,
t: t table value corresponding to the anticipated 99% confidence limit (Yamane, 1967).
The distribution of sample volume by business groups is given in Table 1.

Table 1. Sample volume by enterprises size groups in the research area (n)

Group	Sample Volume (n)
0-20 da (1. Group)	13
21-60 da (2. Group)	32
61-+ da (3. Group)	17
Total	62

Results and Discussion

The average land amount of the enterprises is 209.64 decares. 98.98% of this land belongs to enterprises and 1.02% is rented land. The main reason why most of the lands are property lands is the habit of the landowners in our country to inherit their lands from father to son. When we look at the production pattern table of the enterprises, we have considered 5 different products that the enterprises generally produce. These products are corn, sugar beet, sunflower, wheat, and barley. Among these products, corn ranks first with a rate of 25.47%. Sugar beet is the second crop with 24.31% and sunflower is the third crop with 24.23%.

In addition to machine power, human power is also very important in sunflower cultivation in the research area. The workforce presence of the enterprises was 3.02-2.64-2.62 MLA, respectively, and the family workforce potential was also found to be 846.3-739.62-732.76, respectively. The average of the workforce used was calculated as 2.71 MLA and 760.11 MLD. In addition to family labor, foreign labor was also used in the enterprises. The foreign labor force employed was calculated as 617,17. The total workforce used in the enterprises was calculated as 1,588.14 MLD.

As a result of the survey studies, corn provided the highest return of 44,386.57 $ and 36.60% of the 5 main products that are the source of income for the enterprises. While sugar beet constituted 26.96% of all production with 32696.65 $, sunflower, which is the subject of the article and contracted in the region, provided the operators with the third return with 25,075.10 $ and a share of 20.67%. These are followed by wheat with a share of 17,024.27 $ and 14.04%, and barley with a share of 2,107.52 $ and 1.74%.

In line with the results prepared with the data obtained by calculating the variable costs such as Seed, Fertilizer, Medicine, Fuel, Tools, Equipment, Money, Water and Electricity fees included in the survey, the costs naturally increase as the decare increases. As a result of the survey, it is seen that Sugar beet is the product with the highest variable cost among the enterprises with 6,979.49 $ and a share of 35.46%. Corn crop, on the other hand, takes second place with 5698.04 $ and 28.95% share. Sunflower is in third place with a share of 4.244.20 $ and 21.57%, and the seed cost is 0 TL because the sunflower is contracted here.

The average of the processing average of the gross production value of the contracted sunflowers is 25075.10 $ and the variable costs are 4,244.20 $. By subtracting these values, gross profit is obtained. Its gross net profit is 20,830.90 $. Gross profit per decare is 289.69 $.

Table 2. Climate change impact on enterprises

Variables	0-20	21-60	61-+	Enterprises Average
Drought	4.54	4.38	4.65	4.48
Untimely Rain	4.46	4.34	4.53	4.42
Insufficient Precipitation	4.46	4.41	4.41	4.42
Wind Storm	2.69	2.97	3.00	2.92
Frost	2.54	2.78	2.76	2.73

Excessive Precipitation	1.00	1.00	1.00	1.00

5: Always 4: Often 3: Sometimes 2: Rarely 1: Never

The effect of climate change is frequently seen as drought, untimely rain, and insufficient precipitation in the enterprises producing seed sunflower. As an effect of climate change, drought is seen frequently in Group 1 enterprises (4.54), insufficient precipitation in Group 2 enterprises (4.41), and always Regular Precipitation in Group 3 enterprises (4.65).

Table 3. Information sources used by enterprises on climate change

5: Always 4: Often 3: Sometimes 2: Rarely 1: Never

The source of information used on climate change is the internet (4.36). The most widely used information sources in the 1st group businesses are the internet (4.00), television (4.00) and pesticide dealers (4.00). In the 2nd group enterprises, agricultural engineers (4.86), leading farmers (4.81) and the internet (4.71). In the third group enterprises, pesticide dealers (4.43), internet (4.00) and agricultural engineers (3.69). The internet, agricultural engineers, pesticide dealers, leading farmers, visual and written media should be used to raise awareness about climate change for businesses producing seed sunflowers.

Results and Discussion

In the research area, 98.98% of the total land area of 208.85 da of enterprises is private property. Sunflower is produced on 65.49% of the total farm land. 61.14% of the workforce used in businesses is family workforce. Sunflower is a very important product for the research region and all members of the family are involved in production. For this reason, it is necessary to raise awareness of all family members, taking into account the intensity of the family workforce, that is, those who work on climate change. In the research area, climate change is often seen as drought, untimely precipitation and insufficient precipitation. Sunflower is one of the irrigated crops. It is highly affected by drought, untimely rain and insufficient rain and decreases in yield occur. In this case, it affects the socio-economic structures of the farmers. In order to reduce the impact of climate change in enterprises producing seed sunflowers, it should be ensured that the necessary warnings are made in a timely manner. When looking at the information sources used by the farmers, the internet is used by all groups. In addition, agricultural engineers, drug dealers, leading farmers, visual and written media should be used.

Abstract

Phosphorus (P) is responsible for a number of functions which its major importance to physiological and biochemical function of plant in sustainable agriculture system. However to maximize metabolic functions, legumes need more phosphorus as it is required for energy transformation in nodules. Therefore, an experiment was conducted to understand the yield and phosphorus demand of cluster bean. This trial was arranged as a completely randomized block design with four replications from March to July of 2020 in the outdoor conditions at Izmir, Turkey. An application of phosphorus influences symbiotic nitrogen fixation yield and quality of cluster pods. For this reason, a pot experiment was carried out to investigate the effect of phosphorus levels (0, 60, 90, 120 and 150 kg P ha^{-1}) on the seed yield and some yield components of cluster bean (Pusa Nevbahar cv.). Results shown that rate of phosphorus has a significant effect on plant height, number of pod, biomass weight, seed yield and thousand grain weight of cluster bean. Application of phosphorus at the rate of 120 kg ha^{-1} can be recommended for obtaining the maximum seed yield in cluster bean under Mediterranean climate conditions.

Keywords: *Cluster bean, P level, seed yield.*

Introduction

Cluster bean or guar [*Cyamopsis tetragonoloba* (L.) Taub. (2n=14)] is a valuable crop belongs to the family *Leguminosae*. It is also thought to be developed from African species *Cyamopsis senegalensis* (Kumar and Rodge, 2012). Plant has a deep taproot system, 20-100 cm tall, erect and unbranched stems, trifoliate leaves, white or pink flowers, large and glabrous pods and a life cycle of 80 to 160 days (Chauhan et al., 2020). Guar is an annual legume that can be used for multiple purposes (fresh vegetable, animal feeding, green manure or cover crop) (Batirca et al., 2017). Under the water stress conditions, clusterbean is generally produced semi-arid and arid, tropical-subtropical regions due to its high drought tolerance. It is also a good soil restorative crop, which can fix about 40% N in the soil (Dougles, 2005). The cluster bean includes about 30-33% gum in the endosperm part of seed. The gum is used in many different types of industries like products of food, textile, paper and cosmetics (Pawlik and Laskowski, 2006). Cluster bean gum is biologically made non-toxic, eco-friendly and safe agro-chemical product (Sabahelkheir et al., 2012). This all reasons, guar is as a novel industrial crop with high exchange gaining potential. Phosphorus is the backbone of balanced fertilizer use in the intensive agro-system. P performs early root development, growth, blooming and aids in seed generation when applied to legumes. The supply of phosphorus to legumes is more important than that of nitrogen because, latter is being fixed by symbiosis with rhizobium bacteria (Yadav et al., 2020). This study targets to test the effect of different phosphorus levels on cluster bean seed yield and some yield components under the climates of Mediterranean.

Material and Methods

A pot study was conducted in outdoor conditions on the experimental area of Field Crops Department, Faculty of Agriculture, Ege University (Turkey), from March to July of 2020 with typical Mediterranean climate conditions. Some meteorological data from the experimental area in Bornova-Izmir are presented in Table 1. The experiment soil was analyzed for pH: 5.83, soil texture: loamy, avaiable Ca:1300 ppm, avaiable P: 2.54 ppm, avaiable K: 40 ppm, $CaCO_3$: 0.82%, organic matter: 2.27%, total nitrogen: 0.092%, total salt: 0.03%, sand: 80.2%, clay: 1.8%, silt: 18.0%.

Table 1. Some meteorological data of research area in Bornova, Izmir, Turkey in 2020

	2020		**Long Year Average**	
	Temperature (ºC)	**Precipitation (mm)**	**Temperature (ºC)**	**Precipitation (mm)**
April	14.7	27.6	16.1	46.4
May	20.6	17.7	21.0	25.4
June	23.2	5.2	26.0	7.5
July	26.7	1.0	28.3	2.1
August	26.0	1.0	27.9	1.7
Total-Mean	**22.2**	**52.2**	**23.8**	**83.1**

Pusa Nevbahar cultivar of cluster bean (*Cyamopsis tetragonoloba*) was used as plant material from India. The seeds were sown in multipode on 17th March 2020, under the laboratory conditions. After the one month, the growing plants were planted in the pots of outdoor conditions at trial area. Five rates of phosphorus (0, 60, 90, 120, and 150 kg P ha^{-1}) were used in a completely randomized block design with four replicates. Total dose of phosphorus (triple superphosphate) fertilizer, 30 kg ha^{-1} nitrogen (urea) and 100 kg ha^{-1} K_2O (potassium sulphate) were applied with planting (Gresta et al., 2019). Weed control was provided by hand. No exposed crop diseases or pests were found.

In our study, the pods in the plants were expected to mature for grain harvesting, in other words, it was done when the moisture content of the grains in the lower pod of the plant reached around 13%. The crops were harvested by hand from the pot. The samples were dried to a constant weight at 65ºC during 48 h and then were weighed (g plant^{-1}). The distance between above soil level and the tip point of the dry plant was measured with a ruler for the plant height (cm). All pods on the plant were counted for the number of pods. The weight of the completely dried plant in the laboratory was weighed with digital scales for the biomass weight (g plant^{-1}). The pods in the dried plants were threshed manually and the grains was weighed with a digital scale for seed yield (g plant^{-1}). Cluster bean seeds (100) were weighted and converted for calculation of 1000-seed weights. The obtained data were statistically processed by analysis of variance (ANOVA) with the Statistical Analysis System (SAS, 1998). If ANOVA indicated differences between treatment means, a LSD test (0.01) was performed to separate them (Stell et al., 1997).

Results and Discussion

In this study, plant height was statistically affected by phosphorus level (Table 2). The maximum plant height was recorded in P120 (60.1 cm) but the minimum plant height (50.3 cm) was recorded in the control pots (P0). Moreover, P120 and P150 levels was found non-different group in the statistical analysis. Increasing P levels increased plant height of cluster bean compared to the control. Singh and Tiwana (1995) reported that 60 kg ha^{-1} P level significantly enhanced plant height by 19.5 cm over the 0 kg ha^{-1} P level. On the similar study, the 40 kg ha^{-1} P application positively affected on plant height of cluster bean and also this fertilizer level was higher than compared the control level (P0) (Parihar, 2003). These results are in similar associated with our findings. The P levels significantly affected number of pod of cluster bean (Table 2), in the study. Numerically, the highest number of pod was recorded in P120 (39.3 $plan^{-1}$), whereas the lowest number of pod was recorded in P0 (30.6 $plant^{-1}$) level. In addition, there were no significant differences between P120 and P150. The number of pod of cluster bean enhanced with the application of P, because this element increases flowering and fruit setting. Numerous researchers pointed out that, increased P levels significant rise number of pod compared the control level for cluster bean (Singh and Tiwana, 1995; Shivran et al., 1996; Naagar and Meena, 2004).

Table 2. Effects of different P levels on the seed yield and some yield components of cluster bean

N levels	Plant height (cm)	Number of pod ($plant^{-1}$)	Biomass weight (g $plant^{-1}$)	Seed yield (g $plant^{-1}$)	Thousand grain weight (g)
P0	50.3 d	30.6 b	22.6 c	4.0 c	33.6 b
P60	55.7 c	31.3 b	26.6 b	4.7 bc	39.0 a
P90	56.1 bc	33.4 b	28.5 b	5.5 ab	36.5 ab
P120	60.1 a	39.3 a	32.7 a	6.6 a	35.5 b
P150	59.2 ab	38.6 a	29.5 ab	6.5 a	34.6 b
Mean	56.3	34.6	28.0	5.5	35.8
LSD (1%)	3.16	5.06	3.31	1.34	3.46
CV (%)	2.7	7.01	5.68	11.82	4.65

Same trend has been monitored in biomass weight. (Table 2). P120 gave highest biomass weight (32.7 g $plant^{-1}$) which was followed by P150. There was no statistical difference between these two doses. Moreover, P0 gave lowest biomass weight (22.6 g $plant^{-1}$). Biomass weight of cluster bean progressively increased with the increasing levels of phosphorus up to 120 kg P ha^{-1}. P is a fragment of DNA and RNA, related in cell division and is momentous for biomass yield (Brady and Weil, 2004). Our findings are in similar line with the results of Shivran et al. (1996) who noticed that the high biological yield (5.2 t/ha) of cluster bean was obtained by application of 40 kg P ha^{-1} which was 19% higher as compared to 20 kg P ha^{-1} level. Bahadur (2003) stated that the maximum biological yield (5.8 t/ha) of cluster bean was observed in 30 kg N ha^{-1} & 60 kg P ha^{-1} fertilizer combination.

There were significant differences among P levels for seed yield in our study (Table 2). The lowest seed yield was found (4.0 g $plant^{-1}$) in the control (P0), and P120 gave the highest seed yield (6.6 g $plant^{-1}$) which was followed by P150 (6.5 g $plant^{-1}$) and P90 (5.5 g $plant^{-1}$). Moreover, P90, P120 and P150 levels statistically were observed at the same group. Increasing doses of P significantly increased seed yield of cluster bean. Use of P fertilizer is critical for influential nodulation and contributes to enhance grain yield (Lokose, 2005). A study was conducted by Raiger et al. (2017) to determine the effects of different P levels (0, 20, 40 and 60

kg P ha^{-1}) on cluster bean. The researchers stated that seed yield (1.2 t/ha) was significantly increased with the application of 40 kg P ha^{-1} level. There also has been reported by several researchers that the application of P increased seed yield of guar (Meena and Sharma, 2001; Shivran, 2004). Our findings are in totally agreement with the results of these researchers.
ANOVA indicated that the 1000-grain weight was significantly impressed by the effect of P levels (Table 2). The maximum 1000-grain weight was determined in P60 (39.0 g) whereas the minimum 1000-grain weight was found in P0 (33.6 g). Increasing P levels increased the weight of seed up to P60 level, but after the weight of seed decreased. P60 and P90 were in the same group statistically as well. As it widely known, ATP formed during photosynthesis has P in its structure and processes from the beginning of seedling growth to the genesis of seed shape and weight (Nesme et al., 2014). Contrary to present study, Hago and Guma'a (2001) stated that phosphorus (50 kg ha^{-1}) had no effect on 1000-seed weight of guar. On the other hand, Patel et al. (2010) applied that the same dose on guar but they found that the best fertilizer level was 50 kg ha^{-1} phosphorus for the maximum thousand grain weight (49.1 g). These results are in conformity with our findings.

Conclusions

In the study, higher phosphorus level produced significantly higher yield and yield components of cluster bean compared to the control treatments. As a result, application of 120 kg P ha^{-1} confirmed to be the best fertilizer level for enhanced seed yield and some yield components under Mediterranean agro-ecological conditions. Since the results are based on the research laid out in single year as a pot study, only it may be corroborated with more than one location and year.

Abstract

The sowing date defines the environmental conditions to which the crop will be exposed in important key moments of its developmental cycle that critical period for yield and quality components. Early or late planting dates on crop causes an array of morphological, physiological and biochemical changes which affect growth and development and such changes may lead to a drastic reduction in yield. This research was carried out to determine the potential of teff as a staple crop for the Mediterranean climate during 2015 and 2016 in Soke-Aydin (Turkey). The main goal of the study was to establish the optimal teff planting date for the highest grain production. The effects of different sowing dates on the grain yield and some yield characteristics were investigated. Four different dates of sowing (15th April, 15th May, 15th June and 15th July) were arranged in a Randomized Complete Block Design with three replications. The teff genotype "Dessie" was used as plant material and number of plants, plant height, panicle length, thousand-grain weight, biological yield and grain yield were tested. Two-year average results indicated that there were significant differences in mentioned characteristics among the sowing dates. The experiment has shown that the influence of sowing date on grain yield is mainly due to day-length and temperature differences that are associated with delaying the planting from April to July. Delayed sowing dates reduced the grain yield. The highest total grain yield, 2780 kg ha^{-1}, was obtained for the teff seeds sown on the 15th April under Mediterranean ecological conditions.

Key words: *Grain yield, Mediterranean climate, sowing date, teff.*

Introduction

Teff or lovegrass as a field crop is an ancient staple crop for human consumption and originates from Ethiopia dating back to 4000 BC to 1000 BC (Ketema, 1997). Similarly, it is an annual dual-purpose cereal crop grown in Australia, India, and South Africa as a forage crop. It is a self-pollinated (2n=40), a short-day plant, warm-season grass that uses the C_4 photosynthetic pathway. It belongs to the family *Poacea*, subfamily *Eragrostoidae*, tribe *Eragrosteae* and genus *Eragrostis*. There are about 350 *Eragrostis* species of which *E. teff* is the only species cultivated for human consumption. In the systematic, varieties of its are classified according to grain colour, plant habitus, inflorescence and form of spike clusters, but only grain colours (white, red/brown and mixed) in commercial marketing. The oval-shaped its grain is not glume like wheat or rye. It is the grain of the smallest grain size (less than 1 mm) in the world. A thousand-grain weight is usually 200–400 milligrams (NRC, 1996). Unlike other cereals, the seeds of teff are gluten-free and they are considered a rich source of proteins and nutrients, which can be used as an alternative food source for people with celiac disease and diabetes. It is an excellent food security crop because it is highly resistant to various biotic and abiotic stresses (Spaenij-Dekking et al., 2005).

Teff possesses desirable storage properties without losing viability since the grains are resistant to storage pests compared to the other cereals under the local storage conditions.

One of the key components of plant production is the determination of the sowing date. To obtain high yield and quality products in teff cultivation, it is very important to determine the most adequate growing period where the plant could reach physiological maturity by selecting the most suitable cultivar. Many researchers have overemphasized the effect of sowing time on the grain yield of its. Teff is a newly introduced plant to Turkey, and therefore, knowledge on the productivity and yield of the teff crop under the intensive farming management in the Mediterranean environment has not been well documented so far. Hence, this paper aims to investigate the relationship between yield and yield contributing characters of teff regarding the sowing date under Mediterranean climatic conditions.

Materials and Methods

A field experiment was conducted in two consecutive growing seasons (2015 and 2016) on a private farm in Soke-Aydin (Turkey), located about 35 m above sea level with typical Mediterranean climate conditions. The experimental area is located in the Mediterranean zone of the country with temperate and rainy winters and hot and dry summers. Average temperature and total precipitation data through experimental period (from April to November) were 22.4, 22.9 ºC and 322.2, 144.3 mm, respectively. Average temperature was generally in accordance with long-term average (21.8ºC) but total precipitation of the first year was higher than long-term average (262.5 mm). The soil had sandy texture (80.1% sand, 1.8% clay and 18.1% silt) with a pH of 7.2, organic matter 1.27%, salt 0.05%, total N 0.06%, available phosphorus 2.54 $mg \cdot kg^{-1}$ and available potassium 403 $mg \cdot kg^{-1}$. There are no limiting factors for the establishment and growth of the teff crop in climate and soil conditions of the experimental site.

The Dessie teff cultivar from South Idaho/USA was used as crop material. Four different dates of sowing (15th April, 15th May, 15th June and 15th July) were employed in a randomized complete block design with three replications. Experimental plots were 10.5 m^2 (5 m x 2.1 m), having 12 rows with a row spacing of 17.5 cm. Seeds were sown by hand at a depth of 1 cm on all sowing times at a rate of 20 kg ha^{-1}. The overhead sprinkler system was installed in the field during both growing seasons. The soil was cultivated before sowing, 50 kg ha^{-1} of nitrogen (urea form) and 50 kg ha^{-1} of P_2O_5 were applied before the soil was cultivated again to produce a seedbed suitable for planting and the rest of nitrogen (50 kg ha^{-1}) in the form of $(NH_4)_2SO_4$ was applied at 30–40 cm plant height (Giday et al., 2014). No herbicides were used to control weeds. The weeds were controlled by three hoe weeding regimes throughout the experiment. No diseases or pests were observed in teff plants during the trial.

Plants were harvested at the physiological maturity stage (~13% moisture) from mid-August to late November in both years, collecting the middle 10 rows of plots in order to avoid border effects (Net: 8.75 m^{-2}). Two harvests were done in every experimental year. In each plot, cuttings were made with a hand-sickle at 5 cm above the ground level. The samples were dried under shaded-open conditions for one week, after which the dried samples were threshed by a seed threshing machine. In the study, the following characteristics were investigated: number of plants at grain harvest (plant m^{-2}): The plants in the quadrate of ½ square meter (50 x 100 cm) put in two different sites of the plot before harvesting were counted. Plant height (cm): 10 plants from the ground level to the top of the stem at the time of harvesting were measured. Panicle length (cm): the panicle of each selecting plant was measured from the node (the first panicle branch started) to the tip of the panicle. Thousand-grain weight (mg): the grains were taken from each plot and 1000 grains were counted by hand and then weighed. Biological yield (kg ha^{-1}): after the harvesting, total above-ground biomass (with grains) was measured. Grain yield (kg ha^{-1}): the grains of all the crops of each separated plot were weighed and the grain yield/plot was then converted to kg per hectare. All data were subjected to analysis of variance (ANOVA) using the Statistical Analysis System (SAS, 1998). The Least Significant Difference (LSD) test at $P \leq 0.05$ was used to separate means whenever there were significant differences (Stell et al., 1997).

Results and Discussion

Number of plants: The number of plants at grain harvest was affected by the year x sowing date interaction (Table 1). The maximum number of plants being 2574 plant m^{-2} was recorded on the 15th April in 2016 and the minimum number of plants (1593 plants m^{-2}) was recorded on the 15th July in 2016. The delaying of sowing date (from mid-April to mid-July) decreased the number of plants in both experimental years. Hence, prolonged growing season causes more plant numbers. This could be associated with the facts that rising temperatures and weed competition in late sowings (mid-June and July) was the main effect on the decreasing number of plant. In North Gondar, Ethiopia, Zucca (2016) reported that differences among the sowing dates with regard to the number of tillers per plant were highly significant. Similar results have been reached in research by Geren et al. (2019), with the highest number of teff plants (1734 plants m^{-2}) obtained from the sowing date of mid-April and at 17.5 cm row spacing under typical Mediterranean climatic conditions. It was stated that the number of tillers per plant of teff was affected by the sowing date from early July to late July being 3.8 per plant to 6.9 per plant. In the present study, the delaying sowing date caused the decreasing of the plant number per unit area. In addition, it is widely known that the number of plants at grain harvest reacts positively and directly with the grain yield.

Table 1. The effect of different sowing dates on the grain yield and some yield characteristics of teff crop

Y: year, SD: sowing date, int: interaction, ns: not significant

Plant height: ANOVA results showed that plant height was significantly affected by sowing date and year, but the interaction had no significant effect on plant heights (Table 1). The highest plant height (107.6 cm) was obtained on the 15th April, which was followed by the 15th May (106.7 cm). However, there was no statistical difference between April and May. The lowest plant height was determined in planting on the 15th July being 91.5 cm. There were significant differences between the two years in terms of plant height. The average plant height of the first year (105.0 cm) was higher than that of the second year (96.4 cm). Variability of precipitation recorded during the trial years caused this result. In experimental conditions, the delaying of sowing date in teff crops led to a decrease in plant height in both years. This can be a result of the shortened vegetative growth period available to the crop plants due to changes in the photoperiod that enhanced the rate of development towards the reproductive phase (Assefa et al., 2015). Juraimi et al. (2009) investigated different sowing dates (SDs) on teff plants (the 1st SD [the second week of July], the 2nd SD [delayed by 7 days after the 1st SD] and the 3rd SD [delayed by 15 days after the 1st SD], respectively). They reported that plant height decreased by delaying sowing dates (89, 84 and 78 cm, respectively).

Panicle length: Year effect was also significant, and average teff panicle length of the first year (26.8 cm) was higher than that of the second year (23.8 cm) due to higher total precipitation in the first year. The year x sowing date interaction was significant for the panicle length (Table 1). The highest panicle length (28.8 cm) was obtained on the 15th April in 2015, whereas the lowest was 20.4 cm on the 15th July in 2016. The panicle length of teff decreased noticeably with the late sowing (the 15th July) in both trial years. Some of the previous researchers recommended early sowing for high panicle length during production seasons (Juraimi et al., 2009; Zucca, 2016), and they also stated that an increase in panicle length was a corresponding increase in teff grain yields, provided that there was no delay in sowing.

1000-grain weight: ANOVA results showed that 1000-grain weight was significantly affected by sowing date and year, but not by the interaction. The year effect was also significant for this feature and the average value in the first year (213 mg) was lower than in the second year (219 mg). Thousand-grain weight significantly increased with the delay in sowing date from the 15th April to the 15th July. The heaviest grains (277 mg) were produced in plots sown on the 15th June and, thousand-grain weight on the 15th April, 15th May and 15th July were not statistically at par with each other (Table 1). Numerically, the least grain weight (154 mg) was obtained when teff was sown on the 15th July. In the present study, delaying sowing dates (from mid-April to mid-

July) caused a limited but significant increase in thousand-grain weight in the first harvest in both growing seasons. Nevertheless, we did not obtain any grain from the second harvest of mid-July sowing in the experimental area; therefore, the means of thousand-grain weights were lower. In addition, thousand-grain weight increased due to the decrease of fertile inflorescence per plant. Many researchers (Kebede, 2012; Asefa et al., 2014; Giday et al., 2014) reported that timely sowing gave higher thousand-grain weight as compared to delayed sowing.

Biological yield: The year effect was also significant for this treat and the average value in the first year (8670 kg ha^{-1}) was higher than in the second year (7930 kg ha^{-1}) (Table 1). The highest biological yield was recorded for the first sowing date (9110 kg ha^{-1}) and the lowest biological yield was recorded for the last sowing date (6500 kg ha^{-1}). In addition, there was no statistical difference between April (9110 kg ha^{-1}) and May (9000 kg ha^{-1}) sowings time in terms of biological yield. The sowing date x year interaction was not significant for the biological yield. Delaying of sowing time caused a decrease in biological yield. A single year field experiment at Alem Tena (Central Ethiopia) showed that when sowing dates were delayed by 1 or 2 weeks, the biological yield was reduced by 35% (Juraimi et al., 2009). Contrarily, some studies in other countries showed that the sowing date had no effect on total biological yield (Vos et al., 2013). Roseberg et al. (2007), in Oregon, mentioned that the total biological yield increased (8627, 10728, 10927 and 12567 kg ha^{-1}) remarkably as sowing time was delayed (the 16th May, the 30th May, the 13th June, and the 27th June), respectively.

Grain yield: The ANOVA results indicated that the grain yield was significantly affected by year, sowing date. The average grain yield in the first year (2380 kg ha^{-1}) was higher than in the second year (2250 kg ha^{-1}) (Table 1), most probably due to providing better humidity and precipitation for the maturation of crops in 2015 compared to 2016. According to two-year results, the maximum total grain yield (2780 kg ha^{-1}) was recorded for plants established at the sowing date of the 15th April. However, the minimum total grain yield (1520 kg ha^{-1}) was recorded for plants established at the sowing date of the 15th July. The year effect was also significant. Delaying of sowing time consistently decreased the grain yield. In other words, delays in sowing date also reduced yield components such as the number of plants per unit area, panicle length and the effective duration of grain filling compared with earlier sowings. It is reported that low temperature reduced grain yield as a result of a reduction in basal tiller numbers, grain number and individual grain weight (Fussell and Norman, 1980; Ong and Squire, 1984). In the present study, it was also found that 80% of the total yield was obtained from the first harvest. In both years, teff grain yield could not be obtained in the second harvest of the crop, which was sown late (on the 15th July) under the experimental area conditions. This indicates that regrowth after grain harvest can also be used as a different alternative like grazing.

Grain yield per unit area is a function of the integrated effect of the yield components that are affected differently by growing conditions (Khan et al., 2000). Sherif (2004) reported a similar relationship among different sowing dates (15, 22 and 28 July) for grain yield of teff. When sowing was delayed for 7 and 15 days, grain yields were reduced by 60% and 68%, respectively. Mengitsu et al. (2001) informed that early sowing in teff cultivation affect positively grain yield at the rate of 19% compared with late sowing. In addition, Juraimi et al. (2009) wrote that timely sown teff produced 18% and 19% higher yield compared to sowing delayed for 7 and 15 days, respectively. Conversely, Dent and Reid (2009) expressed that teff grain yield increased (54, 119, 610, 1168 and 94 kg ha^{-1}) with the delaying sowing dates but later decreased (12th October, 25th October, 11th November, 22th November, 7th December, respectively) in South Tasmania. Vos et al. (2013) conducted a field experiment in Wageningen (Netherland), in 2006 for two sowing dates (April 28th and May 16th) with four teff cultivars. They found that there was no difference in grain yield among cultivars and between the 28th April (1075 kg ha^{-1}) and the 16th of May (1068 kg ha^{-1}).

Conclusion

The objective of the study was to determine the optimal teff planting date for maximising grain production. The vast agro-climatic variation among teff producing countries and the seasonal difference within regions do not allow the allocation of a specific date of sowing. Maximum total grain production was achieved from the 15th April planting, which gave yields of 2780 kg ha^{-1} for the 2015/2016 season. As a conclusion, the 15th April can be recommended as a suitable sowing date in terms of maximum grain production under Mediterranean-type ecological climate conditions.

Abstract

This study aimed to determine the phenological and pomological traits of new walnut cultivar named 'KSU-46'. This cultivar was obtained from crossing between 'Maras 18' x 'Franquette'. The reason why these cultivars were chosen as parents in the breeding program was that Maraş-18 had very superior fruit traits and 'Franquette' was the latest leafing cultivar. 'KSU-46' was registered and patented by the Republic of Turkey Ministry of Agriculture and Forestry, Variety Registration, and Seed Certification Center in 2021. In this study, the phenological and pomological traits of 'KSU-46' are presented by comparing them with 'Chandler' and 'Maras 18'. 'KSU-46' have late season leafing same as 'Chandler' and important nut traits. In addition, the cultivar has earlier harvest and defoliation than the 'Chandler'. Time of male flowering compared to female flowering of 'KSU-46' is protandrous. The nut weight, kernel weight, and kernel percentage of 'KSU-46' are 12.53 g, 6.35 g and 50.72%, respectively. The nuts of the 'KSU-46' have medium size, broad eliptic fruit shape, moderately grooved shell structure and yellowish white kernel. In this study, results indicate that this walnut cultivar have good performance considering some phenological and pomological traits.

Keywords: *Walnut, Juglans regia L., Phenology, Pomology, New Cultivar.*

Introduction

Walnut (*Juglans regia* L) is the most produced nut species in the world. Walnut kernel is a nutrient-rich food that has many beneficial contents (unsaturated fatty acid , proteins, vitamins and antioxidant etc.) in terms of human health (Martinez et al., 2010; Xiaoying et al., 2014).
Asia, America and Europe continents stand out in walnut production. The countries that produce the most walnuts in the world are China, USA, Iran and Turkey, respectively. There has been a significant increase in world walnut production after 1984. In 2019, the world production of walnut is approximately 4.5 million tons (FAO, 2021).
The demand for walnuts is increasing due to the increasing world population and the demand for healthy food in people's diets. However, due to the decrease in agricultural areas, the development of more productive and quality cultivars from the existing standard cultivars is one of the primary objectives of breeding in order to meet the increasing demand. In addition, pomological traits such as fruit size, shell strength, ease of removal of kernel halves and kernel percentage are among the other targets of walnut breeding programs. Recently, the adaptation of walnuts to the climatic changes caused by global warming is another important topic in breeding programs (Bernard et al., 2020).

The most important factors limiting walnut cultivation as climatic conditions are late spring and early autumn frosts. In most breeding studies that have been carried out for this purpose, breeders have aimed to identify new genotypes with late leafing and early deciduous. (McGranahan and Lesile, 2009; Ebrahimi et al., 2015; Sütyemez et al 2018; Bükücü et al., 2020). When the walnut breeding studies are examined, one could see that they aimed to collect all or most of the superior traits such as resistance to biotic and abiotic stress conditions, as well as yield and quality criteria into one cultivar. It has been observed that there are significant differences in many studies conducted to determine the phenological and nut traits of walnut populations in different parts of the world (Sharma and Sharma 1998, 2001; Yarilgac et al. 2001; Kazankaya et al. 2001; Solar and Stampar 2003; Zeneli et al. 2005; Cosmulescu and Botu 2012; Cosmulescu 2013; Sütyemez, 2016; Yıldız and Sümbül, 2019). Among the local walnuts with high genetic variation, there is a high possibility of promising genotypes having good fruit quality, late leafing, low chilling requirement and disease resistance. However, finding a genotype that combines all of these traits is very unlikely (Germain, 1997; Zeneli ve ark. 2005). Cultivars or genotypes obtained by selection breeding are very important in terms of both revealing genotypes with superior traits existing in nature and preserving genetic diversity. In recent years, cross-breeding studies have become preferable over selection breeding because of the possibility of collecting more than one heritable trait in one genotype. It should be noted that this process takes longer time than selection breeding. To date, many cultivars have been developed using these breeding methods in the world and Turkey. However, fruit breeding is a long journey that need to be kept up to date and struggled to identify genotypes superior to the old cultivars. This long journey is a major problem that hinders the development of new cultivars.

In the last decades, the number of walnut breeding programs and studies aiming to preserve genetic diversity have increased significantly in the world. In this sense, very important steps are being taken in Turkey as well. Anatolia is a region having significant genetic richness, where walnuts can be found in almost every region. To date, many studies have been conducted and continue to be conducted in Turkey for the screening of genotypes with superior traits. In recent years, there has been a significant increase in the number of new cultivars obtained by crossbreeding.

In this study, some phenological and nut traits of the new cross-breed walnut cultivar 'KSU-46', patented in 2021 by Sütyemez (2005) within the scope of the cross-breeding program, are presented. In addition, performance evaluation was made by comparing the phenological and pomological characteristics of 'Maras 18' and 'Chandler' cultivars planted in the same period with the cultivar 'KSU-46'.

Material and methods

This research was carried out on 'KSU-46' walnut cultivars, which were obtained from cross-breeding program initiated by Prof. Dr. Mehmet Sütyemez in 2005 and patented on 19.03.2021. In the study, phenological and pomologicala comparisons were made with 'Chandler' and 'Maras 18' planted at the same age. 'Chandler' and 'Maras 18' cultivars were also evaluated and compared with 'KSU-46'. The study was located in the Nut Application and Research Center (SEKAMER), Kahramanmaras, Turkey. SEKAMER is located at 37° 35' 27" N latitude, 37° 03' 28" E longitute and 930 m above sea level. The region has a mild climate - an average between Mediterranean and Continental climates with average 727 mm yearly precipitation and 16.9°C yearly temperature. The soil structure in general is suitable for walnut cultivation, and the plants in this study have been irrigated regularly. The trees of each cultivar, were propagated on *Juglans regia* L. seedling rootstocks in 2011. Five plants with similar growing qualities were used for each genotype. The average of the values of the pomological and phenological traits taken for two consecutive years (2019-2020) were presented. The definitions of 14 phenological and 12 pomological traits examined in the study are given in Table 1 and Table 2 (IPGRI, 1994; UPOV, 2014).

Table 1. Descriptors of the phenological traits

Traits	***Description***
Leafing date	Date when 50% of terminal buds had enlarged and the bud scales had split exposing the green leaves
First male bloom date	When first pollen shedding occurred
Last male bloom date	When last pollen shedding occurred
First female bloom date	Date of initial pistillate flower receptivity
Last female bloom date	Date of last pistillate flower receptivity
Male flowering times	Catkins receptive duration
Female flowering times	Female flower receptive duration
Female abundance	Female flower abundance: 3 light; 5 intermediate; 7 high
Catkin abundance	Male flower abundance: 3 light; 5 intermediate; 7 high
Lateral bud flowering	Percent of lateral buds with female flowers
Dichogamy	Female flowers and catkins receptive duration overlap status: 1 Protandrous; 2 Protogynous; 3 Unknown
Yield	The yield per tree of 8 and 9-year-old trees was determined as kg.
Harvest date	When nuts are harvestable
Defoliation date	Date of defoliation

Table 2. Descriptors of the pomological traits

Traits	***Description***
Nut shape	1: Round; 2: Triangular; 3: Broad ovate; 4; Ovate; 5: Short trapezoid; 6: Long trapezoid; 7: Broad eliptic; 8: Eliptic; 9: Cordate
Shell texture	1: Very smooth; 3: Smooth; 5: Medium; 7: Rough; 9: Very rough
Shell colour	1: Very light; 3: Light; 5: Medium; 7: Dark; 9: Very dark
Shell strength	1: Paper; 3: Weak; 5: Intermediate; 7: Strong
Shell thickness (mm)	Near center of half shell was measured with a digital caliper.
Shelled nut weight (g)	Average of total 50 nuts
Kernel weight (g)	Average of total 50 nuts
Kernel percentage (%)	Kernel weight/nut weight × 100
Kernel colour	1: Extra light; 2: Light; 3: Light amber; 4: Amber
Kernel fill	3: Poor; 5: Moderate; 7: Well

Results and Discussion

In this study, information about some pomological and phenological traits of the 'KSU-46' is presented. The leafing date of 'KSU-46' was determined as April 24. While 'Chandler' had a date of April 23, 'Maras 18' had a leafing date 10 days before 'KSU-46'. In order to protect the walnut from late spring frosts, it is desired the leafing date is late. 'Chandler' is classified as a late leafing cultivar among standard walnut cultivars. In terms of this phenological trait, 'KSU-46' showed the same traits with 'Chandler' (Tablo 3). Therefore, it can be said that the 'KSU-46' is suitable for cultivation in regions where late spring frosts are observed frequently. Luedeling and Gasner (2012) reported that the average leafing date of the 'Chandler' was April 4th in California between 1988 and 2007. Türemiş et al. (2017) stated that the leafing date of 'Maras 18' occurred between March 31 and April 24 in 2015. The differences in the findings of the research are due to climatic changes and ecological differences over the years.

It is important to know the flowering traits of a plant species such as walnut with a high dichogamy tendency. In various studies, it has been reported that 'Chandler' and 'Maras 18' have protandrous flowering traits (Sütyemez, 2016; Soleimani, 2019; Sütyemez et al., 2019). As a result of phenological observations made to determine the dichogamy status of 'KSU-46', it was determined that the first and last male bloom date of the cultivar were 22 April and 29 April and the first and last female bloom dates were May 2 and May 11, respectively. In this study, it was determined that KSU-46 had protandrous flowering trait. 'Chandler' and 'Maras 18' cultivars examined in the study had protandrous flowering trait, which were consistent results obtained with the previous studies on these cultivars. The findings of the flowering traits of the cultivars are presented in Table 3.

Lateral bud flowering and female abundance are important parameters to determine the yield in walnut. In addition to these two traits, male abundance was determined in the study. Lateral bud flowering of 'KSU-46' was determined as 80.8%. 'Chandler' is a walnut cultivar with high lateral bud flowering (Manthos and Rouskas, 2021).We found that the lateral bud flowering rate was 90.5% for 'Chandler' and 70.8% for Maraş 18. In terms of lateral bud flowering, 'KSU-46' had a percentage between the standard cultivars. The female abundace of the cultivars were determined as medium for 'KSU-46' and 'Maras 18', and high for 'Chandler'. The male flower abundance determined as light for 'KSU-46', medium for Maraş-18 and high for 'Chandler'. Suyemez et al. (2019) stated that the 'Chandler' has a high male flower abundance. If the maintenance conditions and fertilization status of a cultivar with high lateral bud flowering are at optimum level, the yield per tree would be high. In this study, the average yield per tree at the 8th and 9th years of 'KSU-46' was determined as 4.97 kg. While this value was 7.38 kg for 'Chandler', it was 4.34 kg for 'Maras 18' (Table 3).

In this study, the harvest date of the cultivars were determined, and we found that the 'KSU-46' was harvested on the same date as 'Maras 18' (Sep. 17). 'Chandler' reached harvest maturity on October 6. Manthos and Rouskas (2021) reported that the 'Chandler' reached harvest maturity on October 2. The findings are consistent with our study. Early defoliation dates are an important parameter that is effective in protection from early autumn frosts. 'Maras 18' is classified among early deciduous cultivars (Sütyemez, 2016). In terms of this trait, the defoliation date of the 'KSU-46' was 5 days after one of its parents, 'Maras 18'. For this reason, 'KSU-46' is recommended for regions where frost is observed intensely in the early autumn periods (Table 3).

Table 3. Phenological traits of 'KSU-46', 'Chandler' and 'Maras 18'.

Phenological Traits	***Cultivars***		
	KSU-46	**Chandler**	**Maras 18**
Leafing date	April 24	April 23	April 14
First male bloom date	April 22	April 19	April 14
Last male bloom date	April 29	April 27	April 23
First female bloom date	May 2	April 29	April 22
Last female bloom date	May 11	May 11	April 29
Male flowering times	7	8	9
Female flowering times	9	12	8
Female abundance	Intermediate (5)	High (7)	Intermediate (5)
Catkin abundance	Light (3)	High (7)	Intermediate (5)
Lateral bud flowering	80.8%	90.5%	70.8%
Dichogamy	Protandrous	Protandrous	Protandrous
Yield (kg/tree) (6.-7. Years in tree)	4.97 kg	7.38 kg	4.34 kg
Harvest date	September 17	October 6	September 17
Defoliation date	November 7	December 5	November 2

It is very important to determine the pomological traits of fruits in breeding studies. Fruits with superior pomological traits are always highly demanded in the market and therefore sold at higher prices. The most important traits that determine the nut quality of the walnut are the shelled nut weight, kernel weight, kernel percentage, kernel colour, ease of removal of kernel halves and shell strength. As a result of the pomological analysis, it was determined that 'KSU-46' had a broad eliptic nut shape, smooth shell structure and a light shell color. 'KSU-46' differed from 'Chandler' and 'Maras 18' in terms of fruit shape. Sütyemez (2016) reported that the 'Chandler' and 'Maras 18' has an oval shape. In this study, similar findings were obtained in terms of this trait.

While the shell strength of 'KSU-46' and 'Maras 18' cultivars was intermediate, shell strength of 'Chandler' was weak. As expected, the shell thickness was 1.32 mm for 'KSU-46', 1.22 mm for 'Chandler' and 1.39 mm for Maraş-18. A weak strength is a desirable feature in walnut cultivars. Mahmoodi et al. (2016), in a study conducted in Iranian ecological conditions, stated that the shell thickness of the 'Chandler' was 1.28 mm. It is thought that the difference between these values is due to the age of the plants and the maintenance conditions.

Shelled nut weight is another trait that increases the cultivar's appeal. The shelled nut weight of 'KSU-46' was determined as 12.54 g. The shelled nut weight of Chandler's was 12.51 g, and it was determined that it had close values with 'KSU-46' in terms of this trait. 'Maras 18' had a higher value than the other two cultivars with 14.71 g shelled nut weight. Erturk et al. (2017), found that the shelled nut weight of the 'Chandler' was 12.58 g and the 'Maras 18' was 14.01 g. In addition, Sütyemez (2016) stated that the shelled nut weight of 'Maras 18' varies between 13-15 g and the shelled nut weight of 'Chandler' varies between 12-14 g. The findings obtained in the study showed consistency with our findings.

In walnut breeding, it is desired that the kernel percentage of a cultivar should be higher than 50%. It is seen that the kernel weight changes according to the population used in the studies and ecological conditions. In various studies, it has been determined that the kernel weight in walnuts varies between 1.69 g-14.00 g, and the kernel percentage varies between 28.18%-63.21% (Asma, 2012; Sütyemez, 2016; Ipek et al., 2019; Ergün and Bulduk, 2020; Bujdoso and Cseke, 2021; Kavosi and Khadivi, 2021). In our study, the kernel weight of 'KSU-46' was 6.34 g and its kernel percentage was 50.56%. While these values were 6.04 g and 48.50% for 'Chandler', 7.80 g and 53.05% for 'Maras 18'. 'KSU-46' showed a outstanding performance with its kernel percentage. Generally, there is a corelation between the kernel percentage and kernel fill (Khadivi-Khub et al., 2015). In this study, 'KSU-46' had a well kernel fill in parallel with its kernel percentage. The ease of removal of kernel halves was easy for 'KSU-46' and 'Maras 18', while it was very easy for 'Chandler'. In addition, it all cultivars examined in the study had a satisfactory kernel flavour. The image of the nuts of the 'KSU-46' is presented in Figure 1.

Table 4. Pomological traits of 'KSU 46', 'Chandler' and 'Maras 18'.

Pomological Traits	***Cultivars***		
	KSU-46	**Chandler**	**Maras 18**
Nut shape	Broad eliptic (8)	Ovate (5)	Ovate (5)
Shell texture	Smooth (3)	Medium (5)	Smooth (3)
Shell colour	Light (3)	Light (3)	Very light (1)
Shell strength	Intermediate (5)	Weak (3)	Intermediate (5)
Shell thickness	1.32 mm	1.22 mm	1.39 mm
Shelled nut weight	12.54 g	12.51 g	14.71 g
Kernel weight	6.34 g	6.04 g	7.80 g
Kernel percentage	50.56%	48.30%	53.05%
Kernel colour	Light (2)	Light (2)	Light (2)
Kernel fill	Well (7)	Well (7)	Well (7)
Ease of removal of kernel halves	Easy (3)	Very easy (1)	Easy (3)
Kernel flavour	Satisfactory (1)	Satisfactory (1)	Satisfactory (1)

Figure 1. Visual of the nuts of the 'KSU-46'.

Conclusions

As a result, 'KSU-46', which was obtained from the cross-breeding program in which 'Maras 18' and 'Franquette' were used as parents, is a walnut cultivar that stands out due to its late leafing. The cultivar also reach to early harvest maturity and it has an early defoliation period. In addition, 'KSU-46' has superior pomological traits in terms of some nut quality criteria. The nut weight of 'KSU-46' was determined as 12.54 g, and it is seen that it is a higher than 'Chandler'. This cultivar can be easily recommended for regions where 'Chandler' is not affected by late spring frosts. The authors can be contacted for the supply of scion wood materials and saplings of the cultivar.

Abstract

Many plant species synthesize various biochemical substances from their various organs such as leaves, flowers, fruits, and roots. While some of these biochemical substances have a stimulating effect on the growth and development of other plants, some of them have an inhibitory effect. In this study, the effect of seed extracts of the tesbi (*Styrax officinalis* L.) bush, which spreads naturally in the Mediterranean and Aegean regions, on the seedling growth of sweet fennel (*Foeniculum vulgare* Mill. var. *dulce*), coriander (*Coriandrum sativum* L.), fenugreek (*Trigonella foenumgraecum* L.), camelina (*Camelina sativa* L.) and mustard (*Sinapis arvensis* L.) plants were investigated. In the study, the extracts prepared from the ground tesbi seeds with distilled water at 5% concentration were boiled in three different times (S0: control, S1:15 min, S2:30 min, and S3:45 min). To determine the effects of extracts on seedling growth, seedling height, root length, seedling fresh-dry weights, and true leaf numbers were determined. In S0, S1, S2 and S3 applications, seedling lengths were 14.8-34.5 cm, 9.3-30.4 cm, 12.3-33.5 cm and 10.2-28.0 cm, respectively; root length 5.2-27.0 cm, 4.1-20.1 cm, 6.4-25.6 cm, 4.4-19.5 cm; seedling fresh weight 0.05-0.549 g, 0.033-0.446 g, 0.046-0.136 g and 0.029-0.543 g; seedling dry weight was 0.008-0.123 g, 0.005-0.093 g, 0.007-0.075 g and 0.005-0.074 g and true leaf number was between 1.0-7.0, 2.0-5.0, 2.0-6.0 and 3.0-6.0, respectively. When the findings obtained from the research are evaluated in general, it was found that extracts exhibited an inhibitory effect on seedling growth.

Introduction

Allelopathy is a biological phenomenon by which is one plant affecting another plant's germination, survival, and growth either positively or negatively (Kadıoğlu and Yusuf, 2004). German physiology scientist Albrecht Kossel divided metabolites are two categories named "primer and seconder metabolites". Primer metabolites (protein, fat, carbohydrate) are found in all cells and have various functions. On the other hand, seconder metabolites are not found in all cells or do not have important functions in the life of plants. Up until now, 100.000 seconder metabolites are discovered, and this is thought to be over 1 million (Mammadov, 2014). Seconder metabolites (anthocyanins, carotenoids or flavonols, etc.) are being synthesized in low quantities in plants' metabolism but a major role in the plant's fitness for survival (Thoma et al., 2020). However, important seconder metabolites such as phenolics, alkaloids, terpenoids, glucosinolates, etc. are known allelochemicals. Generally, these compounds act with concentration, low concentrations are promoting plant growth and increasing concentration shows allelopathy effect (Farooq et al., 2011).

Styrax officinalis L. is a deciduous shrub distributed in the east and southeastern Asia and the Mediterranean region (Cesur et al., 2019;). The plant seed constituents some biochemical substances such as eugenol, benzofuran, homoegonol, gonol-β-gentiotrioside, egonol-β-gentiobioside, and fatty acids (Jaradat, 2020; Cesur et al., 2019; Akgul and Anil, 2003).
A lot of research was done on the allelopathic effect of plant extracts to effects on germination. Especially medicinal plant extracts are very important due to their seconder metabolites content. Kadıoğlu and Yanar (2004) used 22 plant extracts for determining and their effect on nine weeds germination. The result of the study, researchers have determined that some extracts can be used as herbicides. Özbay (2017), investigated some medicinal plant extract for effect on pepper (*Capsicum annuum* L.) germination. The results showed that the germination of pepper was affected by the concentration of extracts. Teaca et al. (2008), applied three different medicinal plant extract on soybean, bean, rye, wheat, and triticale. Increasing the dose of extract inhibits seed germination. As these studies show, extracts obtained from different parts of plants can show different effects on plants by showing alleloopathic effects.
This study was conducted to investigate allelopathic effect of tesbi seed extracts on sweet fennel (*Foeniculum vulgare* Mill. var. *dulce*), coriander (*Coriandrum sativum* L.), fenugreek (*Trigonella foenumgraecum* L.), camelina (*Camelina sativa* L.), and mustard (*Sinapis arvensis* L.).

Material and Methods

Tesbi (*Styrax officinalis* L.) seeds were finely ground with a laboratory-type blender. Each 100 ml tap water 4 gram tesbi seed powder added and boiled until reach to 15, 30 and 45 min. The obtained solution is rest for two days and then filtered. The experiment design with small pots with 10 replicates. Each pot bearing three seeds. In the experiment sweet fennel, coriander, fenugreek, camelina, and mustard are used. Soil was used in pots and after sowing control is irrigated with tap water and others irrigation was carried out with the prepared extracts. Seedling grow approximately 15 cm long (56 days later, (after true leaves have appeared and new leaves are formed) experiment is ended and seedling growth, seedling height, root length, seedling fresh-dry weights, and true leaf numbers were determined. After seedling fresh weight was determined, plants were dried in the oven at 70 °C for 48 hours and then dry weight was found.

Statistical analysis

Data were collected and subjected to analysis of variance procedure. Means were separated for significance using LSD Test at $p \leq 0.05$. The statistical analysis was done using the Statistical Analysis System software v.9.0.

Result and Discussion

Effects of seed extract of *Styrax officinalis* on seedling development of *Foeniculum vulgare* Mill. var. *dulce*

The effects of *S. officinalis* at different times doses are observed on morphological traits of sweet fennel, which are given in Table 1. There was a significant ($p \leq 0.05$) difference between treatments (seedling length, root length, and leaf). Our results showed that the S0 and S2 applications of tesbi bush had a positive effect on the seedling length and root length of the fennel.

The shortest seedling length and root length were obtained from S1 and S3 applications, respectively. However, the shortest leaf number of sweet fennel was determined from the S0 application.

Table 1. Effects of *S. officinalis* extracts of different doses on sweet fennel

Dose	Seedling length (cm)	Root length (cm)	Seedling fresh weight (g)	Seedling dry weight (g)	Leaf (number)

Means followed by the same letter within the column are not significantly different at P<0.05. ns, not significant

Effects of seed extract of *Styrax officinalis* on *Coriandrum sativum* L.

At high concentrations were significantly ($P \leq 0.05$) decreased to seedling lengths in coriander. The seedling length of the tesbi shrub applications was recorded as S0>S1>S2> S3. The results showed that different tesbi extracts negatively affected the root length, seedling fresh weight, and seedling dry weight of coriander compared to the control treatments (Table 2).

Table 2. Effects of *S. officinalis* extracts of different doses on coriander

Dose	Seedling length (cm)	Root length (cm)	Seedling fresh weight (g)	Seedling dry weight (g)	Leaf number

Means followed by the same letter within the column are not significantly different at P<0.05.

Effects of seed extract of *Styrax officinalis* on *Trigonella foenum-graecum* L.

The tesbi seed extracts (S1, S2, and S3) significantly ($p \leq 0.05$) reduced the seedling length and root length of fenugreek tested. It has been observed that the extracts affect the root development of the plant negatively. On the other hand, as the boiling time of the extracts increased, the fresh and dry weight, and leaf number of the seedlings increased. (Table 3).

Table 3. Effects of *S. officinalis* extracts of different doses on fenugreek

Dose	Seedling length (cm)	Root length (cm)	Seedling fresh weight (g)	Seedling dry weight (g)	Leaf number

Although the camelina plant emerged in other applications except for the control application, there was no development in the seedlings. Therefore, it was excluded from the study.

In this study, the effects of extracts on seedling growth, seedling height, root length, seedling fresh-dry weights, and true leaf numbers were determined in different plants. When the control application and different applications of the test seed extract were compared, the highest values were obtained from the control, while some decreases were observed with increasing boiling time in different applications. Also, the responses of plant species were different. Allelopathy is one plant's directly affecting another plant's growth either positively or negatively, exuding chemical substances (Rice, 1984). Verma et al. (2012), reported that the inhibitory effect was exhibited by all the extracts with a maximum in leaf followed by root and seed extract. Karaaltin et al. (2004) reported that *Nerium oleander* extracts significantly reduced radicle length. Also, Baličević et. al. (2015), reported that seed allelopathic effect, both stimulatory and inhibitory, was reported in other species.

Conclusion

The results showed that extracts from tesbi bush negatively affected seedling length, root length, seedling fresh weight, and seedling dry weight of all tested crops compared to the control treatments. However, it was observed that it increased the number of leaves in all plants. The effect of the extracts differed depending on the boiling times and the plant species. We can say that the chemical composition of the extract changes depending on the boiling time. The findings obtained from this study are preliminary information and various phytochemical analyzes are needed to fully explain this effect.

THE INFLUENCE OF NITROGEN ON THE GRAIN YIELD AND SOME AGRONOMIC CHARACTERISTICS OF SWEET SORGHUM (*Sorghum bicolor* var. *saccharatum*)

Tugçe OZDOGAN CAVDAR*, Esra CAM, Hakan GEREN

Ege University, Faculty of Agriculture, Dept. of Field Crops, Bornova, Izmir, Turkey

Abstract

Sorghum species are widely grown in the sub-tropical and temperate regions of the world as animal feed, human food, or bioenergy feedstock. It is capable of overcoming adverse climatic conditions through variable growth alternatives and sustains grain and forage production. Sweet sorghum has also many advantages such as wide adaptability, drought and waterlogging tolerance, saline-alkali resistance, and fast growth. Nitrogen is a crucial component of plant nutrition, and its deficiency limits productivity of crops more than any other element. Nitrogen (N) levels can alter performance of sweet sorghum in the sustainable second crop production system. In this reason, a pot experiment was conducted to determine the effects of nitrogen levels on the grain yield and some agronomic traits of sweet sorghum (*Sorghum bicolor* var. *saccharatum*). The experiment was carried out at the Bornova experimental fields of Field Crops Department of Agriculture Faculty, Ege University, Turkey, during 2019 second-crop growing season with typical Mediterranean climate conditions. The experiment was laid out in randomized complete block with four replicates. Seven nitrogen levels (0-50-100-150-200-250-300 kg N ha^{-1}) were tested on sweet sorghum. Plant height, panicle length, biomass yield and grain yield were affected significantly in line with higher N rates except thousand grain weight. Application of the higher rates of nitrogen levels increased the grain yield and some agronomic yield characteristics compared to the control level. The highest grain yield was obtained with the application of 200 kg ha^{-1} N in sweet sorghum under second crop production system.

Keywords: *Sweet sorghum, N level, grain yield.*

Introduction

Sweet sorghum (*Sorghum bicolor* var. *saccharatum*) produces grain, which can be harvested for human consumption, like the grain sorghum, in tropical, temperate, semi-arid regions, and also poor quality soils of the world. It is quantitatively the world's fifth largest most important cereal grain, after wheat, maize, rice and barley. The crop is a C_4 species with greater strength to various agro-ecologies, limited water and fertilizer condition in additional to short lifecycle (Rao and Kumar, 2013). Basically, sweet sorghum provides like food, fodder and fuels all three requirements in one crop. For this reason it is called that 'smart' crop or 'angel' crop. And it is more profitable comparison to competing crops like maize and sugarcane under rainfed conditions (Mokariya and Malam, 2020).
To control nitrogen more succesfully in sweet sorghum production grown as second crop, it is critical to be aware of the N functioning of soil-sorghum ecosystems in more factor, for which knowledge about N uptake by sweet sorghum is needed (Harmsen, 2003). The application nitrogen results in enhancement in the grain yield and model plant growth of any crop until an

ideal rate is reached (Olugbemi, 2017). For food safety management and against the global warming potential, there is an inevitable need to reform nitrogen use planning in sustainable agricultural production system (Anas et al., 2020). The target of this study was to determine the effects of different nitrogen levels performance of grain productivity of sweet sorghum grown second crop production system.

Material and Methods

A pot study was conducted in outdoor conditions on the experimental area of Field Crops Department, Faculty of Agriculture, Ege University, Izmir, Turkey during 2019 second crop growing season with typical Mediterranean climate conditions. Some meteorological data from the experimental area in Bornova-Izmir are presented in Table 1. The experiment soil was analyzed for pH: 5.83, soil texture: loamy, avaiable Ca:1300 ppm, avaiable P: 2.54 ppm, avaiable K: 40 ppm, $CaCO_3$: 0.82%, organic matter: 2.27%, total nitrogen: 0.092%, total salt: 0.03%, sand: 80.2%, clay: 1.8%, silt: 18.0%.

Table 1. Some meteorological data of research area in Bornova, Izmir, Turkey in 2019

	2019		Long Year Average	
	Temperature (ºC)	Precipitation (mm)	Temperature (ºC)	Precipitation (mm)
August	29.8	0.0	27.9	12.7
September	24.6	31.7	23.9	18.0
October	21.2	4.0	19.1	27.7
November	16.9	41.0	13.8	31.5
Total-Mean	23.1	76.7	21.2	89.9

"Sugar-drip" variety of sweet sorghum (*Sorghum bicolor* var. *saccharatum*) was used as tested crop material. The seeds were sown in a plastic pots filled with 17 kg experimental soil on 2th August 2019, at 1 cm depth. Seven rates of nitrogen (0, 50, 100, 150, 200, 250 and 300 kg N ha^{-1}) were distributed in a completely randomized block design with four replicates. Half a dose of nitrogen fertiliser (urea), 80 kg ha^{-1} P_2O_5 (triple superphosphate) and 100 kg ha^{-1} K_2O (potassium sulphate) were applied with sowing, and the rest of nitrogen ($(NH_4)_2SO_4$) was applied at beginning of stem elongation. During the experiment, all of the pots were irrigated by tap water. In possible rainy weather, the experiment was covered by nylon sheet. Weeds were manually removed into the pots; no herbicide was used to control weeds. Alphacypermethrin was applied at 6-7 leaf stage of crops to control European corn borer (*Ostrinia nubilalis*). Panicles in every pot were isolated by net for avoiding bird damage and obtaining grain yield.

The plants were harvested for grain at physiological maturity stage (~13% moisture) by hand. According to the different nitrogen levels applied, the date of grain harvest continued from 28th October to 9th November. Plant height (cm); the plant was measured from the soil surface to the top level of the plant before grain harvest (Anonymous, 2010). Panicle length (cm); the panicle of plant was measured from the origin of panicle to the tip part. Biological yield (g plant^{-1}); after the harvesting, total above-ground biomass of plant (with grains) was measured; Grain yield (g plant^{-1}); the grains of plant were weighted after harvesting (Anonymous, 2010). Sweet sorghum grains (100) were weighted and converted for calculation of 1000-seed weights. The obtained data were statistically processed by analysis of variance (ANOVA) with the Statistical Analysis System (SAS, 1998). If ANOVA indicated differences between treatment means, a LSD test (0.01) was performed to separate them (Stell et al., 1997).

Results and Discussion

Plant height positively responded to increased N fertilization compared the control level (Table 2). The highest plant height was measured with N200 (179 cm), whereas the lowest plant height was observed with N0 (146 cm). And N200 and N250 were statistically in the same group. Nitrogen may influence plant growth through cell division and cell expansion which thus increase plant height (Stals and Inze, 2001). Some reports show that application of N increases plant height in sweet sorghum (Usofzadeh et al., 2013; Geren and Girgin, 2014). For example, Usofzadeh et al. (2013) studied nitrogen at 0 (166 cm), 100 (175.2 cm), 200 (185.4 cm) and 300 (186.5 cm) kg ha^{-1} on sweet sorghum and found that plant height was increased by nitrogen application compared to the control (0 kg N ha^{-1}). Present study totally matches the results of the researches mentioned above. ANOVA results exposed significant effect of N application at different levels on panicle length of sweet sorghum (Table 2). N200 gave the highest panicle length (19.8 cm) which was statistically the same group with N150 (17.8 cm) and N250 (17.9 cm). The lowest panicle length was observed from N untreated pots (N0:15.1 cm) which was statistically similar with N50 (15.6 cm). Gebremariam and Assefa (2015) applicated four various N levels (0, 50, 100 and 150 kg N ha^{-1}) on the sweet sorghum plants. Researchers stated that the increased panicle length at high level of N application in that study (N0:17, N50:18, N100:21 and N150:21 cm). On the other study, Kugbe et al. (2019) found that different N levels (0, 30, 60, 90, 120,150 kg N ha^{-1}) positively influenced panicle length of local sorghum varieties. Present findings are in parallel with those researcher's results.

Table 2. Effects of different N levels on the yield and some yield components of sweet sorghum

N levels	Plant height (cm)	Panicle length (cm)	Biological yield (g plant^{-1})	Grain yield (g plant^{-1})	1000 grain weight (g)
N0	146 d	15.1 d	38.8 g	13.7 e	16.8
N50	151 cd	15.6 cd	73.8 f	16.7 e	16.7
N100	155 c	16.9 bc	110.0 e	28.9 d	16.3
N150	169 b	17.8 b	123.8 d	31.2 d	16.6
N200	179 a	19.8 a	187.0 a	65.3 a	17.0
N250	173 ab	17.9 ab	162.3 b	49.9 b	16.0
N300	166 b	16.6 bc	137.5 c	38.2 c	15.7
Mean	162.6	17.1	119.0	34.8	16.4
LSD	**	**	**	**	ns

**: significant at $P<0.01$, ns: not significant

As shown in Table 3, response of biological yield per plant to different N rates was significant. Increasing N levels enhanced the biological yield up to N200 level, but after that, the biological yield noticeably reduced. The maximum biological yield was recorded at fertilizer level of N200 (187 g plant^{-1}) whereas the lowest biological yield was recorded from nitrogen untreated pots (N0:38.8 g plant^{-1}). Our result is in line with the findings of Melaku et al. (2018) who found higher biomass yield with increased levels of N in sweet sorghum. Their results determined that application of 23, 41, 64 and 87 kg N·ha^{-1} gave a yield increase of 40, 53, 62 and 69% over the control (0 kg N ha^{-1}), respectively. Nitrogen element in the plant displays a positive correlation with the plant biomass, as well as N absorption ability (Nguyen et al., 2003). There was a significant effect of N levels on grain yield of sweet sorghum (Table 2). The least grain yield (13.7 g plant^{-1}) was at N0, and the highest (65.3 g plant^{-1}) was at N200. The grain yield of sweet sorghum progressively increased with the increasing levels of nitrogen up to 200 kg N ha^{-1}, in the experiment. Nitrogen fertilizer occurred in maximum grain yields due to sufficient soil nutrient environment that advanced uptake and promoted efficient nutrient translocation from leaves and stems into the filling seed (Kugbe et al., 2019). Application of 81.25 kg ha^{-1} of nitrogen observed significantly higher values of grain yield on sweet sorghum (2.1 t/ha) than that of 65 kg ha^{-1} (2.0 t/ha) and 48.75 kg ha^{-1} (1.8 t/ha) (Hugar et al., 2010). Increasing nitrogen fertilizer increased grain yield of sorghum by many researchers around the world (Geren and Girgin, 2014; Ajeigbe et al., 2018; Arshad et al., 2020). 1000-grain weight of sweet sorghum was not affected by N levels in our study. Average 1000-grain weight was 16.4 g. Geren and Girgin (2014) stated that increasing N level (from 0 to 375 kg N ha^{-1}) had no effect on 1000-grain weight of sweet sorghum. Almodares et al. (2006) reported that grain yield in sweet sorghum increased by the application of 90 kg N+90 kg K per ha under Iran conditions, although increasing N+K levels did not effect 1000-grain weight. Amiri et al. (2014) emphasized that grain yield in sorghum increased with the increasing N rate, but there were no significant differences among 160 kg ha^{-1} or 240 kg ha^{-1} N doses, and effect of N rate was not significant on 1000-grain weight.

Conclusions

Our findings indicated that N levels had a significant effect on the all of components (except 1000-grain weight) of our tested crop material in this study. Based on the results to obtain highest grain yield, we suggested that sugar-drip cultivar of sweet sorghum may be preferred, which well adapted to experimental area, and 200 kg ha^{-1} N treatment should be applied for higher grain yields and related properties under second crop production system. However, this type of experiment should be repeated different locations and at least two years in order to give complete advice in the local farming system.

POTENTIAL GROWTH AND HERBAGE PRODUCTIVITY OF COMMON BURNET (*Poterium sanguisorba*) AS AFFECTED BY NITROGEN FERTILIZATION

Tugce OZDOGAN CAVDAR*, Deniz Alp AKCAY, Hakan GEREN

Ege University, Faculty of Agriculture, Dept. of Field Crops, Bornova, Izmir, Turkey
*Corresponding author: tugceozdogan1905@hotmail.com

Abstract

The objective of this study was to examine the effects of N fertilization on herbage yield and plant-yield components of common burnet. A pot study was carried out with six different nitrogen levels (0, 50, 100, 150, 200 and 250 kg N ha^{-1}) on common burnet (Bünyan 80 cv). The experiment was arranged as a completely randomized block design with four replications from October 2019 to November 2020 in the outdoor conditions at Izmir, Turkey. Results shown that rate of N has a significant effect on plant height, fresh and dry herbage yield, and crude protein (CP) yield of burnet. Based on the results of this study, application of nitrogen at the rate of 200 kg ha^{-1} can be recommended for obtaining the maximum yield in common burnet under Mediterranean climate conditions.

Keywords: *N level, Poterium sanguisorba, Dry herbage yield, CP yield.*

Introduction

Common burnet (*Poterium sanguisorba*) also known as sheep's burnet or salad burnet, or small burnet is herbaceous, perennial, evergreen forb in the *Rosaceae* family (Andrabi et al., 2012). Crop has a prominent taproot system, simple or branched stems, 20-60 cm tall, lower leaves adherent to the petiole and 10-15 cm long, each flower provides approximately 12 stamens and the four broad sepals (4-5 mm long, white to red or purple), but it has no petal (Cronquist, et al. 1997). It has been reported that a hay yield of 10-35 t/ha can be obtained according to growing conditions, and also 70-80 t/ha total fresh herbage yield can be obtained by cutting 5-11 times a year under irrigated conditions (Tansı and Anlarsal, 1991). Small burnet has well to excellent forage value for livestock and wildlife during all seasons (Arzani et al., 2006). It has drought, heavy frost (up to -12°C) and high summer temperatures (>30°C) tolerance (Wills et al., 1987; Stevens and Monsen, 2004). Burnet plants are also tolerant of intense grazing and satisfactory survival and production under low to moderate fertility conditions (Buckland et al., 1997).

Nitrogen is a paramount element for plants since it is a core component of many plant structures and for both their internal and external metabolic processes. One of the major facts of N is increasing chlorophyll accumulation; this process is done by creating bigger leaf structures with larger surface areas for the photosynthesizing pigment. Extravagant nitrogen fertilization has caused low N use efficiencies and critical ecological problems. For this reason, level N fertilization programs must be noted for achieving high plant yield and sustainable agriculture system (Xu et al., 2012; Zhu et al., 2016). Considering all these literatures, the objective of this study was to evaluate the influence of different nitrogen levels on the herbage yield and some yield components of burnet under Mediterranean climate agroecology conditions.

Material and Methods

A pot study was conducted in outdoor conditions on the experimental area of Field Crops Department, Faculty of Agriculture, Ege University, Izmir, Turkey from October 2019 to November 2020 with typical Mediterranean climate conditions. Some meteorological data from the experimental area in Bornova-Izmir are presented in Table 1. The experiment soil was analyzed for pH: 5.83, soil texture: loamy, avaiable Ca:1300 ppm, avaiable P: 2.54 ppm, avaiable K: 40 ppm, $CaCO_3$: 0.82%, organic matter: 2.27%, total nitrogen: 0.092%, total salt: 0.03%, sand: 80.2%, clay: 1.8%, silt: 18.0%.

Bünyan-80 variety of burnet (*Poterium sanguisorba*) was used as test material. The seeds were sown in a plastic pots filled with 17 kg experimental soil on 22th October 2019, at 1 cm depth. Six rates of nitrogen (0, 50, 100, 150, 200 and 250 kg N ha^{-1}) were distributed in a completely randomized block design with four replicates. 1/3 dose of nitrogen fertiliser (urea), 80 kg ha^{-1} P_2O_5 (triple superphosphate) and 100 kg ha^{-1} K_2O (potassium sulphate) were applied with sowing,

and 1/3 of the rest nitrogen dose was given in the first cutting, and the last 1/3 was given in the form of ammonium sulfate after the second cutting and sprinkled on the pot surface. Weed control was performed by hand. No evident crop diseases or pests were detected.

During the vegetation period, four harvests were made to determine the herbage yield of the burnet plant (21th April, 1th June, 12th August, and 3th November of 2020). It was expected that the plant would start to bloom in the harvests aimed at determining the herbage yield. The distance between above soil level and the tip point of the plant was measured before harvest with a ruler for the plant height (cm). The plant reaching the harvest period was cut by leaving 3 cm of stubble height from the soil level and the green part obtained was weighed for fresh herbage yield. The harvested crops were dried to a constant weight at 65ºC during 48 h and then were weighed (g plant^{-1}). The dried samples were ground in a mill passed through a 1 mm screen. CP contents of samples were determined using the Kjeldahl method (N%) with a conversion factor of 6.25. CP yield was calculated by multiplying the CP content with the dry yield. The obtained data were statistically processed by analysis of variance (ANOVA) with the Statistical Analysis System (SAS, 1998). If ANOVA indicated differences between treatment means, a LSD test (0.01) was performed to separate them (Stell et al., 1997).

Results and Discussion

Results presented in Table 2 shows that nitrogen levels had a significant effect on the all of tested characteristics in this study.

Table 2. Effects of different N levels on the yield and some yield components of burnet

N levels	Plant height (cm)	Fresh herbage yield (g pot^{-1})	Dry herbage yield (g pot^{-1})	CP Content (%)	CP yield (g pot^{-1})
N0	34.2 d	255 e	71 e	10.7 e	7.6 e
N50	36.1 cd	312 d	96 d	12.3 d	11.7 d
N100	37.4 c	368 c	110 c	13.1 c	14.4 c
N150	43.1 a	434 b	133 b	13.6 b	18.0 b
N200	44.0 a	490 a	146 a	14.7 a	21.5 a
N250	39.8 b	446 b	129 b	14.7 a	18.9 b
Mean	39.1	384	114	13.2	15.0
LSD (1%)	2.04	17.62	10.99	0.29	1.53
CV (%)	3.69	3.24	6.81	1.6	7.05

ANOVA indicated that nitrogen levels had significant effect on plant height in this study (Table 2). The maximum plant height (44.0 cm) was observed from N200 while the lowest plant height (34.2 cm) was observed from N0. And also there were no significant differences between N150 and N200 levels. In our study, increasing N levels increased plant height of burnet compared to the control. Çavdar et al. (2021) applied 100 kg N ha^{-1} on burnet and they recorded 20.9 cm for the plant height with irrigated conditions at the indoor experiment. İpek and Sevimay (2002) stated that increased N levels increasing plant height (N0:66.6, N40:68.1, N80:70.0 cm) of burnet plants. N is known to be functional in the construction of amino acids and chlorophyll, which can influence directly plant height by affecting photosynthesis (Xu et al., 2012).

There were statistically significant differences in fresh and dry herbage yield among the different nitrogen levels (Table 2). The highest fresh (490 g pot^{-1}) and dry (146 g pot^{-1}) herbage yield was recorded in N200, whereas the lowest fresh (255 g pot^{-1}) and dry (71 g pot^{-1}) herbage yield was recorded in N0 in our study. And there were no statistical differences between N150 and N250 levels. The yields of fresh and dry herbage of burnet progressively increased with the increasing levels of nitrogen up to 200 kg N ha^{-1}, in the experiment. Doran (2020) applied 100 kg DAP ha^{-1} on different geneotypes of burnet plant and the fresh herbage yield varied between 0.4 and 1.9 t/ha, while the dry herbage yield varied between 0.17 and 0.591 t/ha in this research. Acar et al. (1999) found difference in the fresh and dry herbage yield of burnet during the two years, where 0, 40, 80 and 120 kg N ha^{-1} were applied. They stated that the maximum fresh (2.5 t/ha) and dry (0.9 t/ha) herbage yield were observed from 120 kg N ha^{-1} but the minumun fresh (1.1 t/ha) and dry (0.4 kg/ha) herbage yield were observed from 0 kg N ha^{-1} level (control). N significantly increases and enhances the yield by playing a vital role in biochemical and physiological functions of plant (Leghari et al., 2016). Our findings confirmed those researcher's results.

The CP content of burnet increased noticeably by increasing nitrogen application comparing to the control level (N0) (Table 2). N200 and N250 gave the highest CP content (14.7%) as a same group. The lowest CP content (10.7%) was obtained in N0 level. Researchers examined the effect of different maturity periods on CP content of burnet. CP contents were recorded of as periods of pre-flowering (20.7%), flowering (13.7%) and seed maturing (6.7%) stage, respectively (Kaplan et al., 2014). In another study on burnet crop, the variation range of CP contents is between 10.3% and 14.0% with the applied as constant 100 kg N ha^{-1} (Çavdar et al., 2021). The increase in CP content with increasing in N fertilizer levels perhaps the result of enhancement in amino acid formation due to fertilization (Patel et al., 1994). Our findings in the similar line those researcher's results for the CP content.

Statistical analysis indicated that nitrogen levels had positively significant effect on CP yield in the experiment (Table 2). The highest CP yield (21.5 g pot^{-1}) was determined in N200, but the minimum CP yield (7.6 g pot^{-1}) calculated in N0. There was no statistical difference between N150 and N250 levels. Acar et al. (1999) reported that CP yield (720, 1200, 1500 and 1800 kg·ha^{-1}) of burnet were increased by increasing N level (0, 40, 80 and 120 kg N ha^{-1}), respectively. In other study, 0, 40 and 80 kg ha^{-1} N fertilizers were given to burnet by İpek and Sevimay (2002). Researchers found that increased N levels enhanced the yield of CP as 480, 645 and 775 kg·ha^{-1}, respectively. Our findings in parallel those researcher's results with increase the CP yield by N fertilization.

Conclusions

The results revealed that increasing N levels were significantly improved crop yield and quality of common burnet compared to the control. Application of nitrogen at the rate of 200 kg ha^{-1} can be recommended for obtaining the maximum yield in common burnet under Mediterranean climate conditions. However, these results need to be confirmed in field trials conducted in different locations.

Abstract

Fresh leafy greens are the most consumed vegetables worldwide because of their known potential to enrich human health with minerals and compound shaving antioxidant properties. Recently more greens have been produced in controlled environment agriculture (CEA) systems, where the plants are grown under artificial lighting such as light-emitting diodes (LEDs). The properly selected LED lighting parameters, including photoperiod, can ensure healthy plant growth and productivity. This study aimed to evaluate the influence of LED lighting photoperiod on the development and photosynthetic indices of kale seedlings (*Brassica oleracea* 'Red Russian'). Plants were grown for 17 days in a closed controlled climate chamber: day/night temperature 21/18±2 °C, relative humidity 55±5 %, white LED (5700 K, Heliospectra, Sweden) light at 12, 18 and 24 h photoperiod, and total photon flux density (PPFD) of 200 µmol m^{-2} s^{-1}. The results showed that seedling hypocotyls were shorter due to the prolonged 18 and 24 h photoperiod, but plants grew taller than under the 12 h photoperiod. Seedlings grew under 24 h photoperiod formed longer and wider first true leaves and thicker hypocotyls and had higher fresh and dry weight than those under 12 h or 18 h illumination. Although the light period did not affect the photosynthetic rate and stomatal conductivity, the intercellular CO_2 concentration and transpiration intensity of kale decreased due to the prolonged illumination time. The lower levels of chlorophylls and carotenoids were found in seedlings grown at 18 and 24 h for lighting compared to those exposed at 12 h. In summary, the photoperiod is an important factor determining the vital processes in the plant, so it is necessary to select the duration of lighting to upgrade the growth rates without disturbing the function of the photosynthetic system of kale seedlings.

Keywords: *artificial lighting, controlled environment agriculture, leafy greens, light-emitting diodes.*

Introduction

The climate change and unfavourable climatic conditions promote seedling growers to produce high-quality seedlings in controlled environment agriculture (CEA) systems ("vertical farms", "plant factories") (Gómez et al., 2019). Leafy vegetables are increasingly produced in CEA systems seeking year-round production. Moreover, CEA systems allow the development of short food supply chains related to supply from growers in urban areas and consumers. In high-tech CEA, light is the essential factor because it regulates plants' morphogenesis, photosynthesis, and metabolism through wavelength-specific photosynthetic (chlorophylls and carotenoids) and morphogenetic (UV8, cryptochromes, phototropins and phytochromes) light receptors.

Therefore, to maximise the productivity of plants, it is important to determine optimal conditions of light parameters. As an artificial light source, light-emitting diodes (LEDs) can be used to make the plants grow more quickly in CEA production systems (Xu et al., 2016). The technology of LEDs has many advantages over traditional light sources like high-intensity discharge lamps. The advantageous properties of LEDs include their monochromatic nature, high photon efficiency, long life. All these favourable characteristics make LED applications typical for the cultivation of leafy vegetables indoors. In the recent decade, much attention was paid to evaluating light spectrum and intensity effects on various horticultural plants (Izzo et al., 2020; Qian et al., 2020; Liu et al., 2021). The higher intensity of blue, red and far-red (BRFR) LEDs lighting led to a higher total carotenoid content in red pak choi and mustard microgreens (Brazaitytė et al., 2015); the blue light increased β-carotene concentration in lettuce (Li and Kubota, 2009), and total carotenoids in lettuce, spinach, kale, basil, and pepper (Naznin et al., 2019). Plant soluble sugars, as the main products of photosynthesis can profoundly affect plant growth, particularly cell division and expansion, storage, signalling, and stress acclimation (Eveland and Jackson, 2012). Zhou et al. (2012) showed that increasing the increasing intensity of LED lighting increased the contents of soluble sugars in butterhead lettuce. Sucrose concentrations increased in red- and green-leaf lettuce when the green or red light was added to RBFR LEDs (Viršilė et al., 2020).

Moreover, the light and dark period a plant is exposed to controls many developmental and metabolic responses in plants (Iqbal et al., 2021; Lopes-Oliveira et al., 2021; Lopez et al., 2021). However, the effects of light duration of LED lighting indoors on leafy greens are less studied. Therefore,this study investigated how the LED lighting photoperiod affects the growth, photosynthetic parameters, and accumulation of metabolites in kale 'Red Russian' seedlings.

Material and Methods

The experiments were performed at Lithuanian Research Centre for Agriculture and Forestry, Institute of Horticulture, on August-September, 2020. Kale (*Brassica oleracea*) 'Red Russian' seedlings (CN Seeds, UK) were germinated and grown in a walk-in controlled environment growth room (4 m × 6 m) where the day and night temperatures of 21/18±2 °C and relative air humidity of 55±5 % were maintained. Seeds were sown into 2.5 cm × 2.5 cm rockwool cubes, pre-soaked in deionised water with an adjusted pH of 4.4–4.5 using diluted (1:31) 95–98% sulfuric acid. Seeded cubes were placed in plastic trays and covered with a lightweight agro-textile until the seeds germinated. Seedlings were watered with a modified Hoagland solution to supply the following nutrients (in mg L^{-1}): N, 120; P, 20; K, 128; Ca, 72; Mg, 40; S, 53; Fe, 4; Mn, 0.08; Cu, 0.08; B, 0.16; Zn, 0.8. The pH was 5.5–6.5, and the electrical conductivity (EC) was 1.3–1.7 mS cm^{-1} (GroLine HI9814, Hanna Instruments, USA).

For lighting treatments, kale seedlings were grown at 12-, 18- and 24-hour photoperiod of white (5700K) light-emitting diode (LED) lighting (Heliospectra, Sweden), and the total photon flux density (PPFD) was 200 μmol m^{-2} s^{-1}. The daily light integrals (DLI) of 12-, 18- and 24-hour LED lighting were 8.6, 12.96, and 17.28 mol m^{-2} d^{-1}. The experiment was repeated two times.

After 17 d from seed sow, destructive measurements were conducted on ten kale seedlings from each lighting treatment and replication. Each plant was cut from the rock wool cube and shoot fresh weight (FW, g), and dry weight (DW, g) was measured using an analytical balance (Mettler Toledo AG64, Columbus, OH, USA). Leaf length (cm) and width (cm) of the second fully expanded leaf were measured. Shoots were dried in an oven (Venticell 222, MBT, Czech

Republic) at 105 ºC for 24 h before DW measurements. Water content was calculated as the fraction of the difference between shoot FW and DW in FW and used to re-calculate biochemical compound contents in the DW of plants. The stem diameter (SD, mm) was measured using a digital calliper.

The photosynthetic rate (µmol CO_2 m^{-2} s^{-1}), transpiration rate (mmol H_2O m^{-2} s^{-1}), stomatal conductance (mol H_2O m^{-2} s^{-1}), intracellular CO_2 concentration (µmol mol^{-1}), and the ratio of intercellular to ambient CO_2 concentration (Ci/Ca) were measured on the second developed leaf, using a portable photosynthesis system (LI-COR 6400XT, USA). The leaf chamber conditions were set at 21 ºC, a CO_2 concentration of 400 µmol mol^{-1}, and 60% relative humidity. Artificial irradiation in the leaf chamber was supplied from 665 and 470 nm LED sources (665 and 470 nm), PPFD ~1000 µmol m^{-2} s^{-1}. Photosynthetic parameters were measured from 9 to 12 am. Water usage efficiency (WUE, µmol CO_2 $mmol^{-1}$ H_2O) was also calculated.

The fructose and glucose contents were analysed in leaves of kale seedlings, according to the Ma et al. (2014) method with some modifications. First, 0.5 g of fresh plant tissue was ground and diluted with deionised water. Then, the extraction was carried out for 4 h at room temperature with mixing. Samples were centrifuged at 14.000 g for 15 min. According to Brons and Olieman's (1983) instructions, a clean-up step to remove soluble proteins was performed before the chromatographic analysis. The analyses were performed on a Shimadzu HPLC (Japan) instrument equipped with an evaporative light scattering detector (ELSD). The separation of carbohydrates was performed on a Shodex VG-50 4D HPLC column with deionised water and acetonitrile gradient at a flow rate of 0.8 mL min^{-1}.

Contents of carotenoids (neoxanthin, violaxanthin, lutein and zeaxanthin, α- and β-carotenes and chlorophylls were evaluated according to the modified method of Edelenbos et al. (2001). Carotenoids and chlorophylls were extracted using 80% acetone (0.5 g of sample grounded with liquid N and 5 mL^{-1} of solvent), centrifuged (5 min, 4000 g), and filtrated through a 0.22 µm nylon membrane syringe filter (BGB Analytik Vertrieb GmbH, Germany). The HPLC 10A system (Shimadzu, Japan) equipped with a diode array (SPD-M 10A VP) detector was used for analysis. The separation of carotenoids and chlorophylls was performed on a Chromegabond C30 (120Å 3µm, 2.1 x 150mm) column (ES Industries, Germany). Peaks were detected at 440 nm. The mobile phase consisted of 80% methanol and 20% water and 100% ethyl acetate gradient at a flow rate of 0.2 mL min^{-1}.

The Analysis of variance (ANOVA) and Tukey's honestly significant difference test ($\alpha = 0.05$) and principal component analysis (PCA) ($\alpha = 0.05$) were performed using Microsoft® Excel® for 'Microsoft 365' and Addinsoft XLSTAT 2020 statistical and data analysis solution (Long Island, NY, USA). The results presented in the PCA biplot indicate distinct effects of lighting photoperiod on plant growth, photosynthetic and biochemical parameters, and the Pearson's correlation matrix summarises relationships between measurements of kale seedlings under the lighting treatments.

Results and Discussion

The significantly longer hypocotyls were of kale seedlings under 12- compared to 18- and 24 h photoperiod. Also, kale under 12 h was the lower fresh (FW) and dry (DW) and formed narrower and shorter leaves and thinner stem than seedlings under 18- and 24 h photoperiods. The highest FW and DW were of kale seedlings under 24 h photoperiod (Fig. 1).

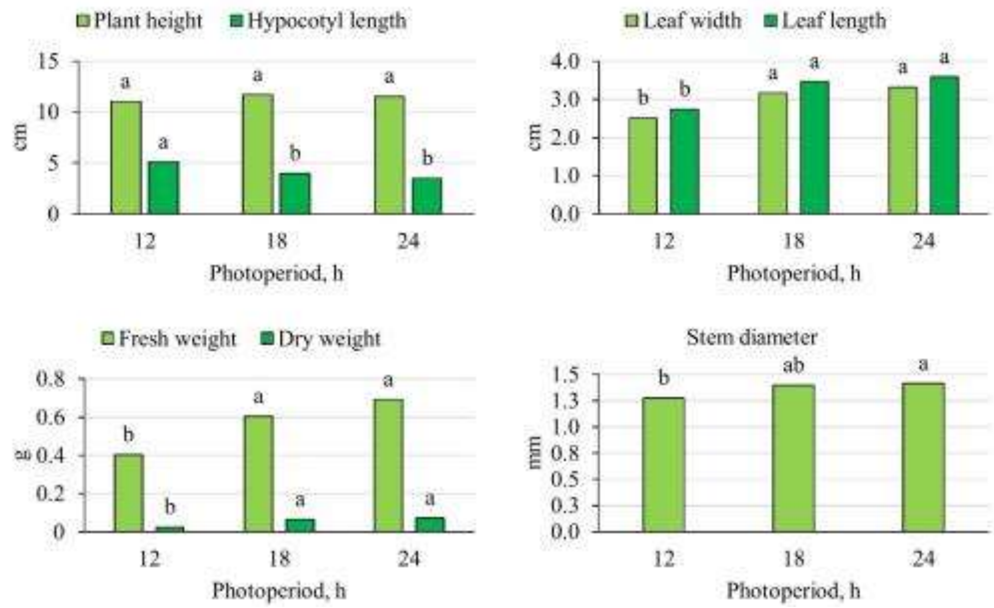

Figure 1. Growth parameters of kale seedlings grown under different LED lighting photoperiods. All values are expressed as mean. Means with different letters are significantly different at the $\alpha = 0.05$ (95%) level according to Tukey's HSD test.

The transpiration rate (Tr) of kale seedlings decreased with increasing LED lighting photoperiod. For example, the Tr of kale under 12 h was 1.3-fold higher than Tr under 24 h lighting. Contrary, the water usage efficiency (WUE) increased with increasing photoperiod determining the lowest WUE at 12- and the highest – at 24 h photoperiod. The photoperiod did not affect the photosynthetic rate, stomatal conductance, intercellular CO_2 concentration (Ci), as well as a ratio of intercellular to ambient CO_2 concentration (Ci/Ca) of kale seedlings (Fig. 2).
However, the changes in leaf pigments were determined (Fig. 3). The contents of chlorophyll *a* and *b* (Chl a, b) decreased with increasing photoperiod. About 2.0-fold lower contents of Chl a and b were determined under 24- compared to 12 h photoperiod. Moreover, the same tendency was determined on contents of neoxanthin, violaxanthin and lutein with zeaxanthin. The contents of α- and β-carotene were significantly 2.8- and 2.4-fold lower, respectively, in plants under 18- and 24 h than 12-h photoperiod.

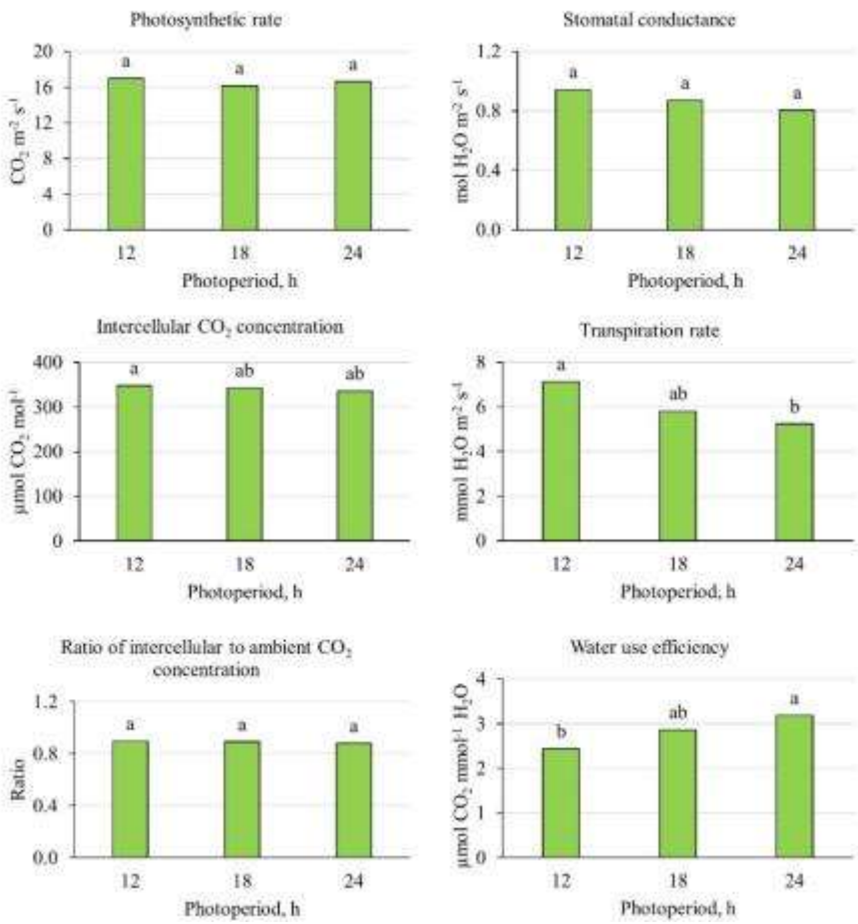

Figure 2. Photosynthetic parameters of kale seedlings grown under different LED lighting photoperiods. All values are expressed as mean. Means with different letters are significantly different at the $\alpha = 0.05$ (95%) level according to Tukey's HSD test.

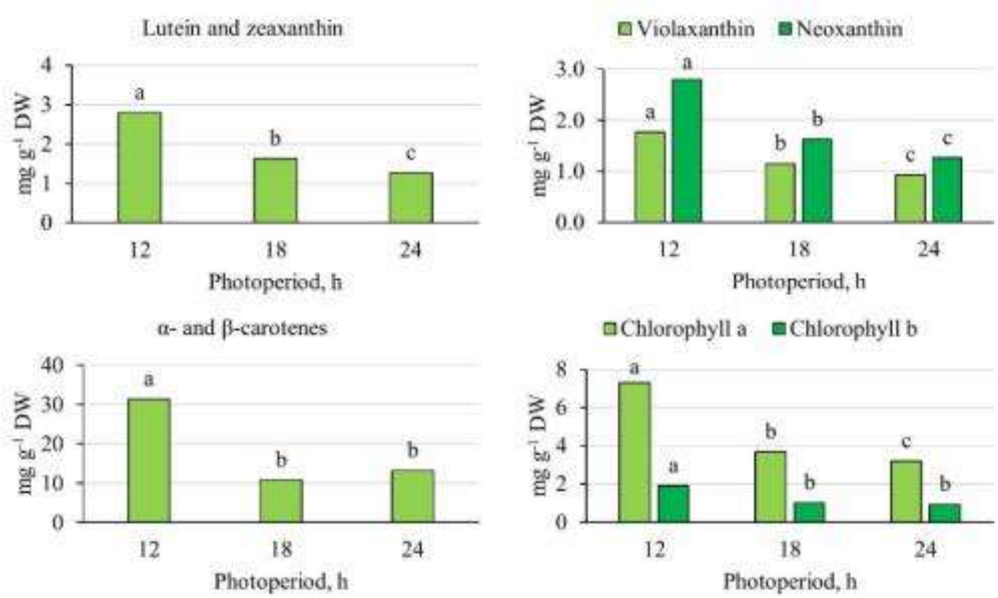

Figure 3. The contents of chlorophylls and carotenoids of kale seedlings grown under different LED lighting photoperiods. All values are expressed as mean. Means with different letters are significantly different at the α = 0.05 (95%) level according to Tukey's HSD test.

On the contrary, glucose and fructose contents increased with increasing photoperiod and were 7.1- and 5.4-fold higher in kale seedlings under 24 h photoperiod than plants grown under 12 h lighting (Fig. 4).

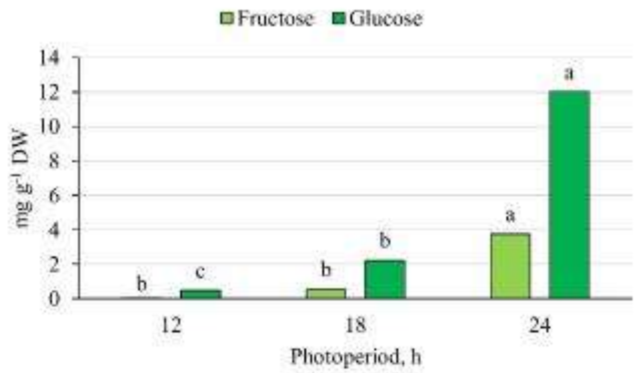

Figure 4. The contents of fructose and glucose of kale seedlings grown under different LED lighting photoperiods. All values are expressed as mean. Means with different letters are significantly different at the α = 0.05 (95%) level according to Tukey's HSD test.

The PCA biplots were analysed according to F1 and F2 factor loadings and scores to evaluate the associations between biometric, photosynthetic and biochemical measurements. It was found that 12-, 18- and 24 h photoperiods had distinct effects on parameters being assessed. The growth indices were associated with 18-, and leaf width and FW with 24 h photoperiod. The hypocotyl length and FW/DW ratio were not associated with any photoperiod, including 12 h. (Fig. 5, A). Tr and Pr were associated with 12- and WUE with 24 h photoperiod for photosynthetic parameters. The Ci, Ci/Ca, and gs were not associated with any photoperiod, including 18 h. (Fig. 5, B). The contents of sugars were linked to 24-, while all investigated carotenoids and Chl a and b were associated with the shortest 12 h photoperiod. The 18 h LED lighting was not associated with any investigated metabolite (Fig. 5, C).

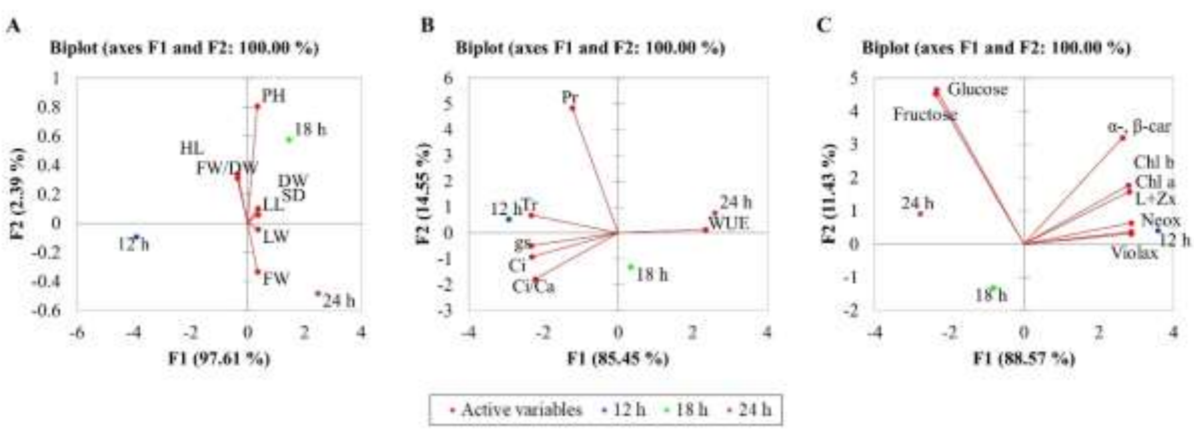

Figure 5. The PCA biplots, indicating distinct differences in growth (**A**) and photosynthetic parameters (**B**), and contents of chlorophylls and carotenoids (**C**) in kale seedlings grown under different LED lighting photoperiods. PH – plant height; HL – hypocotyl length, FW/DW – fresh and dry weight ratio, DW – dry weight; FW – fresh weight; SD – stem diameter; LW – leaf width; LL – leaf length; Pr – photosynthetic rate; Tr – transpiration rate; gs – stomatal conductance; Ci – intercellular CO_2 concentration; Ci/Ca- intercellular to ambient CO_2 concentration; WUE – water usage efficiency; α-, β-car – α- and β-carotene; Chl a and b – chlorophyll *a* and *b*; L+Zx – lutein and zeaxanthin; Neox – neoxanthin; Violax – violaxanthin.

Conclusions

In summary, the 18 h LED lighting photoperiod was the most appropriate for kale seedlings growth parameters. In addition, such lighting did not have a negatively impact on photosynthetic parameters. However, the 12- and 24 h photoperiods had a more pronounced effect on the accumulation of metabolites.

Abstract

In this regard, it becomes necessary to study the processes that ensure the reproduction and restocking of higher plants. Knowledge of reproduction processes is extremely important for solving many problems of botany, including the problem of preserving and increasing the biological diversity of plants, identifying the features of their adaptations during introduction, clarifying the taxonomy, etc. Of no small importance are reproductive features also in the development of methods for rational use of natural resources and the introduction into culture of various economically valuable plants - medicinal, aromatic, ornamental. Since the reproductive biology of plants involves the study of a number of sequential and interconnected processes of the development of flower elements, the formation of generative structures, the peculiarities of flowering, pollination, seed formation and dissemination, knowledge of them makes it possible to establish the patterns of formation of reproductive elements, identify critical periods in reproduction, and develop methods for improving reproduction and propagation of rare plant species, etc. Comparative studies of reproductive biology and, in particular, plant embryology are widely carried out by researchers (Kamelina, 2009; Kamelina, Shevchenko, Kuzmina, Miroshnichenko, 2020; Klank et al., 2010; and others), but not all families have been studied in sufficient detail and deep. Many species of the Campanulaceae family, such as *Campanula sibirica* L., *C. talievii* Juz., *C. taurica* Juz., *C. alliariifolia* Willd., *Adenophora liliefolia* (L.) Ledeb. ex A. DC. (syn. *A. taurica* (Sukacz.) Juz., *Platycodon grandiflorus* (Jacq.) A. DC. deserve special attention. As a result of the studies of these species, common features of embryology and anthecology as well as individual features of their seed formation, were established.

Keywords: *family Campanulaceae, generative structures, anthecology, micro- and megasporangium, seeds formation.*

Introduction

According to the latest literature data (from October 2018), the Campanulaceae family takes 35th place in the system of flowering plants and is represented by 88 genera and 2385 species (https://ru.wikipedia.org/wiki/Flower_plant_families). The family includes 5 subfamilies, represented by different life forms (herbaceous perennials, tree-like forms, vines, etc.), which are found in different climatic zones and communities (Lammert, 2007). The literature contains extensive information on the study of all sorts of aspects: systematic affiliation, morphological features, growing conditions, etc. However, despite the fact that many representatives of the Campanulaceae family have been fairly well and comprehensively studied data on their embryology in the literature are insufficient. At the same time, the study of the reproductive structures, characteristics and possibilities of seed formation of these species will contribute to the expansion of the factual material on general embryology, and will also serve as additional information in solving controversial issues of the systematic affiliation of plants and the development of methods for optimizing their reproduction and propagation. In this regard, the aim of this work was to identify the features of the development of the reproductive structures of the some species, anthecological aspects of their reproduction, a comparative analysis of the possibilities of renewal in the conditions of their natural area or during introduction.

Materials and methods

The objects of these studies were 6 species of flowering plants from family Campanulaceae: *Campanula sibirica* L., *C. talievii* Juz., *C. taurica* Juz., *C. alliariifolia* Willd., *Adenophora liliefolia* (L.) Ledeb. ex A. DC. (syn. *A. taurica* (Sukacz.) Juz.) and *Platycodon grandiflorus* (Jacq.) A. DC. The question of the taxonomic affiliation of *Campanula sibirica* L., *C. talievii* Juz. and *C. taurica* Juz. in the literature it is debated: some authors define them as independent species (Yuzepchuk, 1951; Dremlyuga and Ziman, 2010), others (Viktorov, 1997) *C. talievii* and *C. taurica* refer to species *C. sibirica* as subspecies. Our observations allow us to join the opinion of the former.

C. sibirica (according to our observations and according to literature data) is a biennial herb. The stem is single, erect, slightly pubescent, up to 50 cm tall, with numerous flowers. The structure of the corolla corresponds to the characteristic features of the genus. Aerial shoots are in the form of leaf rosettes. Leaves are lanceolate, sessile. In the Crimea, it blooms from May to August, inclusive. The root of this species is tap-shaped, fusiform, branched, milky-white in color. The species is listed in the Red Books of the Udmurt Republic (2001), the Moscow (2006), the Voronezh (2018), the Rostov-na-Donu (2014), the Yaroslavl (2004) regions and the Republic of Belarus (2006). This species has been assigned the status of the 3rd rarity category.

C. taurica is a perennial plant up to 50 cm tall. Like *C. sibirica*, it blooms from May to August. Generative shoots pubescent, numerous, straight, the middle of which is usually higher than others. The flowers are numerous; the petals are serrated. Aerial shoots are in the form of rosettes of leaves, leaves are lanceolate. Underground shoots are creeping, slightly branched, light white in color.

C. talievii – it is a polycarpic, herbaceous, half-rooted plant up to 25-30 cm tall. According to V.N. Golubev (1996), this is the endemic of the Crimea. Generative shoots are pubescent, numerous. Flowers are also numerous. Above-ground shoots are represented by rosettes of lanceolate leaves. An underground shoot is branched, rod-shaped, fusiform-shaped, light-white in color. The species can be characterized as aeropedophyte and calfyte with a deep rod-root system.

C. alliariifolia (syn. *C. lamiifolia* var. *albotomentosa* Rupr.) is a perennial, densely pubescent plant up to 70 cm tall, stems are straight, ascending. Basal leaves are cordate, with long petioles, stem leaves are reduced, short-petiolate, the uppermost leaves are almost sessile. Blooms in August-September. The flowers are rather large (22-29 mm), fawn, on short pedicels, collected in a one-sided raceme, the teeth of the calyx are broadly lanceolate, ciliate along the edge, much shorter than the corolla. Grows in open limestone areas in the forest belt of mountains. We have noted the species on the bank of the Fiagdon river in the Kadargavan canyon of the Kurtatinsky ravine approximately at an altitude of 950 – 970 m above sea level.

Adenophora liliefolia is a herbaceous perennial with a height of 30-50 cm, with a thick fusiform or radish root and a cylindrical, longitudinally striped, glabrous or sparsely hairy, densely leafy stem. Stem leaves are alternate, elliptical, pointed, unevenly coarsely serrate-toothed at the edges, tiled overlapping each other in the middle part of the stem; upper leaves are lanceolate, sessile. Rosette basal leaves are round-cordate, long-petiolate, 4-10 cm long, drying quickly. *A. liliefolia* blooms in July-August, the flowering is acropetal, although sometimes there are shoots with basipetal blooming. The flowers are collected in a racemose inflorescence. Corolla bell-shaped, blue or light blue, shallowly divided into 5 lobes, up to 1.5 cm long, drooping flowers, spine-petal. The calyx is naked, its teeth are sharp, lanceolate-triangular, equal in length to the tube. The species is included in the European Red List (2011) and Red Books of various regions: Red Book of the Republic of the Crimea (2015), Red Books of Voronezh (2011) and Rostov (2014) regions.
Platycodon grandiflorus is a perennial herb. Stem with a large, single flower at the end and glaucous sessile leaves, ascending or straight from the base, strongly leafy, up to 50.0 cm high. When grown on the Southern Coast of the Crimea, *P. grandiflorus* blooms from late June to late July, bears fruit in August. The flowers are usually apical, the calyx is grayish, with straight, pointed teeth, the corolla is bright blue with pronounced dark veins. There are forms with white flowers and two circles of petals. The corolla is large, up to 7.0-8.0 cm in diameter, divided into ovoid lobes. The bright color of the *P. grandiflorus* flower and its size, which is much larger than the flowers of other representatives of the Campanulaceae family (many species of the genus *Campanula*, *Adenophora*), attract various insects. It should be noted that *P. grandiflorus* is very beautiful not only during the flowering period, but also during the budding period, since its buds are also colored and have an unusual shape, reminiscent of Chinese lanterns.
The material for embryological studies was fixed with a Carnoy solution (6: 3: 1) and Chamberlain fixative (ethyl alcohol 70% -90 parts: formalin 40% -5 parts: glacial acetic acid-5 parts). In the preparing of permanent preparations, conventional methods were used. Sections of 10-12 μm in thickness were obtained using a semi-automatic rotary microtome RMD-3000 (OOO "MedTekhnikaPoint", Russia). The preparations were stained with methylgrunpironin with an Alcyan blue tint and Heidenhain hematoxylin with Alcyan blue tint. The analysis of the preparations was carried out with the help of the AxioScope 1 microscope of Carl Zeiss (Jena), photographs were taken with a digital Axiocam 208 color. Anthecological observations were carried out under conditions of natural growth of the species under study.

Results and discussion

The flowering of three Crimean species of bellflower is rather long, due to which one can simultaneously observe buds, open and wilted flowers on one plant, and fruits are also added in August. The development of reproductive structures occurs in the year of flowering. Generative shoots in *C. sibirica* and *C. taurica* wither at the end of the growing season, and the death of aerial parts is observed after the completion of dissemination. In *C. talievii*, the stems dry out by the end of the growing season, but do not die off, as a result of which new rosettes of leaves are formed from dormant buds the next year. The flowers form loose inflorescences. As already mentioned, *C. alliariifolia* in its natural range blooms in July-September, the flowering is acropetal, the flowers are yellow, turning yellow over time, forming a loose racemose one-sided inflorescence.

It is known that one of the most important structural and functional parts of a flower is the androecium, which is a set of stamens, which largely determine the strategy of the species: how many anthers are in the flower, what is their position and developmental sequence, is there enough pollen for effective pollination. During evolution, the number of stamens can change, and this is due to the biology of pollination and pollinators, the presence or absence of nectaries.
Androecium in the species that we studied is represented by 5 stamens. The stamens are straight and equal, attached to the nectar disc, symmetrically arranged; in the bud they tightly cover the pistil. Filaments have widened bases, which, joining together, form a dome with an opening at the top (figure 1). This facilitates pollination by large insects, which can reach the nectar disc through the hole with their proboscis and extract nectar. As the flower opens, the anthers open up, the pistil grows, but its blades are still closed, that is, the phenomenon of protandria is observed.
The anther is 2-tec, 4-nested, there is a placentoid - a radial outgrowth of the connective tissue, which protrudes into the interior of each nest. The wall of the microsporangium develops centrifugally, the tapetum is a derivative of the primary parietal tissue. In the subepidermal layer, archesporium differentiates, the cell of which is distinguished by its size, a large nucleus. As a result of the division of the archesporial cell, parietal and sporogenic cells are formed, the latter of which forms sporogenic tissue, and a microsporangium wall develops from the parietal cell. After the cessation of divisions in the sporogenic tissue, its cells separate, callose is deposited around them, and microsporocytes are formed.

.

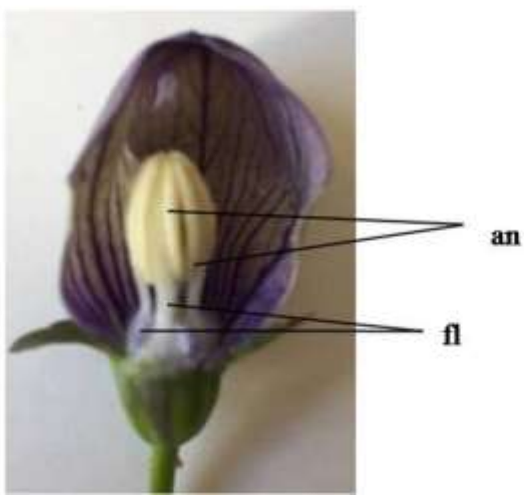

Figure 1. *Platycodon grandiflorus* bud with partially removed corolla (an - anthers, fl - filaments)

As a result of the meiosis passing through them, a tetrad of microspores is formed. The formation of a tetrad of microspores is simultaneous (cell septa are not formed after the first division of meiosis), tetrads of microspores are of isobilateral and tetrahedral types. The formed microsporangium wall consists of the epidermis, endothecium, one middle layer and secretory tapetum. In the young 2-cell pollen stage, individual tapetum cells are observed (figure 2). With the development of microsporocytes and the passage of meiosis in them, the cells of the middle layer gradually flatten and degenerate. Tapetum cells persist for a rather long time and are observed during the period of differentiating mitosis. At the stage of two-celled pollen grains, the microsporangium wall is represented by flattened cells of the epidermis, endothecium with fibrous thickenings, and remnants of tapetum cells. The wall of the mature anther consists of flattened cells of the epidermis, which is covered with cuticle, and the endothecium with fibrous thickenings. The endothecium is often two-row, from the side of the liaison it can be two- and three-row. Mature pollen grains are bicellular; spermatogenesis takes place in pollen grains on the stigma of the pistil. Most of the mature pollen grains are morphologically normal (presumably they are fertile); the amount of sterile pollen grains varies from 15 to 30%.

Female generative structures are the most stable and protected part of the flower, which is relatively resistant to external factors, and pathologies of its development usually indicate serious violations of the reproductive process of the species. In the species we studied, the gynoecium is coenocarpous (syncarpous variety), consists of 3 carpels, each of which contains many ovules that form the inferior ovary.

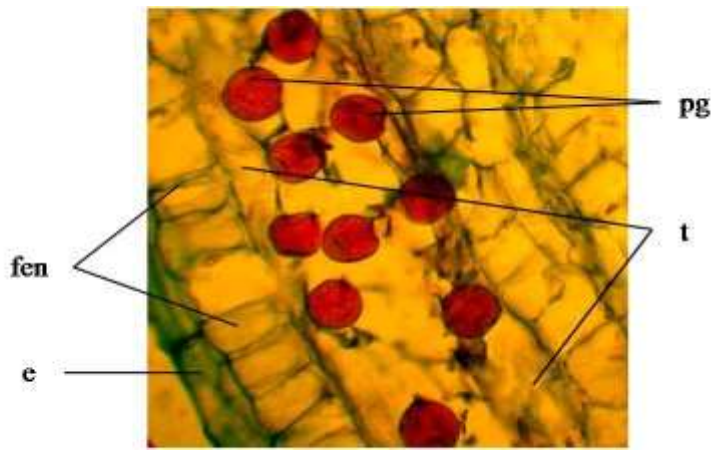

Figure 2. Fragment of the *Campanula taurica* microsporangium at the stage of young 2-cell pollen (pg - pollen grains, t - tapetum, fen - fibrous endothecium, e – epidermis)

The ovule is a structural element in which megasporogenesis occurs, the development of the female gametophyte, the fertilization process, as well as the subsequent processes leading to the formation of the seed. In the species we studied, the ovules are anatropic, medionucellular and unitegmal. The integument of epidermal origin is represented by 6-8 rows of cells. The micropile is simple, narrow, straight. The funiculus is short, weakly expressed, there is a funicular obturator. As a result of the congenital fusion of the funiculus and integument, rafe is formed. The vascular bundle reaches the chalaza. The outer epidermis of the ovule is represented by large elongated cells. Most of the cells of the inner epidermis differentiate into the integumental tapetum, which surrounds the embryo sac from the lateral sides, reaching the level of the egg apparatus.

The cells of the integumental tapetum differ in size; they are smaller at the micropylar and chalazal ends than in the central zone, where they are large, tabular, with rather well-defined nuclei and nucleoli. These data are consistent with the results of the study by I.I. Shamrov and N.A. Zhinkina *Azorina vidalii* (family Campanulaceae), in which a similar development and structure of the integumental tapetum was described. In the chalazal zone, the ovule forms a columnar postamento-podium, the cells of which differ from those around them in a thicker shell and adhere tightly to the embryo sac, and cup-shaped hypostasis.

The embryo sac is formed according to the Polygonum type. In the subepidermal layer of the meristematic tubercle, the archesporial cell differentiates, which differs from the surrounding cells by its larger size, a pronounced nucleus with a nucleolus. As a result of its division, parietal and sporogenous cells are formed, the latter of which is transformed into a megasporocyte. Like many other representatives of the Campanulaceae family, the embryo sac is monosporic and elongated (figure 3). The polar nuclei are first located in the center of the embryo sac, merge before fertilization to form the nucleus of the central cell of the embryo sac, which is then close to the egg apparatus.
The antipodes are located T-shaped in the chalazal zone of the embryo sac. They persist for a rather long time and degenerate after fertilization, in contrast to *Owsrowskia magnifica* and *Campanula latifolia*, in which antipodes are ephemeral and degenerated during fertilization.

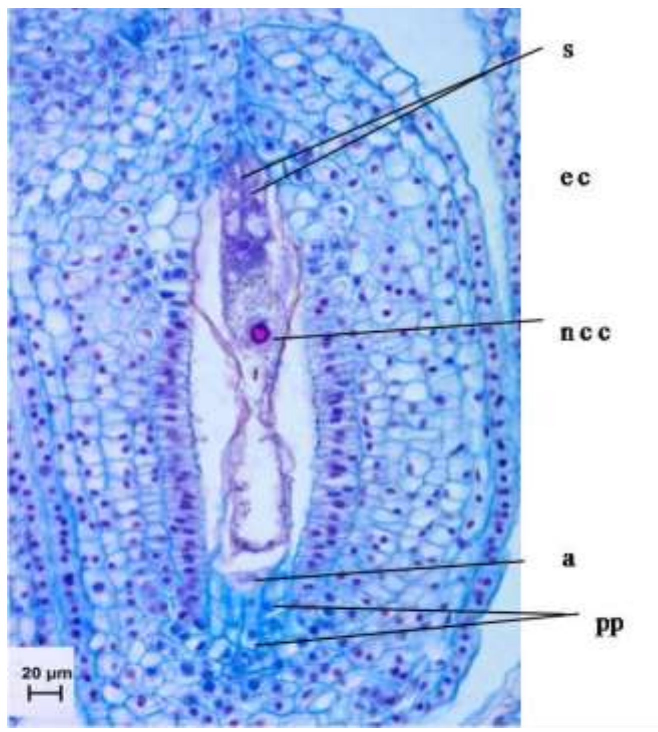

Figure 3. Fragment of the ovule and mature embryo sac *Adenophora liliefolia*
(s – synergids, e c – egg-cell, n c c – nucleus of central cell, a – antipods, pp – postamentopodium).

Thus, in the species of bluebells and adenophores we studied the mature embryo sac is 7-cell, with a well-differentiated egg apparatus, but its maturation occurs later than the male generative structures, and by the time the flower opens, the embryo sac is not yet differentiated and is not ready to accept male gametes. Its differentiation occurs later, which indicates the presence in these species of the phenomenon of protandria, which contributes to allogeny.
One of the most important stages in the process of reproduction of flowering plants is the period of their flowering, when the differentiation and maturation of the reproductive elements of the flower is completed and pollination is possible, which subsequently determines the processes of fertilization and seed formation. At the same time, it is necessary to note the importance of coordinated actions and processes of flower development and pollination agents, the effective

interactions of which ultimately determine the reproduction, dispersal and conservation of the species.

Depending on the method of pollination, its syndrome in various plant species is represented by various adaptations that maximally ensure the ingress of pollen on the stigma of the pistil. Members of the Campanulaceae family have a very specific pollination mechanism. In the species we studied, the flower is full, bisexual, actinomorphic; the limb of the flower, which attracts insects and serves as a landing site for them, is of great importance. Calyx toothed, wilting, non-falling. There are bent appendages equal to the length of the calyx, toothed petals. The corolla is bell-shaped, agglomerate, pubescent (the outer part of the corolla is not pubescent, and the inner part is weakly pubescent), 15-20 mm long, wilting, non-falling. At the closed-bud stage, the stamens completely encircle the pistil column. Filaments are short, widened at the base, in the lower part, joining together, form a kind of dome with small holes. The anthers break open at the stage of a loose bud; the stigma lobes are still closed at this time. The nectary is intra-flowered, in the form of a disk above the ovary. One pistil, central column, open, with a canal in the center, non-falling, covered with many unicellular hairs of epidermal origin. The stigma is apical, dissected, 3-lobed. The originality of pollination lies in the fact that the pollen from the flower is not carried out by the anthers, but by the columns covered with hairs. As the pistil grows, the hairs pry up the pollen grains from the open anthers and extract them, as a result of which the entire column is covered with pollen. In search of nectar, the pollinator insect flies up to the flower and goes to the nectar disk, which is covered with a dome of staminate filaments widened at the base. In the upper part of the dome there is a hole through which the pollinator reaches the nectar disc with its proboscis. As it moves to the nectar disc, the insect with its paws, belly, and sometimes wings, removes the pollen on the column. After visiting one flower and when flying to another, an open flower, the insect, moving to the nectar disk, touches the open lobes of the stigma of the pistil, leaving pollen on them, and thus carrying out pollination.

It should be noted that the studied species have the phenomenon of intussusception, or retraction, which is as follows. After the function of extracting pollen from the anthers and removing it from the column by insects, the hairs covering the column do not fall off, but are drawn into the surface tissue of the column, expanding the base of the hair until only its tip remains above the surface of the epidermis (figure 4). The retraction phenomenon encourages insects to reach the nectar disc and leave the flower, collecting pollen and transferring it to other flowers. After pollen enters the stigma of the pistil, spermatogenic division occurs, leading to the formation of two spermatozoa, the pollen tube grows along the canal in the column, reaches the embryo sac, passes through one of the synergids, bursts and pours out its contents. One of the sperm fuses with the nucleus of the central cell, and the second with the nucleus of the egg, that is, double fertilization occurs. In the species we studied, fertilization of the premitotic type, which is characterized by the union of the reproductive nuclei before the first mitotic division of the zygote. The zygote is in a dormant state for some time, then it stretches somewhat inside the embryo sac.

As a result of the fusion of sperm with the nucleus of the central cell, the primary endosperm nucleus is formed, the first division of which is transverse with the formation of chalazal and micropilar cells. The micropilar cell divides longitudinally, then these two cells divide transversely, resulting in the formation of a haustorium. The chalazal cell divides transversely and the endosperm itself is formed from the formed upper cell, and the lower cell divides longitudinally, forming a chalazal haustorium, which can be unicellular or bicellular. The micropilar haustorium begins to form even before the active development of the endosperm (figure 5). The endosperm observed in these species, according to the characteristics of the Campanulaceae family, is cellular. In accordance with the classification of O.P. Kamelina, it is tubifloral, characterized by the transverse division of the primary nucleus and the formation of micropilar and chalazal haustorium, which perform nutritional and secretory functions. According to I.I. Shamrova (2008), such endosperm formation can be defined as a micropilar-chalazal subtype of the cellular type with terminal haustoriums. The embryo in the species studied by us develops according to the Solanad-type. The zygote is at rest for a long time, increasing in size and growing inside the central cell. The first division of the zygote is transverse. Then both cells of the proembryo also divide transversely, forming a linear tetrad.

Further, cells derived from the apical cell divide longitudinally, and the basal cell divide transversely, forming a long suspensor and carrying the proembryo to the center of the embryo sac. Both the apical and the basal cells take part in the formation of the embryo itself - the main part of the embryo is formed from the apical cell and the derivatives of the basal cell form the suspensor and pituitary gland.

In accordance with the classification of Z.T. Artyushenko and A.A. Fedorov in the species Campanulaceae that we studied, the fruit is a lower, three-celled, multi-seeded, covered with stiff hairs, drooping, wilting, non-falling capsule. At the base of the capsule of the studied species, there are three pores, first covered with caps, which fold back during the drying of the capsule. An axicornus, a month-like outgrowth attached to an axial column, serves as a device for the formation of a pore and a cap. The resulting seeds are small, light brown, about 1 mm long, most of which are endosperm.

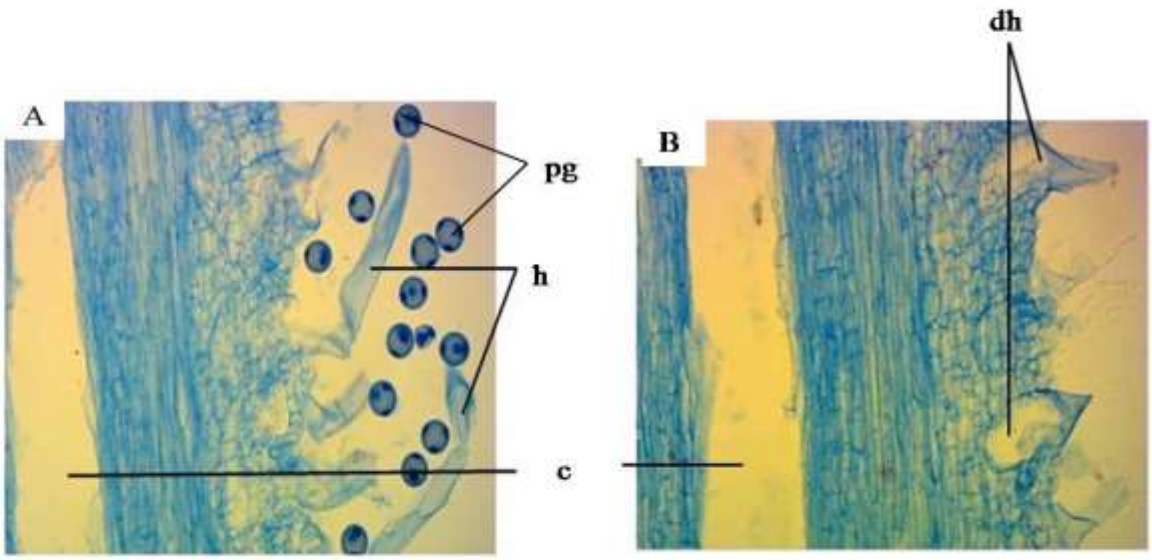

Figure 4. Fragments of style *Campanula sibirica* with epidermal hairs and pollen grains at the period pollination (A) and at the time of draw the hairs into style tissue (B) (h – hairs, pg – pollen grains, c – canal, dh – draw the hairs)

It should be emphasized that *Platycodon grandiflorus* stands out among the studied species. So, its flowers are large, more than 2 times the flowers of bells. Corolla bright blue with distinct veins. There are forms with white flowers and two circles of petals. *P. grandiflorus* is very decorative not only during the flowering period, but also during the budding period, since its buds are also colored and have an unusual shape, reminiscent of Chinese lanterns. In contrast to the bells studied by us, the sporogenic tissue in the microsporangium of *P. grandiflorus* is most often three-layered and only occasionally single-layered.

When *P. grandiflorus* is grown in the Peter the Great Botanical Garden V.L. Komarov Botanical Institute of Russian Academy of Sciences (St. Petersburg), microsporangium of fibrous thickenings is not formed in the endothecium, while when grown under conditions of the Southern Coast of the Crimea, endothecium with fibrous thickenings is formed, spermatogenesis in *P. grandiflorus* takes place in a pollen grain, and mature pollen grains in pollination period three-celled, 6-furrowed with a very small number of abnormal ones.

In contrast, N.A. Zhinkina and E.E. Evdokimova (2020) indicate that when this species is grown under the conditions of the Peter the Great Botanical Garden, 2-cell pollen with a significant number of anomalies is formed. The fruit of P. grandiflorus resulting from effective pollination and fertilization is a straight, ovoid, upwardly directed capsule with five holes at the top for dispersing seeds, in contrast to the three-nested bell capsule with three pores at the base.

Under the conditions of cultivation on the Southern Coast of the Crimea, a lot of seeds are formed, their viability after stratification in the refrigerator for a month is about 95.0%, in contrast to the Peter the Great Botanical Garden, where P. grandiflorus seeds are not set at all (Zhinkina, Evdokimova, 2020; Shevchenko and others, 2020).

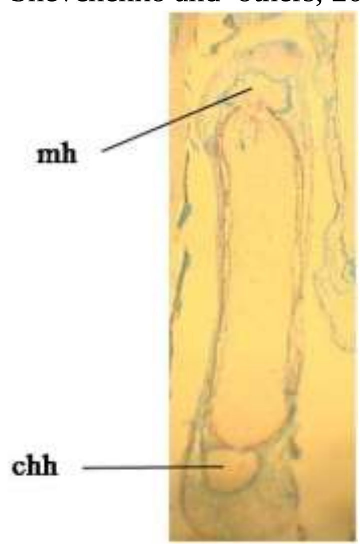

Figure 5. Fragment of the *Platycodon grandiflorus* seed with micropilar (mh) and chalasal (chh) haustoriums

Conclusions

Thus, the species studied by us are characterized by certain common features: dicotyledonous type of formation of the microsporangium wall, anatropic, medionucellular, unitegmal ovule, Polygonum-type of formation of the embryo sac, the presence of an integumental tapetum, tubifloral endosperm with micropylar and chalazal haustoriums. *P. grandiflorus* has some specific features that distinguish it from others: the size of the flower, the shape and color of the buds, a five-nested ovary and a stigma of a pistil with five lobes, unlike *Campanula* species with a three-nested ovary and a three-lobed stigma, large 3-celled six-furrowed pore pollen grains.

The insignificant amount of abnormal pollen grains in the total mass of pollen during the pollination period suggests a high viability and fertilizing ability of male generative structures of the studied species. The formation of a large proportion of high-grade seeds in their total mass indicates their high reproductive potential, the possibility of seed reproduction and use in landscaping parks on the Southern Coast of the Crimea.

It should be emphasized that the development of flower elements in the studied representatives of the Campanulaceae family, coordinated movements during the flowering process and the period of activity of pollinating insects, the pollination mechanism are closely interrelated, and their conjugation ensures the efficiency of pollination and subsequent seed formation processes, which indicates about high plasticity and reliability of their reproduction systems.

Abstract

In the last few decades, new soybean varieties with different characteristics, grain quality and purpose have been created, contributing to its expansion and increase in the cultivation area. Thanks to good agronomic characteristics, soybean has found its place in sustainable production systems. In order to increase the yield and quality of grain in sustainable soybean growing systems, different foliar treatments with different active substances have been increasingly applied. The aim of the study was to determine the impact of the application of EM Aktiv with effective microorganisms on the number of pods per plant, weight of 1000 grains and grain yield of different soybean cultivars grown in an integrated cultivation system. The research was conducted in the period 2016-2019 in the experimental field of the Institute of Field and Vegetable Crops Novi Sad. Varieties from three maturing groups Galina (0 group), Sava (I group) and Rubin (II group) were grown. Variants of fertilization application were: T1 control, T2 EM Aktiv was applied to the soil before sowing 20 $l.ha^{-1}$, and later in vegetation 6 $l.ha^{-1}$ (the first foliar treatment in the phase of three to four trefoils and the second before flowering in the budding phase), T3 NPK 8:15:15 300 $kg.ha^{-1}$ in basic treatment and T4 combination of T2 and T3 treatments. On average for all three years of the study were found statistically significant differences between the variables in all properties. The highest values were determined when applying T4 treatment. The number of pods was 55.92, the weight of 1000 grains was 163.61 g and the yield was 4.240 $kg.ha^{-1}$. The cultivar Rubin (II maturing group) showed the highest values for all examined variables on average after all treatments.

Key words: *soybean, fertilization, effective microorganisms, yield.*

Introduction

Soybean (*Glycine max* (L.) Merr) is one of the most important crops for the diet of the population due to its multiple purposes. Today, a large number of scientific and technological knowledge is constantly confirming its value and increasing its constant use. In addition to protein (40%) and oil (20-25%), soy contains various plant specialized (secondary) metabolites, such as isoflavones and saponins (Ahmad et al., 2014; Singh et al., 2017). Soybeans have a special genetic predisposition for a symbiotic relationship with bacteria that fix atmospheric nitrogen and arbuscular mycorrhizal fungi, which gives it an advantage for growing in a sustainable production system. Due to all that, the areas under soybean increase, however with greater oscillations in yields. For stable production of soybeans, it is necessary to know well the needs of the plant for nutrients, agroecological conditions for its production, to apply adequate technology as well as the appropriate assortment. The problem of soybean fertilization has been studied, but, in addition, many issues of nutrition of this plant have not yet been clarified, so there is no increase in yield under the influence of fertilization as in other plants. Soybean responds well to supplemental feeding foliar treatment of a variety of nutrients. Silberbush (2002) states that foliar nutrition of soybeans is widely used to correct plant deficiencies caused by improper root supply. Camberato et al. (2010) reports that if symptoms of nutrient deficiency occur during the growth phase, the most effective method to overcome deficiencies is to use a foliar diet. Mallarino (2005) concluded that foliar nutrition of soybeans in the early stages of growth increases grain yield by 10-30%. Oko et al. (2003) state that foliar treatment of soy with urea in phases R2 and R3 increases the yield by 6-68% compared to the control, while Haq and Mallarino (2005) pointed out that foliar application achieves an increase in protein and oil yield. However, with the development of methods in sustainable production systems, there is an increasing number of research related to the application of biophysics methods and various biofertigators. By applying low frequency electromagnetic waves with organic fertilizers, soybean yield can be increased (Cvijanović 2018) as well as the protein content in the grain (Đukić et al. 2017).

The use of microbiological multiple inocula with effective microorganisms (EM) is increasingly used in plant production. Different types of microorganisms and a large number of highly effective strains affect the stimulation of plant growth, protection against disease, increase resistance to abiotic stresses, improve the chemical properties of fruits (Filipović et al., 2020; Cvijanović et al., 2019) and increase yield. The use of effective microorganisms in plant production can increase the nutritional properties of fruits, according to the results of studies by Daiss et al., (2008), which found an increased content of phosphorus and magnesium in chard leaves. Yue et al., (2002) found that the application of EM can increase the intensity of photosynthesis in functional leaves during mid-vegetation. Using EM, the same authors found that there was a decrease in stomata openness, the activity of the enzyme nitrate reductase increased in the grain, while increasing the yield and quality of the grain (% protein and fat). The aim of the research was to determine the influence of EM Aktiv preparation with effective microorganisms on the number of pods per plant, weight of 1000 grains and grain yield of different soybean cultivars grown in an integrated cultivation system.

Materials and methods

The research was conducted in the period 2016-2019 in the experimental field of the Institute of Field and Vegetable Crops Roman trenches in Novi Sad. The land is of the chernozem type. The experimental field experiment in dry farming was set up according to the design of a split-plot experiment on an area of 2475 m^2. The experiment was set up in four replications, and the size of the basic plot was 15 m^2. Sowing was performed in the optimal agrotechnical period with three soybean genotypes of different FAO maturation groups: Galina (group 0), Sava (group I) and Rubin (group II). The fertilization was based on the principles of integrated production, where NPK fertilizer 8:15:15 was used for basic fertilization, the amount of 300 kg ha^{-1} during autumn tillage and the application of effective microorganisms in the preparation EM Aktiv (trade name) in the following variants:

T1-Control without fertilization; T2-Variant with the use of effective microorganisms in the preparation EM Aktiv (application initially on the ground before sowing in the amount of 20 liters per hectare and secondly foliar treatments in the development phase of plants from three to four trefoils and budding phase, ie buds on the soybean tree in the amount of 5 liters per hectare); T3-Variant with application of NPK fertilizer during basic tillage in autumn, fertilizer formulation 8:15:15, amount 300 kg ha^{-1}; T4-Variant where T2 + T3 treatments are combined.
In the phase of technological maturity of soybeans, 10 plants were taken from each basic plot for analysis. In this paper, the number of pods per plant, weight of 1000 grains and soybean grain yield were analyzed.

Results and discussion

The number of pods per plant represents the total number of pods from one soybean plant, from the main tree and branches. The average number of pods for the entire research period was 53.47. Observing the average values for the number of pods by individual varieties, it can be noticed that the highest value was recorded in the cultivar Rubin (59.91), which was statistically significantly higher than in the cultivar Galina (49.77). No statistically significant difference was found in relation to the Sava variety (55.06). According to the variants of fertilization, the number of pods was the highest when applying T4 treatment (55.92), which is statistically significantly ($p < 0.05$) higher number of pods compared to T3 treatment (52.60) and in relation to control (50.87) the significance was at the level of $p<0.01$. The number of pods in the variant with the preparation of EM Aktiv T2 (54.49) was statistically very significantly higher in relation to the control variant, while in relation to the T4 treatment no statistically significant difference in the number of pods per plant was found. The largest number of pods was found in the treatment of T4 with variety Rubin (62.94). According to Wiebold et al. (1981) by increasing the number of pods, soybean grain yield can be increased, which is one of the priority tasks in soybean cultivation and selection research. The obtained results can significantly improve soybean production.
The weight of 1000 grains is an important component of yield and an indicator of seed size. Grain mass can be affected by genotype, nitrogen diet, supplementation by various means. The average weight of 1000 grains for all three years of research was 162.28 g. Observing the average values for the weight of 1000 grains by individual varieties, it is noticed that the varieties Rubin (167.82 g) and Sava (162.94 g) had a statistically significant difference in the weight of 1000 grains in relation to the variety Galina (156.10 g). The difference in the mass of 1000 grains between the cultivar Rubin and Sava was not at the level of statistical significance. Observing the values for the weight of 1000 grains by fertilization variants, it is noticed that the highest value was recorded on the variant with application of T4 (163.61 g), and the lowest value on the control variant of the experiment (160.19 g), however these differences were not statistically significant. In the interaction of cultivars and treatments, the Rubin cultivar had the highest weight of 1000 grains at T4 treatment (169.73 g). According to the obtained results, it was determined that this trait is conditioned by a genetic factor, the amount of nitrogen (Haq and Mallarino, 2000), as well as foliar treatments. That soybean responds differently to foliar treatments has been shown by Dozet et al. (2016) in studies of foliar application with cobalt and molybdenum where there was a decrease in 1000 grain weight and yield height by 0.56%. Accordingly, the results of the application of a combined diet with mineral nitrogen and effective microorganisms are of great importance in the cultivation of soybeans of different genotypes.

Grain yield, as the ultimate goal of production, averaged 4034.81 kg ha^{-1}. The highest grain yield was in the variety Rubin 4240.22 kg ha^{-1}. In relation to the Sava variety, the increase was 300.06 kg ha^{-1} and in relation to Galina 494.10 kg ha^{-1}, which was a statistically significant increase in grain ($p < 0.01$). Regarding the treatment, the highest values were determined in the treatment T4 4240.22 kg ha^{-1}. The determined yield was higher by 583.17 kg ha^{-1} compared to the control (3657.05 kg ha^{-1}) ($p<0.01$). The other two treatments had statistically significant ($p<0.01$) differences (T2 for 486.16 kg ha^{-1} and T3 for 441.71 kg ha^{-1}) compared to the control. Between treatments T2 (4143.21 kg ha^{-1}) and T3 (4098.79 kg ha^{-1}) the difference of 44.42 kg ha^{-1} was not statistically significant.

The obtained results are compatible with the results of Xiaohou et al. (2001) who state that spraying with effective microorganisms can increase the yield and grain quality of different crops. The same authors state that by adding photosynthetic bacteria to the soil, the amount of nitrogen compounds that are the secretions of photosynthetic bacteria increases, which affects the increase of mycorrhizal fungi. These fungi can coexist with nitrogen-fixing bacteria, increasing nitrogen-fixing ability and grain yield. According to Javid (2006) foliar application of EM with the use of NPK fertilizers in the production of peas (*Pisum sativum* L.) increases grain yield by 126%. The same author found that applying EM in wheat production can increase grain yield by 27% compared to production where only chemical fertilizers were applied. By applying effective microorganisms, the yield of soybeans in two-year studies increased by an average of 10.84%, and by 6.86% and 14.81% per year (Dozet et al., 2014). Differences in yield were also conditioned by different agroecological factors.

Conclusion

The use of NPK fertilizers is justified in the production of soybeans, and the use of preparations with effective microorganisms has a positive effect on the tested properties. The application of effective microorganisms had better results compared to NPK treatment. The best results were obtained by applying a combination of NPK and effective microorganisms in all soybean genotypes. The Rubin variety, which belongs to 000 matures, had the best results.

EVALUATION OF PRESPRAUTING AND DIRECT COVERING TO ENHANCE OF EARLY TUBER YIELD OF POTATO CROPS (*Solanum tuberosum* L.)

Dragan ŽNIDARČIČ*

Biotechnical Centre Naklo, Strahinj, Naklo, Slovenia
*Corresponding author: dragan.znidarcic@bc-naklo.si

Abstract

The research focused on early potato (Solanum tuberosum L.) production in Gorenjska region, Slovenia. A field study was conducted during 2020 growing season, at the Experimental field of the Biotechnical Centre Naklo (an altitude: 420 m; φ = 46° 16′ 18″; λ = 14° 18′ 56″). The soil of the experimental plot was gravel clay with pH 6.7. The experimental layout was a split-split-plot design with four replications. Cultivar was the main plot ('Arrow', 'Esme' and 'Adora'), agro-textile covering (under polypropilene and non-covered) the subplot and presprauting the sup-subplot. The potato seeds of a size 28 to 35 mm were divided into two lots (presprouted and not presprouted tubers) over a four weeks period. Potato seeds planted mechanically within the rows of 30 and 75 cm between the rows. Planting date was 1 April and tubers were harvested at optimum maturity, 76 days after emergence. The crops were managed according good farming practices. Presprauting treatment gave on average 3.2 days earlier emergence compared with the control tubers. Cover crops enhanced speed of emergence to 3.9 days. In addition, presprouting seed produced significant more stems (3.4 stem/plant) than control-grown seed (2.7 stem/plant). Cover crops showed significant higer plants (36.8 cm), while no cover plants revealed shorter plants (32.1 cm). The leaf area index under cover crops was higher on average by 0.6 compared to the control crops. Covered treatments gave significant higer total (34.6 t/ha) and commercial (28.5 t/ha) yield of tubers compared to control (28.2 t/ha and 23.7 t/ha, respectively). Dry matter content in the tubers showed significantly higher level in presprouting and covering treatments compared with the control. The variation in total soluble sugar contentration in tubers depended mainly on the genetic potential of the cultivars.'Esme' contained more total soluble sugar than the other two cultivars (6.9% Brix). Potatoes grown by the different agricultural practices did not show any significant difference in the nitrate content.

Key words: *potato, cultivars, nonwoven polypropylene cover, presprouting, yield.*

Introduction

Potato (Solanum tuberosum L.) is the main crop among those producing tubers and one of the most popular vegetable crops grown all over the world in terms of human consumption and after rice, wheat and maize holds the 4th largest crop by global production volume (Marcomini et al., 2019). There are three main types of potato to grow, named according to when you plant and harvest them: first earlies, second earlies and main crop.

First early or 'new' potatoes are so-called because they are the earliest to crop, usually in May or early June. Early season potatoes reach maturity within 65 to 80 days. From a commercial standpoint, the term early potato may be applied to potatoes which aregenerally harvested before it is completely mature, marketed immediately after harvesting and whose skin can be easily removed by rubbing. Early potato is of high biological and nutritional value, a real delicacy

intended for garden-fresh home meals or placement through green markets or stores. Early potato tuber contains high levels of useful nutrients, it is easily digestible, high in energy and very low in harmful substances, primarily harmful nitrogen (Ilin et al., 2000).
Potato cultivation for early cropping involves considerable risk, due to the possibility of early frosts in the initial period of growth, which may cause significant damage to entire plantations. Growers can reduce some of the risks associated with early planting by adjusting management practices to fit the situation. For example, the soil surface covered by agrotextile (Wadas, 2016). Coverings not only provide protection against early frosts but also protects crops from high intensity rainfall (Benoit and Ceustermans, 1990) and the behaviour of insects that visit the plants (Qureshi et al., 2007). Coverings can also move up crop emergence by 3 to 8 days, and increase both total and commercial yields (Rębarz et al., 2015). In addition, covers reduce solar radiation (Benoit and Ceustermans, 1987), wind influences (Mermier et al., 1995) and evaporation rates (Choukr-Allah et al., 1994) while increasing air humidity (Hemphill, 1989) as well as the soil humidity (Wolfe et al., 1989). The most often used plants cover is made of spun bonded polypropylene (PP). Spun bonded cover is extremely lightweight (10–50 g/m2), transmits enough light (80–94%) and can be placed directly over crops without the use hoops for support (Wells and Loy, 1985).
Presprauting tubers is a further measure that can encourage the faster cultivation of potato. According to Struik (2007) presprouting is a way of affecting physiological age, which can be an agronomic tool to help the crop adjust to the ecological conditions of the growing season and perform optimally for its intended purpose.
In Slovenia, where the growing season is restricted, the early potatoes harvested in spring have a higher market value than later potatoes. This provides a good incentive for developing different methods to promote early tuber initiation, such as early cultivars, direct covering, presprouting etc.
Therefore, the present work was carried out aiming to evaluate the effect of nonwoven polypropylene (PP) covering and presprauting on the quantity and quality of early tuber yield of potato.

Material and Methods

Field experiment was conducted during the spring 2020 growing season at the Experimental field located at the Biotechnical Centre Naklo (46° 16′ 18″ N latitude; 14° 18′ 56″ E longitude, 420 m above see level) which is an area recently destined for early crop potato cultivation in Gorenjska region, Slovenia.
The soil samples from the upper horizon (0-25 cm depth) were collected before the experiment. Elemental analysis indicated that this soil was gravel clay with pH (water 1:1) 6.7, an organic matter content of 3.8%, and phosphorus and kalium contents (ammonium acetate extraction) of 24 mg and 32 mg per 100 g of dry soil, respectively. The preceding crop in the year before growing potato was annual ryegrass. Cattle manure was incorporated into the soil 20 days prior to planting seed potatoes. A basal dressing of 350 kg NPK (15-15-15)/ ha was applied prior to planting on to soil surface by hand and incorporated. Additional fertilizer other than N was supplied uniformly across the plot areas to correct any deficiencies indicated by soil test results.
Three cultivars: 'Arrow', 'Esme' and 'Adora' were evaluated. 'Arrow' is the most common variety grown in Gorenjska region, while 'Esme' and 'Adora' have been recently introduced at a local level by seed potato companies as promising cultivars for early potato production. These

cultivars are all considered to be suitable for the fresh market, with a comparable medium to medium-early maturing cycle.
The experimental layout was a split-split-plot design with four replications. Cultivar was the main plot, agro-textile covering (under PPand non-covered) the subplot and presprauting (presprouted and not presprouted tubers) the sup-subplot.The potato seeds of a size 28 to 35 mm were randomly divided into two lots and stored for three weeks at 70-80 %. The tubers of first lot were sprouted under fluorescente lights and the second (control) lot were left in bags until planting, when any sprouts present were removed.
Potato seeds planted mechanically within the rows of 30 and 75 cm between the rows. The crops were managed according good farming practices. Planting date was 1 April and tubers were harvested at early and optimum maturity by hand from 4 m of the middle two rows from each main plot, 76 days after emergence.
Analysis of variance was performed to assess the significance of treatment effects. Differences between treatment means were compared by using Tukey's multiple range test at the 0.05 probability level.

Results and Disscusion

The Voltcraft DL-121TH Multi-channel data logger was used to record the temperature. With the advance of the vegetation period, the values of daily mean temperatures under the cover and in open field were slightly increasing and consequently the differences between covered and no covered treatments were noticed. The mean temperatures during the growing season are presented in Figure 1. From the beginning of Aprile until the middle of June the mean temperature under the cover was 2.1 °C higher compared to outside temperatures.

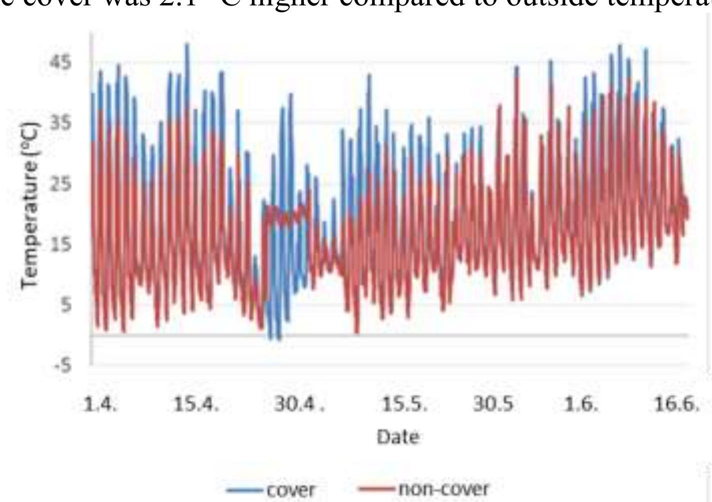

Figure 1. Temperature (°C) during the early potato growing period under PP cover and in open field

Some previous works showed that potato emergence can be affected by many factors, such as cultivar, seed-tuber age, cultural and enviromental conditions (Knowles and Knowles, 2006). As can be seen in Table 1 the percent of emerged plants was not significantly affected by the treatments; almost all planted tubers produced stems.
Presprauting treatment gave on average 3.2 days earlier emergence compared with the control tubers. The earlier emergence with presprouting were also reported by Möller and Reents (2007)

and Hagman (2012). The period from planting to emergence difference among cover and no cover treatments. Days to emergance was significant enhanced by 3.9 days. According Cholakov and Nacheva (2009) the application of PP covers enables earlier potato planting and forcing planting emergence. Wadas (2016) mentioned that PP covers shortened the period between planting and emergence by 2 to 8 days.

The number of main stem per plant was no significantly affected by cultivar and covering. But on the other hand this parameter consistently increased with presprouting. On average, presprouting seed produced significant more stems (3.4 stem/plant) than control-grown seed (2.7 stem/plant). These findings agree with the results of Caliskan et al. (2004). On the other hand, our results are not conformity with those of Allen and O'BRien (1986) who mentioned that presprouting have negligible effect on number of above ground stems. Dimante and Gaile (2014) assume that one of the main traits defining the physiological status of the seed tuber and potato plant growth vigour is number of stems per emerged plant. The number of stems is a crucial trait as it influences tuber number per plant.

Plant height from tubers of different cultivars was no significant varied. We also observed that presprouting had no effect on plant height. Nevertheless, differential responses of plant height performed by covering: on average, cover plants showed significant higer plants (36.8 cm), while no cover plants revealed shorter plants (32.1 cm). Our results are in accordance with previous findings of Cholakov and Nacheva (2009). The authors found out that potato growing under non-woven PP developed a higher stems compared to cultivation without covering.

A higher soil and air temperature under covers provides better conditions for plants immediately after planting and allows them to produce a higher leaf area index (LAI), which was confirmed in the present study. The LAI under PP fibre was significant higher on average by 0.6 compared to the plants cultivated without covers. According to Liu et al. (2012), a higher assimilation leaf area and LAI value could cause an increase in yield and improve its quality. No signifficant differences were recorded on LAI among cultivars and among presprauting tubers.

Table 1. The effects of presprauting and covering on percentage of emergence (%), on time to emergence (in days after planting-DAP), stem number (plant^{-1}), plant height (cm) and leaf area index of potatoes

Treatment	Emergence (%)	Emergence (DAP)	Stem number (plant^{-1})	Plant height (cm)	Leaf area index

Presprouting					
Yes	99.7 a	25.2 a	3.4b	32.2 a	2.6 a
No	99.6 a	28.4 b	2.7 a	31.8 a	2.5 a

Mean values within treatment not followed by the same letter are significantly different at P = 0.05.

The cumulative total and commercial yield (tubers with a size of >45 mm) at the end of the experiment per unit area, was significantly enhanced by the all treatments.The different potato cultivars significantly affected potato yield. The highest total yielding cultivar were 'Arrow' at 32.4 t/ha and 'Adora' at 33.8 t/ha. The similar trend was observed in context from commercial yield. The 'Arrow' and 'Adora' cultivar were quite similar with 28.4 and 28.8 t/ha, respectively. 'Esme' provided the lowest average commercial yield (24.6 t/ha).
The application of PP fibre improved the growth and development conditions of plants and as a result increased the yield. Covered plants gave significant higer total (34.6 t/ha) and commercial (28.5 t/ha) yield of potato compared to uncovered plants (28.2 t/ha and 23.7 t/ha, respectively). Rębarz et al. (2015) reported a similar increase of total yield and share of commercial tuber yield of early potato. Presprauting had no effects on total yield but a significant variations in the commercial yield. On average, presprauting treatments gave higher yield (27.2 t/ha) compared with the control (23.4 t/ha). Our results are conformity with those of Caliskan et al. (2004).
The dry matter (DM) content were obtained after drying the samples in a forced air oven (65–70 °C) to constant weight. The obtained results proved that cultivar had a significant impact on the size of the percent of DM of tubers. 'Arrow' tubers showed the highest DM (22.1%) than those from the other two cultivars. Baranowska (2018) stated that genetic features of potato cultivars had a signifcant impact on the size of the yield of DM. The % of DM were higher in potato tubers cultivated under agro-textile (21.6%) than in potatoes cultivated without coverings (16.8%).This increase of DM in the treatment under thecover at early harvest is in relation with results obtained by Hamouz et al. (2005). Measurements of the DM content in the tubers showed significantly higher % of DM content in presprouting treatments (20.4%) compared with the control (17.2%). The higher DM content in the presprouted treatments indicated that these physiologically older seed tubers had reached a more mature stage at the time of harvest (Pandeyet el., 2017).
Total soluble sugar (TSS) concentration of the tuber extracted juice was determined using a hand-held Atago PR1 refractometer. TSS was mainly affected by cultivar and less by covering and presprouting. The maximum TSS (6.9% Brix) of tuber was recorded by 'Esme' and the minimum (4.6% Brix) was recorded by 'Adora'.
Furthermore, we noted that potato cultivar and type of the production system had no impact on the nitrate content in potato samples. Nitrate content was determined by HPLC according to Kmecl and Žnidarčič (2015). The nitrate content in all treatments was practically the same, the differences were within the experimental error.

Table 2. The effects of presprauting and covering on tuber yield (t/ha), dry matter (%), total soluble solids (%Brix) and nitrate content (mg/kg) in tubers

Treatment	Tuber yield (t/ha)		Dry matter (%)	TSS (%Brix)	Nitrate (mg/kg f.w.)
	Total	Commercial

Conclusions

Production of early potato in Slovenia is importand because it provides this highly valued delicates food during the period from May to June, when is on the market low offer of other fresh vegetables. The greatest benefits of sprouting and direct covering of nonwoven PP cover were significantly influenced on commercial tuber yield. The efficacy of these agronomic treatments not only affected tuber yield quantity, but also contributed to improving of the tuber quality, especiallyby an increase in dry matter.

DETERMINATION OF THE PRODUCTIVITY AND DEVELOPMENT STATUS OF THE SECONDARY BUDS IN THE KARAERIK GRAPE VARIETY

Muhammed KUPE, Sezai ERCISLI*

Ataturk University Agricultural Faculty Department of Horticulture 25240 Erzurum, Turkey
*Corresponding author: sercisli@gmail.com

Abstract

This study was carried out to reveal the size of the secondary buds and the number of clusters they contain in the Karaerik grape variety. In addition, it was tried to determine whether there was a relationship between secondary bud size and cluster outline formation. In the study, winter buds in the first, second and third node of the grape variety Karaerik (*Vitis vinifera* L.), fertile in bottom buds, suitable for short pruning and have a very high table value in the region, were used as material. Secondary buds were separated from the primary and tertiary buds in winter buds with the help of a scalpel and were subjected to fixation, vacuuming, paraffin impregnation, paraffin embedding, freezing, sectioning and tissue staining, respectively. The stained samples were examined microscopically, their images were taken and these images were transferred to the computer, and the secondary bud size and cluster number were determined. In the study, it was revealed that the secondary buds in the second node were statistically different ($p<0.05$) from the secondary buds in the first and third nodes in terms of both cluster number and bud size. In addition, it was determined that there was a relationship between the bud size of the secondary buds in the second node of Karaerik grape variety and the number of clusters.

Keywords: *Secondary bud, bud size, cluster number.*

Introduction

Winter buds on the grapevine are quite complex due to their anatomical and morphological structure. Winter buds are of various shapes and appearances, but are generally large and angular. They contain leaf scales, shoots, leeches and cluster primordium and take their final shape in autumn. The bud core after the protective scales consists of three shoot beds. These shoot beds are expressed as primary bud, secondary bud and tertiary bud according to their growth capacities (Celik et al., 1998; Agaoglu, 1999). One of the shoot beds is in the middle and the other two are on the sides. The scales of the middle shoot bed are larger and the organs are better developed.

With the beginning of the vegetation period, the shoot bed in the middle develops and forms the summer shoot. In the shoot bed called the secondary bud, the organs are weaker than the middle shoot bed and in some case they may form clusters. The growth cone, which is called the tertiary bud and located at the top of the middle shoot bed, is more primitive than the other two shoot beds and does not contain clusters.

In addition, more than three shoot beds can be seen in a winter buds, although not very often. Although it is thought that the number of exile beds in the winter bud can be affected by genetic structure, the location of the bud on an old branch, cultural practices a year ago (Ilter, 1980; Agaoglu, 1993), this may occur under the influence of many factors. There is no clear explanation of the situation.

In terms of productivity of the grapevines, it is understood the productivity of the primary buds in the winter buds. The efficiency of secondary buds is important only in terms of compensating the losses that will occur due to the damage of the primary bud and ensuring the continuity of vegetative organs (Agaoglu, 1969).

In temperate climates, bud burst of grapevine is expected to occur with the continuation of the primary bud located in the middle of the winter buds, which have completed their development at the beginning of April. If this bud is damaged by late spring frosts, diseases and pests and mechanical impacts, the secondary bud comes into play, and if it is damaged, the tertiary bud becomes active. During this period, the dead primary bud can be observed among the other two developing buds (Dry and Coombe 1994).It is well known that primary buds in the winter buds are more efficient than secondary and tertiary buds, but they are more sensitive to frost damage than secondary and tertiary buds (Hemstead and Luby, 2000; Sivritepe et al., 2001) Smiley et al., 2008).Although the Üzümlü district of Erzincan province, where the study was conducted, has a microclimate feature, the low winter temperatures that occur in some years cause significant damage to the winter buds of the grapevine. Primary buds, which are primarily sensitive, are damaged in years when frost damage is observed. In this case, the secondary buds, which act as insurance, continue and the vegetative development of the grapevine continues. The continuation of secondary buds ensures the continuity of vegetative organs, and depending on the variety and year, sometimes products can be obtained at levels close to the normal product. Therefore, the productivity of the secondary bud in viticulture is also important (Guner, 2005). In different studies, it has been determined that secondary buds can yield varying levels according to the variety and year (Karaagaç, 2000; Aydın, 2001; Guner, 2005). However, in many national and international studies, all yield calculations were made on primary buds, ignoring the productivity of secondary buds in grapevine winter buds.

The main purpose of this study is to determine the size and productivity of the secondary buds, whose productivity is often neglected in winter buds, according to the node (position they are on an old branch). In this context, this study conducted on *Vitis vinifera* cv. Karaerik, secondary bud sizes and cluster primordia within the buds, depending on their positions, were determined by histological analysis. In addition, the relationship between the secondary bud size and the number of clusters in the Karaerik grape variety has been tried to be put on the line.

Material and Methods

Material

This study was carried out between 2019-2020 on a 30-year-old Karaerik vineyard established with the Baran system under the conditions of the Üzümlü district belongs to Erzincan province, which has microclimate characteristics in the Eastern Anatolia Region. The Karaerik grape variety, which is suitable for short pruning, is usually pruned over 2-4 buds, and taking into account the growth capacity of the vines, usually 30-40 buds are left on one vines (Kupe and Kose 2015). In the study, one of the old branches of the Karaerik grape variety, which is consumed for table consumption and has a very high market value in the region, was taken just before pruning (March) at the end of the winter rest period. Samples taken from the vineyard were delivered to the laboratory on the same day in polyethylene protection bags in order to avoid lost of moisture.

Methods

In the study, the other two buds (primary and tertiary buds) in winter buds were separated with the help of a scalpel in order to determine the productivity status of secondary buds. The remaining secondary buds are grouped according to their node (position) where the winter buds are on an old branch. For this purpose, the cluster primordia within the secondary buds inside the suspended winter buds with mixed bud structure were determined according to Odabas (1976). In the study, the first 3 nodes from the bottom, which are fertile for the Karaerik grape variety, were evaluated.

Each of the secondary buds grouped according to their nodes (the position they are on an old branch) were placed in separate bottles and placed in the desiccator by adding 2 ml of fixation liquid consisting of 5 ml formaldehyde, 5 ml glacial acetic acid, 90 ml 70% alcohol, and vacuuming process was carried out at regular intervals. Each fixed sample was passed through Johansen solutions (water + ethyl alcohol + tertiary butyl alcohol mixture) at concentrations of 50%, 70%, 85%, 95% and 100%, respectively, according to Johansen (1940).

The samples were kept in each solution for at least two hours. After the fixation process was completed, paraffin was added to completely cover the samples taken into the empty bottles, and paraffin impregnation was carried out by keeping them in the oven at 60 °C for 24 hours. Samples removed from the oven at the end of 24 hours (through liquid paraffin) were embedded in paraffin so that a longitudinal section could be taken. The paraffin blocks in which the samples are embedded were kept in the freezer at -20 ºC for 24 hours. Samples taken out of the freezer are stored at room temperature (22-24 ºC) for 5 minutes. After waiting for a period of time, longitudinal sections were taken with the help of a rotary microtome in thicknesses varying between 08-12 microns. The sections taken were laid in a gelatin-poured hot water bath (30 ºC). The samples adhered on the slide were heat treated in the oven at 60-70 ^{0}C for 1 hour and the paraffin was melted. In order to remove the melted paraffin from the tissue in the samples taken from the oven, it was kept in xylol (10 minutes) and 100% ethyl alcohol (5 minutes). After waiting for the water on the slide to dry, a drop of Toluidine blue was dropped on each section sample, after 5 minutes, the sections were washed with water and allowed to dry. The coverslips were adhered by dropping 1 drop-holding gel on each of the dried sections and the sections were made ready for examination under a light microscope. In histological examinations, images were transferred to the computer with the help of a camera (Moticam 480) integrated with the microscope.

With the help of the program installed on the computer (Motic images 2010), investigations were made on the photographs of the tissues. During the investigation, cluster outline numbers within the secondary buds were determined according to the positions of the buds. In addition, while determining the size of the buds according to their position, the width x height value measured in mm was taken into consideration as the bud size (mm^2) (Figure 1). In this study, some statistical analyzes have been made to determine the differences between the cluster plots that the secondary buds contain according to their location and years. T-test (One way Anova) was performed in SPSS program to determine how cluster outline numbers and bud sizes in secondary buds vary by position and year.

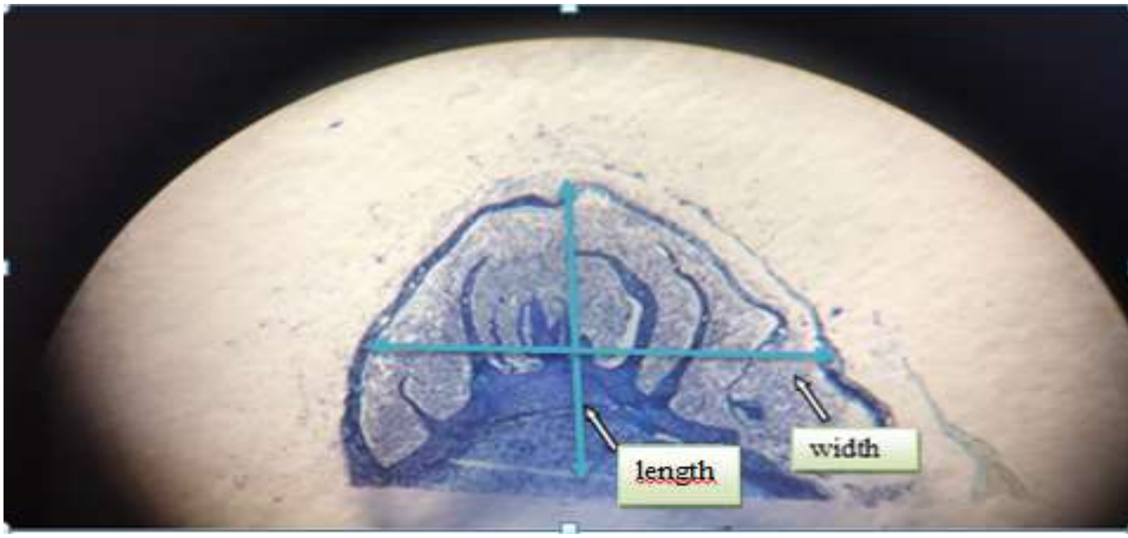

Figure 1. Determination of secondary bud size

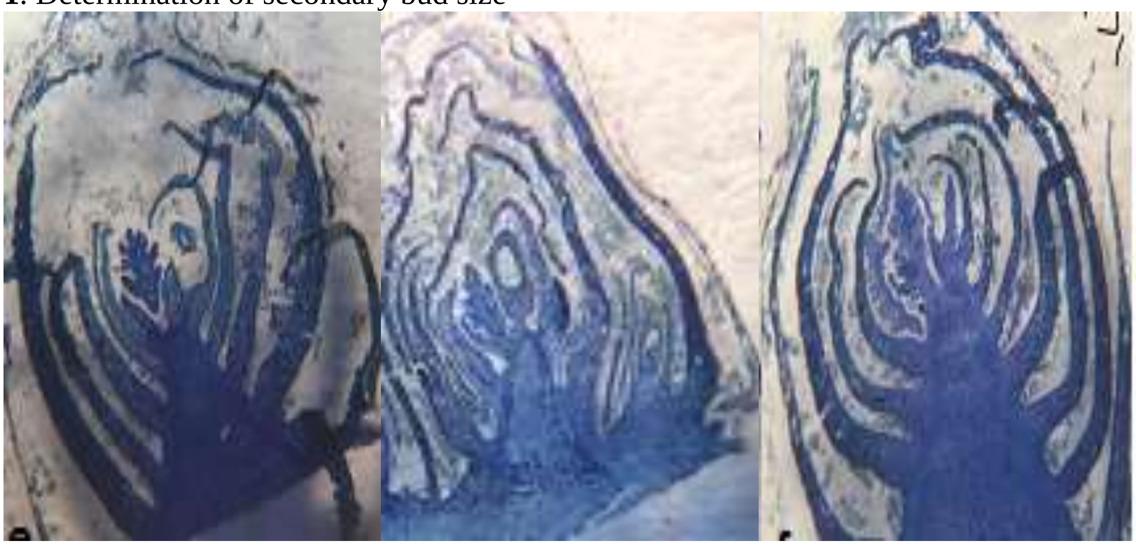

Figure 2. Samples of secondary buds containing clusters

Results and Discussion

The T Test (Oneway ANOVA), we made in order to reveal how the number of clusters contained in the secondary buds in the winter buds change according to the position is presented in Table 1. According to the results obtained in the study in which the number of clusters contained by the secondary buds were evaluated according to the first 3 nodes; It was determined that there was a statistically significant ($p < 0.05$) higher number of clusters between the 1st node and the 2nd node. Although it was determined that the number of clusters in 3rd nodes was higher than the 1st node and less than the 2nd node, the difference between these groups was statistically insignificant ($p > 0.05$). Similar results were obtained in both years of the study (Table 1).

Table 1. The number of clusters in secondary buds according to their position

Position	**Cluster numbers**			
	Year 1		**Year 2**	
	$\bar{X}$	S_x	$\bar{X}$	S_x
1. node	0.000^{b}	0.000	0.077^{b}	0.053
2. node	0.177^{a}	0.043	0.311^{a}	0.061
3. node	0.077^{ab}	0.053	0.111^{ab}	0.062
Mean	0.121	0.029	0.220	0.040
P	*		*	

a, b: There is no statistical difference between the values indicated with the same letter.
*: Significant difference at $p < 0.05$ level

In the first year of the study, no clusters were found in the secondary buds located in the first node. In the second node, it was determined that 17.7% of the secondary buds examined had 1 cluster. In the third node, it was determined that there was 1 cluster in 7.7% of the samples examined. In the second year of the study, it was determined that 7.7% of the secondary buds in the first node, 31.1% of the secondary buds in the second node, and 11.1% of the secondary buds in the third node. When the years and positions are evaluated together, it has been determined that 17% of the secondary buds have 1 cluster each (Table 1).
The T Test (Oneway ANOVA) we made in order to reveal how the size of the secondary buds in suspended winter buds changes according to the position is presented in Table 2. When the secondary bud sizes were examined in terms of their position in the study, the size of the secondary buds in the 2nd node was found to be statistically ($p < 0.05$) higher than the size of the 1st and 3rd buds in both years. In addition, no statistically significant difference ($p > 0.05$) was determined in terms of the size of the 1st and 3rd buds in both years of the study (Table 2).
According to the results of the study, it was determined that the largest secondary bud was in the second node in both years, and the secondary buds in this node had a size of 0.041mm^2 in the first year of the study and 0.048 mm^2 in the second year of the study. Although there was no statistically significant difference between the secondary buds in the first and third node in both years of the study, the secondary bud in the first node was larger than the secondary bud in the third node, and in the second year, the secondary bud in the third node was found to be larger than the secondary bud in the first node (Table 2).

Table 2. Secondary bud size according to their position

Position	**Bud Size**			
	Year 1		**Year 2**	
	$\bar{X}$	S_x	$\bar{X}$	S_x
1. node	0.031^{ab}	0.003	0.027^{b}	0.003
2. node	0.041^{a}	0.004	0.048^{a}	0.004
3. node	0.025^{b}	0.002	0.029^{b}	0.003
Mean	0.035	0.003	0.040	0.003
P	*		**	

a, b: There is no statistical difference between the values indicated with the same letter.
*: Significant difference at $p < 0.05$ level

In the test performed to determine the relationship between bud size and the number of clusters, the first year was significantly ($r = 0.199$, $p < 0.05$), and the second year was very significantly ($r = 0.359$, $p < 0.01$) between the number of clusters and the bud size in the study. In the correlation analysis, it was understood that there was a very significant relationship ($r = 0.250$, $p < 0.01$) between the number of clusters in the 2nd node and the size of the buds, but there was no significant relationship in the 1st and 3rd node.
Some important results were obtained in the study of determining the size and productivity of secondary buds on Karaerik grape variety (*V. vinifera* L.), which is widely grown in Erzincan (Üzümlü) province in Eastern Anatolia region of Turkey. It is known that primary buds in winter buds are more productive than secondary and tertiary buds, but they are more susceptible to frost damage than secondary and tertiary buds. Although this region where the study was conducted has a microclimate feature, the low winter temperatures that occur in some years cause significant damage to the winter buds of the grapevine. Primary buds, which are primarily sensitive, are damaged in years when frost damage is observed. In this case, secondary buds, which assume the role of insurance, continue the vegetative development of the grapevine. In this study, cluster numbers were examined in order to determine whether the secondary buds of the Karaerik grape variety had an effect on the yield of the grapevine. At the end of the study, it was revealed that Karaerik grape variety had 1 bud in 17% of the secondary buds.
When the number of cluster primordia contained by the buds according to their positions at the end of the study is evaluated, it is seen that the secondary buds in the 2nd node contain more cluster primordia than the secondary buds in the 1st and 3rd node. Since the yield of grape obtained from vineyards can vary depending on the position of the winter buds on the 1 year branch, it is of great importance to be able to determine the winter bud productivity in different positions (Karatas et al., 2010; Kupe and Kose 2015). Agaoglu and Kara, (1993), in their study, in which they determined the productivity of 37 grape varieties grown in Tokat region according to the positions of the first 10 internodes, reported that the maximum productivity varied between the 3rd and 10thbuds, and the first nodes were unproductive in some varieties. Agaoglu (1999) stated that the number of buds and clusters in anbud varies according to the position of the bud, and although it varies according to the varieties, generally the bottom and tip of the shoot contain fewer buds (shoot beds) than the middle part of the buds.
Although this situation is expressed for primary buds, it has been revealed that it has a similar relationship in secondary buds. In addition, the lowest number of cluster primordia was observed in the first node in both years of the study. We believe that this situation may cause very few cluster primordia or no cluster primordia to be seen in the secondary buds due to excessive lignification in the first node, where old branches begin to lignify from the bottom. Agaoglu (2002) and Celik (2008) stated that very strong vegetative developments delay the formation of cluster primordia in winter buds and decrease the number of clusters/bud ratio, and Celik (2008) stated that the growth power is one of the most important factors affecting the cluster and flower formation. Considering the fact that there is more wooding in the bottom buds as a part of vegetative development, it is seen that it supports our result. Similarly, Sartorius (1968) reported that very strong developments reduce bud productivity.
In the study, when the sizes of the secondary buds are compared according to their position, it is understood that the secondary buds in the second node have a larger structure than the secondary buds in the first and third node. Since we thought that there might be a relationship between bud size and the number of clusters in the study, we determined that there was a relationship between the size of the bud and the presence of a cluster outline in the statistical analysis we made to

determine this relationship. It has been demonstrated that this relation is strongest in the 2^{nd} node in the Karaerik grape variety, whose bottom buds are fertile. Lavee (2000) reported that shoots developed better due to the long vegetation in hot regions and there was a positive correlation between shoot development and bud development. However, Sartorius (1968) reported that very strong growth decrease bud productivity. Indeed, Huglin (1958), who stated that the growth power is one of the most important factors affecting the cluster and flower formation, reported that there is a positive relationship between the growth of the shoots and the number of clusters/bud, flower number/flower number/shoot ratio. In other words, the presence of clusters in the bud reinforces the possibility that the bud size may increase or the possibility of cluster outline formation in buds with large structure may be higher.

Conclusion

As a result of the study, it was observed that the secondary bud size for the Karaerik grape variety and the number of cluster outline in the bud may vary according to the position of the bud on an old branch and the bud size. Considering that the low winter temperatures that occurred in the region where the study was conducted for some years caused significant damage to the winter buds of the grapevine, it is very important to know how efficient these buds are, and the secondary buds that take on the role of insurance in the years of frost damage. If the secondary bud continues, it is ensured that the vegetative development of the grapevine will continue. In addition, by knowing the productivity levels of secondary buds, it will be possible to make a more accurate annual yield estimation for the variety in years of frost damage.

Abstract

Turkey is one of the richest countries in the world in terms of both horticulture crop production and diversity. Turkey is origin or second homeland of many fruit species. Diverse climate and soil conditions supports to growth a large number of fruit species, cultivars, genotypes, accessions even clones in the country. During the last two decades due to increasing interest to plant-derived natural products, apricots and its products has been gained more attention not only by consumers but also industries. Present study describes fatty acid profile of cv. Aprikoz and 4 wild apricot (Zerdali in Turkish) genotypes that has sweet kernels. A total nine fatty acids were found in cv. Aprikoz and four wild apricots and statistically significant differences are evident for major fatty acids among all searched cultivar and genotypes. Among the major fatty acids, oleic acid (18:2) were found to be the highest ratio for all analyzed apricot kernels which in range of 67.11% (wild apricot 4) and 70.44% (wild apricot 3), respectively. The other dominant fatty acids were linoleic acid and varied from 19.92% (wild apricot 4) 5) to 22.10% (wild apricot 3). All apricot samples had more monounsaturated fatty acids (MUFA) than saturated fatty acids (SFA) in seed oils. ΣPUFA/ΣSFA were in range of 3.22 and 3.75 among samples. Results indicated that fatty acid compositions of wild apricots are comparable with cv. Aprikoz.

Keywords: *apricot, wild, fatty acids, metabolic profile.*

Introduction

Turkish fresh fruit industry is not only the great diversity in the number of fruits grown but also the astonishing quantity of the total produce, about 20 million tons. The fresh produce grown in Turkey mainly consists of berries, pome fruits, stone fruits and citrus fruits. For apricots, the country leading both fresh and dried apricot production of the world for a long time. Turkey shares around 20% of world fresh apricot production and the country realizes more than 70 percent of the world dried apricot production. Uzbekistan, Italy, Iran, Algeria, Pakistan, Iran, Egypt, Ukraine, France and Spain were the other important apricot producer countries in the world (FAOSTAT 2020). Last two decades Turkey sharply increased apricot production from 315 thousand tons in 2002 at 750 thousand tons in 2018. During that period most of the main apricot producer countries either decreased their production or keep the same amount.
Approximately 35-40 percent of apricots produced in Turkey are consumed fresh and the remaining amount is dried or used in juice industry (Paydas et al. 1992; Ercisli 2009). In the production of dried apricots, the seeds are separated from the fruit flesh and the fruit flesh is dried and in general send to local markets or exported. Turkey is also an important apricot kernel producer in this sense. Apricot trees consisted in both cultivated and wild forms in Turkey, are

generally grown in semi-hot and arid regions, as well as in parts of the mountains that receive plenty of sun, and on the mountain slopes that do not hold water and are slightly calcareous in the south-facing parts of the mountains. These apricots are generally disease-free, delicious, sweet-tasting fruits with high dry matter content. Apricot trees are grown in Turkey mainly Malatya, Elazig, Mersin, Aras valley, Antalya, Kahramanmaras provinces, respectively (Asma et al., 2007; Polat et al., 2010; Caliskan et al., 2012; Polat et al., 2018). Aras valley, which has the one of the higher number of both cultivated and wild apricot trees, has traditional use of apricot kernels. In the Kagizman district, located in the Aras valley, apricot kernels are used especially in the production of pestil (a traditional product consisting of mulberry fruit, honey, milk and apricot kernels). In recent years, the kernels of apricot have been used as snacks as well and formed an important market segment (Gecer et al., 2020). In 2020, approximately 25 thousand tons of shelled kernels and 8 thousand tons of apricot kernels are obtained from dried apricots in Malatya city and average of 6-7 thousand tons of kernels exports per year. Italy is one of the most important buyers and approximately 2 thousand tons of apricot kernels exported to Italy. Malatya apricot kernel has also geographical indication (Anon. 2020). Consumers' orientation towards natural and unprocessed oils is increasing day by day. Oils that contain more phenolic components, high in oleic acid and rich in omega-3, can be offered for consumption in salads and sauces. In this sense, the fact that it is an alternative product to olive oil and rich in functionality reveals that it can have an important place in the market (Petrescu et al. 2020). The fatty acid composition of oil from kernels of apricot is highly favorable in human nutrition (Turan et al., 2007; Akinci et al., 2010). Apricot kernel oils had high oleic and linoleic oils and both had superior stability and nutritional importance. Linoleic acid, the main polyunsaturated fatty acid found in vegetable oil, nuts and seeds and lowers risk of coronary heart diseases (Farvid et al., 2014). Apricot kernels make up about 12% of the apricot fruit weight and consist of 15-20% protein, 4-5% cellulose, 52% oil. The oil content of the kernels varies between 27.7% and 66.7% (Femenia et al., 1995; Alpaslan and Hayta 2006). Apricot kernel oil is a raw material rich in unsaturated fatty acids, mostly consisting of oleic and linoleic fatty acids. Apricot kernel oil contains 58.3-73.4% of oleic acid and 18.8-31.7% of linoleic acid (Ozcelik, 2017). This content consists of 91.5-91.8% unsaturated fatty acids and 7.2-8.3% saturated fatty acids, as well as 95.7-95.2% neutral lipids, 1.3-1.8% glycolipids and 2.0% phospholipids. Seed oil contains 11.8 mg of campesterol, 9.8 mg of stigmasterol and 177.0 mg of sitosterol per 100 g (Alpaslan and Hayta, 2006). Apricot kernel oil contains high levels of γ-tocopherol, which can reach up to 475 mg/kg in oil. It also contains lesser amounts of α and β-tocopherol than γ-tocopherol (Ozcelik 2017).
The fact that there is not much research in fatty acid profiling of apricot kernel in particular on wild apricot kernel. Thus, the aim of this study is to determine fatty acid profile of 4 wild apricot kernels and cv. Aprikoz grown together in Kagizman district in Aras valley.

Material and Methods

Plant material

In present study cv. Aprikoz, and 4 wild grown apricots (kernels have sweet taste) used. All plants are grown in Kagizman district located in Aras valley in 2018. After harvest the apricot seeds separated from flesh and also removed of foreign substances.

Oil extraction

Automatic soxhlet device was used for total oil (lipid) extractions. Approximately one hundred fifty grams of dried grape seeds were used for oil extraction. Hexane used as solvent.

Determination of fatty acids

The fatty acids were analyzed by a GC (Perkin Elmer, Shelton, USA). Chromatographic separation was done using a (30 m×0.25 mm) column equipped with a flame ionization detector (FID). The oven temperature was 120 °C for 2 min, raised to 5 °C/min to 220 °C, which was held for 10 min, while the injector and the detector temperatures were set at 280 °C and 260 °C, respectively. The results were expressed in GC area % as a mean value and ± standard deviation.

Statistical analysis

All data were analyzed using SPSS software and procedures. Analysis of variance tables were constructed using the Least Significant Difference (LSD) method at $p<0.05$.

Results and Discussion

The data of the fatty acid profiles of cv. Aprikoz and 4 wild apricot kernels are presented in Table 1. Statistically there were a great variation ($p<0.05$) in the palmitic acid, oleic acid and linoleic acid in seed oils of used cultivar and four wild apricot genotypes (Table 1).

Oleic acid, linoleic acid, palmitic acid and stearic acid were in range of 67.11-70.44%, 19.92-22.10, 4.56-5.46 and 0.97-1.23%, respectively (Table 1). For all apricot samples, oleic acid was predominant and the highest oleic acid content was obtained from wild apricot 3 genotypes (70.44%), and followed by wild apricot 1 (70.04%), cv. Aprikoz (68.10%), wild apricot 2 (67.33%) and wild apricot 4 (67.11%), respectively. However statistically there was no differences between wild apricot 1 and wild apricot 3 genotypes (Table 1). The kernel oil of the wild apricot 3 contained higher content of linoleic acid (22.10%) than those of the cv. Aprikoz (21.41%), wild apricot 1 (20.33%), wild apricot 2 (21.89%) and wild apricot 4 (19.92%) (Table 1) The wild apricot 2 genotypes had the highest palmitic acid (5.46%) in kernel than rest of the genotypes and cv. Aprikoz. The other three genotypes of wild apricots had lower palmitic acid content than cv. Aprikoz. The cultivar cv. Aprikoz and 4 wild apricot genotypes were differed each other in terms of saturated fatty acids (ΣSFA), monounsaturated fatty acids (ΣMUFA) and polyunsaturated fatty acids (ΣPUFA (Table 1). Apricot kernels were characterized by high ΣMUFA (67.86-71.24%) and followed by ΣPUFA (20.02-22.24%) and ΣSFA (5.82-6.86%), respectively (Table 1). Σ fatty acids were in range of 94.23-99.47% (Table 1). Considering general classification of fatty acid, sequence was MUFA>PUFA>SFA in seeds oils of cv. Aprikoz and wild apricots. We found PUFA/SFA ratio between 3.15 in wild 4 apricot and 3.75 for cv. Aprikoz, which shows good values for nutritional perspective as dietary fat by British Department of Health (Anon. 1994). Previous studies related to fatty acid profile of apricot kernels in apricot producing countries located in Asia (kernel is traditionally have been used and has special importance in Turkey and the other Asian countries) showed that the major fatty acids in apricot kernel oils was oleic acid and followed by linoleic and palmitic acid. The concentrations of oleic, linoleic and palmitic acid varied from 62.07-71.00%; 20.15-27.76%; 4.20-7.79% in India (Gupta et al., 2012; Yadav et al., 2018), 62.34-80.97%; 13.13-30.33%; 3.35-5.93% in Pakistan (Manzoor et al., 2012) and 70-29-71.25%; 22.31-23.00%; 4.57-4.87% in China (Zhou et al., 2016), respectively. In Turkey Juhaimi et al. (2018) found that apricot seed oils contain 65.98-71.86% oleic acid, 20.18-22.74% linoleic acid and 5.87-6.78% palmitic acid.

Sengun et al. (2021) used Hacihaliloglu apricot seed to characterize fatty acid composition and found that approximately 97% of kernel oil consists of oleic (63.5%), linoleic (28.1%) and palmitic acid (5.2%). Compared with the results of previous studies, it was determined that the oleic, linoleic and palmitic acid amounts of the apricot kernel oil examined in this study were in accordance with the literature. These studies revealed that the fatty acid components of apricot seed oil may vary depending on the genetic background, harvesting period, processing, storage conditions, geographical region in which apricot trees are grown etc. Candan (2019) examined fatty acid composition of apricot kernels obtained from supermarket and determined that it contained 63.87-69-53% of oleic acid, 23.35-26.01% of linoleic acid, and its α-linolenic acid content was below 1%. Gundogdu et al. (2011) used Sakit, Bebeco and Colomer apricot cultivars to determine fatty acid profile in eastern Turkey and they found quite variable fatty acid profile. They reported oleic acid, linoleic acid, palmitic acid and stearic acid were in range of 26.51-59.88%, 29.24-53.65%, 5.73-10.89%, 3.05-3.84%, respectively. Matthaus et al. (2016) used Hasanbey, Hacihaliloglu, Kabaasi and Soganci apricot kernels to determine fatty acid content. They found that fatty acid compositions of the oils extracted from apricot kernels collected at the different harvest times are variable. Oleic and linoleic acids were determined as major fatty acids in kernels. While oleic acid contents of apricot kernel oils increase depending on maturation at the harvest times, both palmitic and linoleic acid contents of apricot kernel oils decreased. Uluata (2016) used Hasanbey apricot cultivar kernels for fatty acid analysis by using solvent and listed fatty acids as oleic acid (72.10%), linoleic acid (19.90%), palmitic acid (6.40%), respectively. The total SFA, MUFA and PUFA values of Hasanbey apricot kernels were 7.50%, 72.60% and 19.90%, respectively. The same study indicated PUFA/SFA ratio 2.65 that was a little bit lower than our finding.

Conclusions

In literature, very limited studies have been concerned with fatty acid composition of oils obtained from wild apricot seeds. This highlights the importance of the present study. Results also indicate that cv. Aprikoz and wild apricots was outstanding with better PUFA/SFA ratio. Taking all these facts into account, apricot kernels can be recommended for human consumption due to comparable fatty acid profile. This study has its limitation, where the fatty acid profiles were only identified using limited number of apricot cultivar and wild apricot samples as well.

Abstract

In this study, research is focused on the application of pyrophyllite fertilization in combination with mineral fertilizer NPK (15:15:15) on the vegetative growth of cabbage hybrids Bravo F_1. Research was conducted during 2018 and 2019at the Institute of Agriculture of Federation of Bosnia and Herzegovina (FBiH).The aim of the study was to determine the extent to which the vegetative growth of cabbage depends on different doses of pyrophyllite combined with a standard amount of NPK mineral fertilizer. The influence of the following fertilization variants was investigated: var. 1 (control) - 800 kg/ha NPK 15:15:15, var.2 – 800 kg/ha NPK 15:15:15 + pyrophyllite 2.200 kg/ha, var.3 - 800 kg/ha NPK 15:15:15 + pyrophyllite 700 kg/ha, var.4 -800 kg/ha NPK 15:15:15 + pyrophyllite 1.200 kg/ha, var.5 800 kg/ha NPK 15:15:15 + pyrophyllite 700 kg/ha.The highest dose of applied pyrophyllite per unit area (2.200 kg/ha) had the greatest impact on the vegetative growth of cabbage.The results of the study indicate that the application of pyrophyllite can reduce the use of mineral fertilizer in the production of cabbage without adverse effects on the parameters of its vegetative growth.

Introduction

Most agricultural land due to the continuous loss of nutrients in different ways, consequently lose their fertility and fertilizer efficiency and renewal of soil fertility remains insufficient. Precisely because of this, the use of pyrophyllite is taking on an increasing role in preserving and restoring soil fertility. Prospects for greater use of pyrophyllite in agriculture are based on the characteristics of its high adsorption capacity, high selectivity for some heavy metals and radionuclides (Hodžić,2016). According to Stoiljković (2002), pyrophyllite is one of the most promising minerals for use in agricultural production as a nutrient and biostabilizer. According to research of Churakov (2016) the pyrophyllite thanks to its physical and chemical properties has a positive effect on the fertility of the soil, improves the structure and the ability to retain moisture in the soil, regulates and distributes nutritional materiesand water to the plant when it needs most, at the same time for its crystal structure is tightly bound by heavy metals and polycyclic hydrocarbons. The results of Hasanbegović (2018) indicate that pyrophyllite is an important resource in the agricultural sector and other economic activities and its use in wider production practice can prevent serious environmental problems while obtaining quality agricultural products. In production practice, according to the research of Murtić et al. (2020) the application of pyrophyllite in agriculture is not significantly present due to poorer availability and insufficient knowledge of its potential for use.

Taking into account the previously mentioned facts, the aim of the study was to examine whether the application of pyrophyllite can reduce the use of mineral fertilizers in the production of white cabbage. Headed white cabbage was chosen as the subject of this experiment primarily because often in the production of cabbage with intentions for the highest possible yield there is an expensive irrational application of mineral fertilizers which inevitably causes harmful consequences not only on product quality but poses a potential risk of environmental pollution.

Material and methods

The research analyzed the pyrophyllite at the mine site Parsovići-Konjic, Bosnia and Herzegovina. In laboratory conditions of the Institute of Technology and Nuclear Physics in Belgrade and the Mining and Geology Institute of Tuzla were determined that certain physical and chemical parameters pyrophyllite. Physical traits of analyzed pyrophyllite were: specific weight of 2.7 g/cm^3, bulk density of 0.380 g/cm^3, pH value 8.5, the hardness (Mohs) 1. Chemical composition of a pyrophyllite are: SiO_2 62.35% Al_2O_3 15.00%, Fe_2O_3 2.03%, FeO 1.65%, MnO 0.08%, MgO 2.32%, CaO 5.11%, Na_2O 0.67%, K_2O 0.88%, CO_2 5.85%, SO_3 0.56%, H_2O 3.43%.
The head cabbage hybrid Bravo F_1 was used for the experiment. The hybrid Bravo F_1 is aDutch hybrid popular mainly for fresh consumption and it is also used for fermentation. Hybrid Bravo F_1characterized by tightly packed cabbage heads, good yield and uniform morphological characteristics. The average weight of the head is about 2-3 kg, the growing season is 90-95 days, the recommended harvest time is autumn.
The field experiment was set up on the experimental range of the Federal Institute of Agriculture in 2018 and 2019 by the block method with a random arrangement of plots in four replications. Before sowing, basic tillage was performed by plowing to a depth of 25 cm, followed by pre-sowing soil preparation by milling. Each experimental plot was 7 m^2(1.4 m wide x 5 m long). On the basic plot, 20 cabbage plants were planted per treatment in two-row strips at a distance of 70 cm between rows and 50 cm in a row. The distance between the plots was 100 cm. The total area of the experimental plot was 360 m^2. The following variants of pyrophyllite fertilization were used in the experiment:

Var. 1 - 800 kg/ha NPK 15:15:15 (control),
Var. 2 - 800 kg/ha NPK 15:15:15 + pyrophyllite 2,200 kg/ha,
Var. 3 - 800 kg/ha NPK 15:15:15 + pyrophyllite 700 kg/ha,
Var. 4 - 800 kg/ha NPK 15:15:15 + pyrophyllite 1200 kg/ha,
Var. 5 - 800 kg/ha NPK 15:15:15 + pyrophyllite 700 kg/ha.

During the development of cabbage, standard measures of cabbage care were taken.
The basic properties of the soil on which the experiment was set up were: pH in water 6.96, pH in KCL 5.90; N content 0.17%; $CaCO_3$ content 0.5%; humus content 2.26%; P_2O_5 7.65 mg/100g; K_2O 22.30 mg/100g. Soil analysis was performed in the Department of Agropedology of FBiH according to the standards: BAS ISO 10390: 2005, pH, $CaCO_3$, content N according to BAS ISO 11261: 2000, content P_2O_5 and K_2O Al - method.
The growth parameters were monitored: cabbage plant height (cm), cabbage rosette diameter (cm), cabbage head diameter (cm). The assessment of the significance of individual examined factors and their interrelation were tested on the basis of the LSD test for significance levels of 1% and 5%. The obtained results were processed by the method of analysis of variance of two - factorial experiment (ANOVA) using SPSS software.

Results and discussion

Fertilization with different doses pyrophyllite had a statistically significant effect on the plant height. Variant 2 exhibited statistical significance in comparison with all other variants, while variant 5 did not show statistical significance related to the control group. Similar results were obtained by Hasan and Solaiman (2012). The same authors state that the height of the plant depends exclusively on the type of fertilization. Olaniyi and Ojetayo (2011) mention that aplant grown with organic fertilizer obtains higher plants than plants grown with organomineral fertilizer and mineral fertilizer. A group of authors (Olaniyi et al., 2010; Olaniyi and Ojetayo, 2011) explain that organic fertilizer releases a significant amount of nutrients for plant use resulting in better vegetative growth.

Cabbage rosette diameter

The largest diameter of the rosette of cabbage plants was in variant 2 in both years of research. In variants 3, 4 and 5 in both years of the study, the diameter of the cabbage rosette decreased depending on the amount of pyrophyllite applied.

Table 3. Cabbage rosette diameter ($\bar{x}$ - cm/plant) depending on year and fertilization ± s.

Year	Date of measurement	Var. 1	Var. 2	Var. 3	Var. 4	Var. 5
2018	12.05 18.06	14.0 ± 0.34 28.2 ± 0.48	24.4 ± 0.45 44.0 ± 0.30	21.0 ± 0.78 33.2 ± 0.39	16.5 ± 0.33 30.0 ± 0.81	14.1 ± 0.36 28.2 ± 0.31

Cabbage head diameter

Based on the average value of the diameter of the cabbage head, it can be concluded that the plants in variant 2 with the largest amount of pyrophyllite applied had the largest average diameter of the cabbage head in both measurements. Our results are in parallel with the results of Murtić et al., (2020) who emphasize the positive influence of pyrophyllite on vegetative growth and lettuce yield.

Statistical difference was exhibited in the Variant 2, in respect of all other variants, while Variant 5 with the least amount pyrophyllite do not reach statistical significance compared to the control. Variants 3 and 4 in relation to the control also showed statistical significance. Similar to our results, Sarker et al. (2003) indicate that organomineral fertilizer has an effect on the diameter of the cabbage head.

Conclusion

Based on two years of research on the influence of fertilization with pyrophyllite on the vegetative growth of head cabbage of the Bravo F_1 hybrid and the obtained results, it can be concluded:

Conducted two-year research confirmed the effective fertilization with pyrophyllite on the parameters of vegetative growth of cabbage Bravo F_1,

- The most significant difference on the vegetative growth of cabbage was shown by variant 2 with the highest application of pyrophyllite (2.200 kg of pyrophyllite/ha) in relation to all other variants ,
- Variant 5 with the lowest applied amount of pyrophyllite (700 kg of pyrophyllite/ha) did not show statistical significance compared to the control,
- The results of the study indicate that the application of pyrophyllite can reduce the use of mineral fertilizer in the production of cabbage without adverse effects on the parameters of its vegetative growth.

Abstract

Grain spike index indicate wheat productivity and can be used as criterion in wheat selection in the wheat breeding program. Aim of this investigation is study of variability of grain spike index in wheat cultivars grown under different environmental condition. Ten genetically divergent winter wheat cultivars were included in two year investigation in field experiment in randomized block design in three replications. The seeds of varieties were sown at the distance of 0.10 m in rows of 1.0 m length with the distance of 0.2 m. For analysis of grain spike index determined in proportion of grain mass spike^{-1}/mass of spike, 60 plants in full maturity stage (20 plants per replication) were used. On the base of analysis of variance by using MSTAT C (5.0 version) and computed F-test values, differences among cultivars according to value of grain mass spike^{-1}, mass of spike and also, spike harvest index were established. In the first year the highest spike harvest index was 0.82 (Fortuna) and the lowest 0.76 in Ljubičevka, with average for all varieties 0.79, while in the second year the highest spike index was 0.83 in Somborka, and the lowest 0.77 in Ljubičevka, with average value 0.80. The different values of spike harvest index indicate response of genotypes to environmental factors as well as interaction of genotype/environment.

Key words: *wheat, cultivar, variability, index of spike.*

Introduction

In wheat plant the large number of spike on the one hand and many grains spike^{-1} on the other hand is advantages in forming yield. There is differences in estimation of advantages number of spike per plant and mass of spike per plant based on negative correlation of size of spike and number of spike. The spike length has strong indirect influence on yield through number of spikelets spike^{-1} and further on number of grain and size and weight of grain (Zečević *et al.*, 2004). In breeding program in the aim of creating variety with high yield, the concept of plants contains more productive tillers, more spikes, spikelets spike^{-1}, grain spike^{-1}, mass of grain spike^{-1} (Knezevic et al., 2014**).** In many cases yield and biomass showed significant correlations with average yield and yield components example thousand grain weight. Height of plant have a weak negative association with yield. Absence of height reduction (*Rht*) gene alleles associated with high height of plant which is in negative association with harvest index (HI) (Rebetzke et al., 2011; Reynolds and Langridge, 2016). In production of total dry matter in wheat the biological yield is not main criterion for selection because grain yield is a main economic part of yield. The ratio of grain yield (economic) of plant and biological yield indicate on efficiency of genotype for formation of the economic yield or harvest index of plant (Knežević et al., 2015a). This indicate that model plant need have large spike and high mass (Knežević et al., 2011; 2019), especially high mass of grain spike^{-1} (Knežević et al., 2015b). The ratio of grain mass spike^{-1} and mass of spike variate due to fertilization of spikelets spike^{-1} or its number of fertilised florets as well number of grains spike^{-1} indicate efficiency of transport and translocation of dry matter through vessel bundles (phloem and xylem) to spike and grain of spike. Also, this indicate index of receptive capacity of grain spike^{-1} and post-anthesis photosynthetic capacity of stem. The large spike of wheat means that is a optimal number of florets per spike to ensure that their capacity of the spike does not represent a limit for fotosynthates translocation to grain. Size and number of spike per plant, number of spikelets spike^{-1} are genotype characters related to tillering (Moeller and Rebetzke, 2017) that are under genetic control and variate due to environmental condition as well as density of crops, seed rate, supply of nutrition and water in soil (Dodig et al., 2008). Aim of this investigation is study of variability of grain spike index in wheat vatieties grown under different environmental condition.

Materials and Methods

Ten genetically divergent winter wheat cultivars were used for investigation on experimental field in Kraljevo in two vegetative season 2015/16 and 2016/17. The experiment set up in randomized block design in three replications. The seeds of varieties were sown at the distance of 0.10 m in rows of 1.0 m length with the distance of 0.2 m. For analysis of grain spike index determined in proportion of grain mass spike^{-1}/mass of spike, 60 plants in full maturity stage (20 plants per replication) were used.

Based on the obtained average values of the mass of the seed and spike, the spike harvest index is calculated according to the formula:

$$Spike\ index\ (\%) = \frac{mass\ of\ seeds^{-spike}}{mass\ of\ spike}\ \mathrm{x}\ 100$$

Statistical data processing was done using the MSTAT C 5.0 version for analysis of variance by the mono factorial system for each year. The significant differences between the average values were estimated by F-test values. The analysis of variance was performed according to a random block system with one factor and significant differences among cultivars according to grain index of spike were tested by means of test value of $LSD_{0.05}$ and $LSD_{0.01}$.

Weather conditions in the vegetation period

The total amount of precipitation and average temperature per month and per year were different in two year of experiment, during vegetative season (2015/16 and 2016/17) and differed in

relation to the long-term period (2000-2010). In the first year of the experiment, the average temperature was 9.9 °C and the total rainfall was 651.00 mm, which is significantly higher than in the second year and than in ten year period. In the second year the average temperature during the growing season was 8.7 °C and similar to ten year period while the total rainfall 523.1 mm was significant higher than in ten year period. During the grain filling phase of plants in the first year in April the average temperature was higher and in May the average precipitation was higher and favorable than in second year of experiment and than in ten year period (table 1)
.

Table 1. Average monthly temperatures and total monthly precipitation in Kraljevo

Results and Discussion

The spike harvest index varied from 0.76 in Ljubičevka to 0.82 in Fortuna variety with average value of 0.79 in the first year of experimental vegetative season. The values of spike harvest index in second year of experiment varied from 0.77 in Ljubičevka to 0.83 in Somborka variety with average value 0.80 of all varieties (table 2). Wheat varieties with higher spike harvest index (SPHI) should be with developing more kernels spike^{-1} and a higher grain mass spike^{-1}, what depends on genotypes and their plasticity and response to environmental conditions.

In research on chernozem, similar results of spike harvest index 0.75 in winter wheat in sole crop and in intercrop (wheat/pea) 0.71 was found by Grčak et al. (2019a), while in spring wheat varieties spike harvest index was 0.72 in sole crop and 0.71 in intercrop wheat/pea (Grčak et al., 2019b). In earlier investigation of 22 divergent wheat genotypes presented that index of spike was in range from 0.68 to 0.91 Petrović et al. (2002).

Spike harvest index is value of ratio grain mass spike^{-1} and mass of spike. In this study the grain mass spike^{-1} varied in the range from 2.66 g in Morava to 3.22 g in Danica cultivar with average value 2.96 g in first year of experiment. The values of grain mass spike^{-1} in second year of experiment varied from 2.23 g in Kosmajka to 3.03 g in Somborka variety and average value was 2.63 g (table 2).

Generally, in all studied wheat varieties in first year expressed in average higher value of grain mass spike^{-1} than in second year. This indicates response of genotypes to environmental conditions. The obtained results showed significant differences in the average values of grain mass spike^{-1} and mass of spike per year, that indicating diversity of studied varieties (table 2).

In other studies the significantly lower of grain mass spike^{-1} were obtained, in a sole crop of 1.18 g while in intercrop (wheat/pea) 1.19 g in winter wheat grown on chernozem type soil (Grčak et al., 2019a) as well as in spring wheat grain mass spike^{-1} in a sole crop was 1.02 g and in intercrop (wheat/pea) 0.87 g (Grčak et al., 2019b).

The mass of spike varied in the range from 3.33 g in Morava to 4.07 g in Somborka variety with average value 3.75 g in first year of experiment. The values of mass of spike in second year of experimental vegetation season variate from 2.79 g in Kosmajka to 3.64 g in Somborka variety and average value was 3.29 g (table 2). Generally, the all tested varieties had higher mass of spike in the first year than in second year of experiment. The mass of spike were significantly different among the varieties and between the years of experiment. (table 2).

In other investigation of ten genotypes in two vegetative seasons were found significant differences in wheat varieties for the mass of spike which varied in range from 3.44 g and 4.12 g in first vegetation season and in the range from 3.28 g to 4.8 g in second year (Knežević et al. 2011). Similar values of mass of spike established in ratio 3.30 g – 4.49 g with average of 3.97 g in the first year and 3.20 g – 3.92 g with average 3.61g in the second year of investigation, which depending of variety and environment (Knežević et al., 2019). The significantly lower average values of mass of spike were obtained in research of winter wheat variety on the chernozem soil type, in a sole crop of 1.56 g while in intercrop (wheat/pea) 1.6 g (Grčak et al., 2019a). Also on chernozem in spring wheat varieties obtained in average similar values of mass of spike in sole crop 1.41 g an in intercrop (wheat/pea) 1.23 g (Grčak et al., 2019b). The obtained differences are due to differences of studied genotype (wheat variety) and environmental condition (soil, weather conditions, nutrition).

In these studies, it was found that some varieties, although they have a higher grain mass spike^{-1}, had a lower spike harvest index. For example in Danica found grain mass spike^{-1} 3.22 g, mass of spike 4.01 g and spike harvest index was 0.804 in the first year, on the other hand in Kosmajka grain mass spike^{-1} 2.85 g, mass of spike 3.53 g and spike harvest index was 0.806. In the second year, in Danica variety, the grain mass spike^{-1} was 2.86 g, the mass of spike was 3.57 g and the spike harvest index was 0.801, while in the Kosmajka variety the grain mass spike^{-1} was the lowest 2.23 g, the mass of spike was the lowest 2.79 and the value of the spike harvest index was 0.801, the same as in Danica variety. This indicates that the mass of chaff and rachis was higher in the variety Danica, i.e. that a larger amount of assimilate deposited in the chaff and rachis and was not fully translocated into grain.

Somborka variety in first year of experiment had the highest values of grain mass spike^{-1} (3.22g) and the highest mass of spike (4.07 g) but values of spike harvest index 0.79 it was not the largest, but it was smaller than in Morava, which in the first year had the lowest grain mass spike^{-1} of 2.66 g, the lowest mass of spike 3.33 g and the high value of the spike harvest index 0.799. Generally, in average all studied wheat varieties in first year expressed higher values of grain mass spike^{-1} as well mass of spike than in the second year. However, spike harvest index was higher in the first year in two variety (Fortuna 81.8% and Morava-79.9%) than in the second year (Fortuna 78.7% and Morava-78.5%).
These data indicate different efficiency of uptake, utilization of water and minerals and different efficiency of photosynthesis and translocation of photosynthesized organic matter into grain. Also, the obtained values of the spike harvest index indicate that they are not a reliable criterion for predicting higher values of grain mass spike^{-1} and grain yield, In early studies showed that correlation between spike HI, estimated on the basis 10 spike sample and plot harvest index, was low and statistically nonsignificant. Based on this study, one could not recommend using spike HI as a predictor of plot harvest index (Hucl and Graf, 1992).
For achieving high mass of grain spike^{-1} and grain yield of wheat the significant role has efficiency of photosynthesis related to efficiency of water absorption and plant nitrogen absorption, utilization and translocation into grain in highly favorable environmental conditions. Flag leaf area and green leaf duration have impact in grain filling and in relation to spike forming of grain number and potential size of grains significantly contribute to grain mass. Genetic and physiological characterization of wheat variety can help in creation new high yielding variety by crosses in terms of complementary traits and alleles (Reynolds and Langridge, 2016).

Table 3. Components of variance for spike harvest index, grain mass spike^{-1} and mass of spike

	Spike harvest index						Grain mas spike^{-1}					Mass of spike				
Source of variance	DF	SS	MS	F	Components of variance		SS	MS	F							
					σ^2	%				σ^2	%				σ^2	%
Repetitions	2	30.121	15.060	3.5698*	-	-	0.206	0.103	2.7149^{ns}	-	-	0.184	0.092	1.8222^{ns}	-	-
Variety	9	168.349	18.705	4.4337**	1,868	25,63	2.609	0.290	7.6285**	0,039	29,32	3.492	0.388	7.6722**	0,052	23,85
Year	1	10.753	10.753	2.5487^{ns}	0,109	1,50	1.588	1.588	41.7796**	0,051	38,35	3.234	3.234	63.9492**	0,106	48,63

Error	38	160.319	4.219	-	4,219	57,89	1.444	0.038	-	0,038	28,57	1.922	0.051	-	0,051	23,39
Total	59	437.006	-	-	7.288	100,0	6.337	-	-	0.133	100,0	9.531	-	-	0.218	100,0

The analysis of the components of variance showed that genotype had the greatest influence (25.63%) on expression of spike harvest index, while the share of environment was 1.50% and the share of interaction G/E was 14.98% (table 3). Different results reported Petrović et al. (2002) which found higher impact of environment. The highest impact on grain mass spike^{-1} had environmental condition (38.35%) and higher than genotype (29.32%), while the least impact had interaction G/E (3.76%). Analysis of component of variance showed that environment had the highest impact (48.63%) on expression of mass of spike and higher than impact of genotype (23.85%) while the impact of interaction G/E (4.13%) was the least (Table 3). The environmental factors as well temperature, precipitation, nutrition have influence on increasing of capacity of spike (Petrović *et al.*, 2008; Knežević *et al.*, 2016) and grain yield (Marijanović *et al.*, 2010).

Conclusion

In this study were established that the mass of spikes, grain mass and harvest index of spike are different between varieties and between years of experiment. The highest values of spike harvest index (83.1%) in Somborka variety expressed in the second experimental year, while the least (75.7%) in wheat Kosmajka in the first experimental year. The genotype had the greatest influence (25.63%) on expression of spike harvest index. The highest values of grain mass spike^{-1}, (3.22 g) in Danica and Somborka variety expressed in the first experimental year, while the least (2.23 g) in wheat Kosmajka in second experimental year. The highest values of mass of spike (4.07 g) in Somborka variety expressed in the first experimental year, while the least (2.79 g) in wheat Kosmajka in second experimental year.

Abstract

The Maize Research Institute, Zemun Polje (MRIZP) has been working intensively on maize breeding for 75 years and today occupies an important position in maize seed market in Serbia and region. Some of the main characteristics of the crop production in Serbia are many different environmental conditions (soil, weather) and farmers with very different crop management practices. Considering that genotype x environment interaction plays an important role in grain yield performance of maize, testing in a wide range of environments is necessary for precise evaluation of maize cultivars. Every year, the Marketing Department of the MRIZP conducts multi-environmental testing of the bestselling and the new promising commercial maize hybrids (so-called ZP hybrids) and uses these results for recommendations to farmers. The main goal of this research was to evaluate the grain yield and its stability of the ZP commercial maize hybrids and based on these results to determine which hybrid could accomplish the best its potential in which growing conditions. Seven maize hybrids (ZP 427, ZP 555, ZP 560, ZP 600, ZP 606, ZP 666 and ZP 707) of different maturity groups (FAO 400 – FAO 700) were grown at 99 locations in Serbia during three years (2018, 2019 and 2020). Based on the grain yield data, the stability analysis was performed using linear regression model proposed by Eberhart and Russel (1966). The mean grain yield ranged from 9.823 t/ha to 10.691 t/ha in the hybrids ZP 427 and ZP 606, respectively. The values of regression coefficient (b_i) differed between hybrids and ranged from 0.845 in the hybrid ZP 427 to 1.0951 in hybrid ZP 666. The results were compared, and the adaptation of the evaluated hybrids to different environments and growing conditions were discussed. Based on the results certain conclusions were made.

Key words: *maize hybrids, grain yield, genotype x environment interaction, multi-environmental testing, grain yield stability*.

Introduction

The Maize Research Institute, Zemun Polje (MRIZP) has been working intensively on maize breeding for 75 years and today occupies an important position in maize seed market in Serbia and region. Maize is the most important crop in Serbia where it is grown on approximately million hectares every year (FAOSTAT, 2021). The economic significance of the maize for Serbia is reflected in the fact that maize had a share of the gross national income of Serbia between 6 and 6.8% in the period from 2015 to 2017 (http://www.minpolj.gov.rs/), and that it regularly represents one of the most important export items of Serbia. According to the report of the Association for the Improvement of Production and Export of Oilseeds and Cereals from 2017, when it comes to the produced quantities of maize grain, Serbia is in the 6th place in Europe behind Ukraine, France, Russia, Romania and Hungary, while it is the 8th largest exporter of maize grain in the world (https://www.zitasrbije.rs/download/Izvestaj_Jun_2017-99.pdf).

Some of the main characteristics of the crop production in Serbia are many different environmental conditions (soil, weather) and farmers with very different crop management practices. It is well known that maize cultivars often very differ in their performance across environments (Kang et al., 1989; Crossa et al., 1999; Signor et al., 2001; Admassu et al., 2008; Kandus et al., 2010; Anley et al., 2013; Choukan, 2013; Ndhlela et al., 2014), for example genotypes that are the best in certain locations in some other locations are bad and vice versa. Considering that genotype x environment interaction plays an important role in grain yield performance of maize, testing in a wide range of environments is necessary for precise evaluation of maize cultivars. In order to establish the stability of the genotype performance on the basis of big data from many environments, stability analysis was designed. Many researchers proposed various different statistical methods for identification of the stable genotypes which are based on linear regression (Yates and Cochran, 1938; Finlay and Wilkinson, 1963; Eberhart and Russel, 1966; Perkins and Jinks, 1968).

Stability analysis aims to examine reaction of genotypes to different environments (Bernardo, 2020) which is very important in commercial breeding programs. It can provide information of the pattern of genotype performance in the different groups of environments in which farmers, breeders, seed producers and distributors are interested. For example, stability analysis aims to identify cultivars best suited to specific environment so that the production in that environment is maximized (Bernardo, 2020).

The main task of maize breeders is to develop cultivars with the best phenotype in the different growing conditions i.e. cultivars with good performance and stable. Both maize breeders and farmers want maize cultivars which express low genotype x environment interaction (Babić et al., 2010). For that reason, maize breeders and breeding companies are looking for genotypes, not only with high average grain yield, but with known yield stability. Farmers with very good crop practices show interest for genotypes which give the best results in the best growing conditions, and on the other hand farmers in poor environments who don't have a high level of crop practise want cultivars which give satisfactory results in bad or limited growing conditions. Based on all this, it is concluded that stability analysis of the maize cultivars can help all participants in the maize production, such as breeders, companies, seed producers and distributors, and what is the most important it can help farmers to achieve the best possible results with the offered assortment of maize cultivars at the market.

Every year, the Marketing Department of the MRIZP conducts multi-environmental testing of the bestselling and the new promising commercial maize hybrids (so-called ZP hybrids) and uses these results for recommendations to farmers. The main goal of this research was to evaluate the grain yield and the grain yield stability of the ZP commercial maize hybrids and based on these results to determine which hybrid can reach the best its potential in which growing conditions. Extensive stability analysis takes many locations and years and therefore the multi-environmental testing approach was selected.

Material and Methods

Seven commercial ZP maize hybrids (ZP 427, ZP 555, ZP 560, ZP 600, ZP 606, ZP 666 and ZP 707) of different maturity groups (FAO 400 – FAO 700) were grown at 99 locations in Serbia during three years (2018, 2019 and 2020). Plot area was 1000 m^2 and sowing density for each hybrid was the one generally recommended (Table 1). Standard crop practise of maize production was applied and harvesting was done mechanically. Based on the grain yield data, the stability analysis was performed using linear regression model proposed by Eberhart and Russel (1966). Data processing were done in Microsoft Excel and stability analysis were done in software GEA-R (Pacheco et al., 2015).

Table 1. Tested maize hybrids, their maturity groups and sowing densities

Maize hybrid	Maturity group	Sowing density (seeds/ha)
ZP 427	FAO 400	73500
ZP 555	FAO 500	68000
ZP 560	FAO 500	68000
ZP 600	FAO 600	63000
ZP 606	FAO 600	63000
ZP 666	FAO 600	63000
ZP 707	FAO 700	63000

The linear model proposed by Eberhart and Russel (1966) is:

$P_{ij}= (\mu + g_i) + b_i t_j + \delta_{ij} + e_{ij}$,

where P_{ij} is the mean of genotype I in environment j; $\mu + g_i$ is the mean of genotype i across all environments; b_i is the linear regresssion coefficient of P_{ij} on t_j; t_j, which serves as the environmental index, is the effect of environment j; δ_{ij} is the deviation of P_{ij} from the regression-fitted value of genotype i in environment j; and e_{ij}, is within-environment error, averaged across replications, associated with genotype i in environment j (Bernardo, 2020).

The b_i measures the change in the mean performance of a particular genotype per unit change in the mean of an environment (Bernardo, 2020). This measure of stability is estimated for each genotype as: $b_i = \Sigma_j P_{ij} t_j / \Sigma t_j^2$

The value of the regression coefficient (b_i) indicates genotype response to different environments and growing conditions as follows (in case that higher values of the trait are desired):

1. $b_i = 0$ indicates that the performance of a genotype is constant across environments;
2. $b_i = 1$ indicates that the response of a genotype to different environments is the same as the mean response of all other genotypes in the experiment;
3. $b_i > 1$ have genotypes which are well adapted to favorable environments and bad adapted to unfavourable environment (better than average response to good growing conditions and worse than average response to bad conditions);
4. $b_i < 1$ have genotypes which are adaptable to poor environments and bad adapted to good environments (better than average response to unfavorable environments and worse than average response to good environments).

Results and Discussion

The results showed that commercial ZP maize hybrids differed in the grain yield and the grain yield stability (Table 2). The highest average grain yield was recorded in the hybrid ZP 606 (10.691 t/ha), which is the best-selling hybrid of the Maize Research Institute, Zemun Polje. This hybrid also exhibited good response to favorable environments and to good growing conditions, according to the value of b_i above 1 (1.0782). Similar result for this hybrid was found by Crevar et al. (2011). The lowest average grain yield was recorded in the earliest hybrid (FAO 400) in this study, ZP 427 (9.823 t/ha). However, hybrid ZP 427 expressed a very good response to unfavorable environments considering very low value of b_i regression coefficient (0.8450), which is in accordance with results of Crevar et al. (2011) and Pavlov et al. (2011) who also found better adaptation of early maturity hybrids to poor environments.

Table 2. The average grain yield and b_i coefficient of tested maize hybrids

Maize hybrid	Average grain yield (t/ha)	b_i coefficient
ZP 427	9.823	0.8450
ZP 555	10.165	1.0033
ZP 560	10.250	0.9993
ZP 600	10.357	0.9577
ZP 606	10.691	1.0782
ZP 666	10.345	1.0951
ZP 707	10.567	1.0215

Hybrids with the most stable grain yield performance were ZP 555 and ZP 560 with regression coefficient values near 1 (1.0033 and 0.9993, respectively). The best adaptation to favorable environments was recorded in the hybrid ZP 666 (b_i = 1.0951), which is in accordance with results obtained by Crevar et al. (2011). Hybrids ZP 600 and ZP 707, third and second in grain yield in this research (10.357 and 10.567, respectively), expressed medium adaptation to poor environments (b_i = 0.9577) and good environments (b_i = 1.0215), respectively.

Conclusions

Based on the results of the grain yield and the grain yield stability obtained from multi-environmental testing, growing conditions in which certain maize hybrids can reach their potential were recognized. Hybrid ZP 606 as the most yielding and well adapted to favorable environments was recommended mostly for good growing conditions and good crop management practices. For the best results in the best growing conditions and the best environments hybrid ZP 666 is proposed. Hybrid ZP 427 is recommended only for poor growing conditions considering its best adaptation to unfavorable environments and the lowest average grain yield of all evaluated hybrids. Hybrids such as ZP 427 are not expected to disappoint farmers even in the worst environments and years. Hybrids ZP 555 and ZP 560, as the most stable hybrids in this research, represent hybrids which will meet expectations of farmers in any environment and year. Hybrids ZP 600 and ZP 707, as high yielding and relatively stable hybrids, are suitable for achieving high performance under different conditions.

Acknowledgement

Authors would like to express their special thanks of gratitude to Marketing Department of the Maize Research Institute, Zemun Polje and its Head Dr Života Jovanović for sharing results of trials that authors used in this research. As well, authors would like to thank Head of Scientific and Technical Cooperation Department of the Maize Research Institute, Zemun Polje Dr Jovan Pavlov for his support and useful suggestions which shaped this study.

Abstract

Tomato (*Lycopersicon esculentum* Mill.) is one of the most important vegetable species, which is result of its high nutritional value and the area on which it is grown. Tomatoes are mainly produced from seedlings and the quality of seedlings is one of the basic elements of achieving high yields. The quality of seedlings largely depends on the vegetation space, ie the size of the cells in the containers in which they are produced. Thus, the aim of this study was to examine the influence of vegetation space size on the quality of tomato seedlings grown in containers with different cell volumes. The study used a cv. Big Beef F1 which seedlings were produced in containers with 24, 40, 60 and 104 cells. As indicators of growth and quality of tomato seedlings the following parameters were analyzed: height and diameter of hypocotyl, length and width of cotyledons, number of leaves, length and width of leaves, height and diameter of stem and mass of whole plant, aboveground part and roots. The dynamics of seedling growth was directly dependent on the size of the vegetation space. The highest quality seedlings were obtained in containers with 24 cells, in which 4 leaves were formed, the height of the plant was 36.117 cm, and the weight of the whole plant was 14.24 g.

Keywords: *Tomato, Vegetation space, Seedling quality, Growth dynamic*.

Introduction

Tomatoes are produced in the open field as an early, medium early and late culture and in all forms of greenhouses. Production can be directly from seeds (field, industrial) and from seedlings (field and in a greenhouse). The combination of both productions enables the supply of fresh tomatoes to the market throughout the year (Kumar and Singh, 2015).

Tomatoes in our country, are mainly produced from seedlings. Seedling is a young plant with 4-10 well-developed leaves and in the 4th or 5th phase of organogenesis, well-developed root system, firm, elastic and compact stem with high dry matter content, appropriate age depending on the time and method of production (Đurovka *et al*., 2006). The quality of seedlings according to Murtić *et al.*, 2018 is one of the most important items in tomato production. Several researchers state that yield, especially early yield and number of fruits per plant depends on seedling quality (Jankauskiene *et al*., 2013). Seedling quality is affected by a number of factors. The factors can significantly affects the morphological appearance even if they are minimall (what is visible to the eye - the development of the root system, height, thickness and elasticity of the stem, number and arrangement of leaves) and seedling quality (flow of individual stages of organogenesis of generative organs) (Todorović *et al*., 2015; Zeljković *et al*., 2017). Therefore, the management and maximum control of critical points in the production of seedlings ensures high quality and economy of seedling production, as well as vegetable production as a whole.

The purpose of vegetable production through seedlings is to shorten the time required for fruiting, save energy, better and more economical use of protected space (Todorović *et al*., 2019). In our country, seedlings are mostly produced in containers or pots. Container seedlings are mainly used for the production of seedlings in the open field. Very often, due to the economic effect and obtaining a larger number of plants per unit area, used containers do not provide enough space for quality growth of the tomato root system, which can be a limiting factor for obtaining quality seedlings (Lin *et al*., 2015). For these reasons, the aim of this study was to determine the influence of vegetation space size, ie the number of cells in the container, on seedling quality and tomato growth in the nursery period, where the length and width of cotyledons, height and width were measured as growth factors, as well as hypocotyl diameter, height and diameter of the stem, and the dynamics of leaf formation, number and size of leaves, as well as the mass of the seedling plant.

Material and Methods

The tests were performed on a tomato, a cv. Big Beef F1 (Monsanto Holland BV). Big Beef F1 is an early indeterminate beef-type tomato. The fruits are large, oval red in color, with excellent taste and medium firmness. Styrofoam containers with different number of cells were used: K1-24 cells (diameter 6.80 cm), K2-40 cells (diameter 4.30 cm), K3-60 cells (diameter 4.10 cm) and K4-104 cells (diameter 3.05cm). In each variant, 40 plants were analyzed. The experiment was set up in a greenhouse of 30 m^2 without additional heating with additional tunnels in the village of Jelicka, Prijedor municipality (N 44 ° 49′31.04 ″; E 16 ° 55′9.52 ″; altitude: 223 m) in Bosnia and Herzegovina. The research was conducted from April 2 to June 2, 2016. During the experiment, tomato seedlings were fed with water-soluble fertilizer Kristalon "Yara" formulation 13 + 40 + 13 + micro, as well as other care measures. The dynamics of growth and development of tomatoes was followed by the BBCH monograph (Meier, 2001). Eight days after emergence (BBCH_1: 10), the length and width of fully formed cotyledons and the height and diameter of the hypocotyl were measured in all four variants. Then, 9 days after complete formation of cotyledons, the length and width of the first leaf, diameter and height of the plant were measured in containers with 24 and 40 cells (BBCH_1: 11), and in containers with 60 and 104 cells, measurements were performed 12 days after complete formation of cotyledons. Measurement of the second leaf in a 24-cell container was performed 12 days after the appearance of the first leaf (BBCH_1: 12), as well as the height and diameter of the plant. Measurement of the second leaf in containers with 40 and 60 cells was performed 13 days after the formation of the first leaf, and in containers with 104 cells was performed 14 days after the formation of the first leaf. Measurement of plants in the third leaf phase (BBCH_1: 13) in a 24-cell container was performed 9 days after the formation of the second leaf, in a 40-cell container the measurement was performed after 10 days, and in a 60-cell container plants were measured after 12 days of forming another leaf. When measured in 104 cells containers the third leaf was not formed. The fourth leaf in a 24-cell container was measured eight days after the formation of the third leaf (BBCH_1: 14). At the time of transplanting, ie at the time of measurement, buds were formed in plants in a 24-cell container (BBCH_5: 51). Analysis during vegetation and at the end of the seedling production cycle included: length and width of cotyledons (cm), diameter and height of hypocotyl (cm), number of leaves, length and width of leaves (cm), stem diameter (cm), plant height (cm), the mass of the whole plant (g), the mass of the green part (g) and the mass of the root (g). Measurements of plant dimensions were done with a ruler and caliper MAUSER INOX, while the measurement of the mass of the whole plant, green part and roots was done on a digital scale AE ADL 600 in the laboratory at the Faculty of Agriculture, University of Banja Luka. Statistical analysis of morphometric data was done through analysis of variance and t-test.

Results and Discussion

Germination, ie emergence of cotyledons above the soil's surface (BBCH_0: 09) was determined in all four variants at the same time or 10 days after sowing. Measurement of cotyledons and hypocotyls was done in the phase of complete opening and occupying the vertical position of cotyledons (BBCH_1: 10).

Table 1. Characteristics of cotyledons

Variant	Cotyledons			
	Length (cm)		Diameter (cm)	
	$\bar{X} \pm S\bar{x}$	*Vk*	$\bar{X} \pm S\bar{x}$	*Vk*
K1-24	2.993±0.06	12.894	0.696±0.01	11.077
K2-40	2.764±0.05	12.907	0.641±0.01	11.292
K3-60	2.864±0.07	16.092	0.642±0.01	14.161
K4-104	2.850±0.05	11.596	0.685±0.01	9.475

Based on the results, it can be determined that there was no large variation in the length and width of the cotyledon depending on the vegetation space (Table 1). However, it should be noted that the largest cotyledons were in 24-cell containers, which averaged 2.993 cm long and 0.696 cm wide, while the smallest were in 40-cell containers, where they averaged 2.764 cm long and 0.641 cm wide.

Table 2. Characteristics of hypocotyls

Variant	Hypocotyl			
	Length (cm)		Diameter (cm)	
	$\bar{X} \pm S\bar{x}$	*Vk*	$\bar{X} \pm S\bar{x}$	*Vk*
K1-24	2.620±0.05	12.378	0.153±0.002	9.833
K2-40	2.402±0.03	9.996	0.134±0.002	11.757
K3-60	2.430±0.05	13.696	0.133±0.002	10.511
K4-104	2.461±0.04	11.215	0.124±0.002	12.169

The height and diameter of the hypocotyl in all variants were approximately the same, ie there were no significant differences. It must be emphasized that the plants from the container with the smallest number of cells (K1-24) had both the largest length (2.62 cm) and the diameter of the hypocotyl (0.153 mm).

Table 3. Plant height and seedling stem diameter (seedling age 60 days)

Variant	Plant height (cm)		*t-test*	Stem diameter (cm)		*t-test*
	$\bar{X} \pm S\bar{x}$	*Vk*		$\bar{X} \pm S\bar{x}$	*Vk*	
K1-24	36.117±0.374	6.483	K1:K2 20.925** K1:K3 30.228** K1:K4 59.529** K2:K3 11.324** K2:K4 39.066** K3:K4 17.455**	0.511±0.004	5.077	K1:K2 28.119** K1:K3 31.703** K1:K4 66.411** K2:K3 10.632** K2:K4 43.266** K3:K4 17.455**
K2-40	25.817±0.320	7.760		0.370±0.003	6.629	
K3-60	20.320±0.365	11.222		0.308±0.005	10.344	
K4-104	11.661±0.170	9.157		0.214±0.002	8.105	

The tallest and thickest seedlings were produced in 24-cell containers, with a plant height of 36.117 cm and a stem diameter of 0.511 cm. At the same time, the smallest seedlings were in 104-cell containers, with plant height of 11.661 cm and stem diameter of 0.214 cm. By testing the level of significance of differences in the height and diameter of the stem depending on the size of the vegetation space, ie the size and number of cells in the container, it was determined that there is a statistically highly significant difference between the examined variants.

Similar results were obtained by Liptay and Hoffmann (1988) who found that in containers with a larger cell volume (over 16 mm^3) seedlings of better quality were obtained and that its height did not vary significantly with a further increase in substrate volume. Also, the same law applies when it comes to the thickness of the seedling stem. As Weston and Zandstra (1986) found, the height of tomato seedlings varies from 10.1 to 26.8 cm depending on the size of the cells in the containers. Jankauskiene *et al*. (2013) came to the results that show that with increasing number of leaves, the height of the plant also increases.

Table 4. Dynamics of leaf formation

Variant	Days between the phases			
	BBCH_1:11	BBCH_1:12	BBCH_1:13	BBCH_1:14
K1-24	27	12	9	8
K2-40	27	13	10	
K3-60	30	13	12	
K4-104	30	14		

Based on the results of examining the influence of vegetation size on the quality of tomato seedlings, ie the number of leaves, it was determined that variant K1-24 showed the best where 4 leaves were formed, while variant K4-104 showed the worst where only 2 leaves were formed. In their research, Ilin *et al*. (2003) came to similar results, where they found that with increasing substrate volume in containers and pots, the formation of plants with a larger number of leaves occurs. Shopova and Haytova (2015) in their research found that with increasing size of vegetation space by reducing the number of cells in the container, the number of leaves increases.

Table 5. Leaf length and width (seedling age 60 days)

Variant	Leaf length (cm)		*t-test*	Leaf width (cm)		*t-test*
	$\bar{X} \pm S\bar{x}$	*Vk*		$\bar{X} \pm S\bar{x}$	*Vk*	
K1-24	13.492±0.145	6.731	K1:K2 20.650** K1:K3 25.890** K1:K4 44.847** K2:K3 8.854** K2:K4 23.757** K3:K4 8.256**	8.592±0.106	7.775	K1:K2 18.917** K1:K3 21.757** K1:K4 28.537** K2:K3 7.847** K2:K4 15.065** K3:K4 5.359**
K2-40	9.952±0.121	7.912		6.189±0.07	7.566	
K3-60	7.766±0.167	13.435		5.092±0.121	14.905	
K4-104	6.271±0.07	7.166		4.212±0.111	16.490	

Based on the results obtained during the monitoring of the increase in leaf length, differences in the examined variants are noticeable. In variant K4-104, the length of the first and second leaves was the same, and did not increase until the end of the nursery period. In other variants, an increase in leaf length was observed. In variants K2-40 and K3-60, the largest difference in leaf length was observed between the first and the second, ie a significantly larger length of the second leaf was observed in relation to the first, in both examined variants. The difference in leaf length between the second and third leaf was smaller. The intensity of growth of seedling leaf length in variant K1-24 was the highest in the period of development between the first and second leaf. The second and third leaves were almost the same length, while the fourth was significantly longer than the third leaf. In addition, it can be seen that the influence of vegetation space on leaf size is significant. Plants had the largest leaves in the variant with the largest vegetation space (K1-24), and the smallest with the smallest vegetation space (K4-104).
Similar tendencies of leaf width growth were observed as with its length. The smallest leaf width was in plants in variant K4-104, where there was no significant difference in width between the first and second leaf. In other tested variants, the largest width was in the second leaf, while the third leaf had a smaller width in relation to the second. In K1-24, in which the fourth leaf is formed, a smaller width is noticeable in relation to the third. It should be noted that the width of the leaves is directly dependent on the size of the vegetation space. Thus, the largest leaf width was in K1-24, while the smallest was in the container with the largest number of cells (K4-104).

Table 6. Plant weight (seedling age 60 days) (g)

Variant	Whole plant mass (g)		
	$\bar{X} \pm S\bar{x}$	*Vk*	*t-test*
K1-24	14.240±0.275	10.416	K1:K2 26.838** K1:K3 33.112** K1:K4 41.819** K2:K3 11.301** K2:K4 28.723** K3:K4 16.192**
K2-40	6.240±0.115	9.994	
K3-60	4.457±0.108	13.145	
K4-104	2.373±0.07	15.960	
	The above-ground part mass (g)		
K1-24	10.741±0.212	10.646	K1:K2 27.223** K1:K3 33.964** K1:K4 42.379** K2:K3 11.842** K2:K4 28.759** K3:K4 16.270**
K2-40	4.471±0.09	11.130	
K3-60	3.045±0.08	14.968	
K4-104	1.510±0.05	18.285	
	The root mass (g)		

K1-24	3.467±0.08	12.892	K1:K2 20.014** K1:K3 24.227** K1:K4 31.784** K2:K3 8.485** K2:K4 25.266** K3:K4 15.281**
K2-40	1.757±0.03	11.334	
K3-60	1.397±0.03	12.715	
K4-104	0.846±0.02	15.692	

The test results showed that the highest plant weight was in variant K1-24 (14.240 g), and the lowest in variant K4-104 (2.373 g). By testing the level of significance, a statistically highly significant difference was found between all examined variants. Ilin *et al*. (2003) came to similar results, they also determined the influence of vegetation space size on plant mass, whereby they obtained the plants of the largest mass in containers and pots that give the largest vegetation space. Jankauskienė *et al*. (2013) found that the most developed seedlings (formed 9–10 leaves) had the highest fresh weight. Oagile *et al*. (2016) found that as the cell size increases, so does the fresh mass of the plant. Fresh weight of 50-day-old seedlings ranged from 0.65 g to 3.6 g depending on the cell size of the container (Liptay and Hoffmann, 1988).
The largest mass of the green part of the plant had a container with 24 cells, which was 10.741 g, and the smallest container with 104 cells, which amounted to 1.510 g. By testing the level of significance, a statistically highly significant influence of the size of the vegetation space on the mass of the green (aboveground) part of the tomato seedling plant was determined.
The highest root mass was in variant K1-24 which was 3.467 g, and the lowest K4-104 which was 0.846 g. By testing the significance level, a statistically highly significant influence of the size of the vegetation space on the root mass of tomato seedling plants was determined. Some of researches came to similar results, who found that the largest mass of roots had seedlings produced in the largest pots and containers with a smaller number of cells, ie seedlings that had the largest volume of substrate for the development of the root system (Ilin *et al*., 2003).

Conclusions

Based on the research of the influence of the size of the vegetation space on the quality of tomato seedlings, it can be concluded that the volume of the container, ie the size of the cells in the container, significantly affects the quality of tomato seedlings. By measuring the length and width of the cotyledons and the height and diameter of the hypocotyl after tomato emergence, no significant differences were found between the examined variants. The variant with the smallest number of cells, ie the largest cell diameter, recorded the largest number of leaves, while the other variants recorded a smaller number of leaves. In all examined variants, it was determined that there is a statistically highly significant difference between them.

PLANT PROTECTION AND FOOD SAFETY

MICROBIOLOGICAL STATUS OF WATER IN FOOD INDUSTRY OF ANIMAL ORIGIN IN REPUBLIC OF SRPSKA (BOSNIA AND HERZEGOVINA) IN THE PERIOD 2018-2020 IN RELATION TO THE EXAMINED PARAMETERS

Bojan GOLIĆ*, Vesna KALABA, Tanja ILIĆ

Public Institution Veterinary institute of Republic of Srpska „Dr. Vaso Butozan", Banja Luka, Republic of Srpska, Bosnia and Herzegovina

Abstract

Zero-probability level of microbiological contamination of drinking water does not exist. The microbiological quality of water is commonly defined as a maximum acceptable number or concentration of bacteria that do not constitute a health hazard. The experiment used samples of water from food industry of animal origin from the territory of the Entity of Republic of Srpska (Bosnia & Herzegovina) sampled in the period 2018-2020. A total of 390 samples were examined. The aim of this study is to determine the microbiological status of water used in food industry of animal originin Republic of Srpska, in order to identify the risks to food safety. For microbiological testing of water methods BAS EN ISO 6222, BAS EN ISO 7899-2 and BAS EN ISO 9308-1/A1 were used. Research shows that the microbiological status of water used in food industry of animal origin in Republic of Srpska in the period 2018-2020 differs significantly between individual regions. The analysis revealed a significantly higher number of unsatisfactory samples of well water with presence of intestinal enterococci, coliforms and *E. coli*. Water from water supply system has a better microbiological status, but pathogenic bacteria have also been detected in it, which is of concern because it can affect food contamination during the production process.

Keywords: *water, microbiology, food industry.*

Introduction

The production and distribution of biological stable drinking water can only be achieved by adequate monitoring and control of microbial processes during water treatment and distribution (Prest *et al*., 2016). Water supplies within food production premises should be subject to risk and hazard assessment to ensure that appropriate water quality is maintained throughout the production process (Dawson, 1998; Dawson, 2000). In order to eliminate the risk related to disease transfer, water intended for mass consumption is treated and disinfected before use (Sasakova *et al*., 2013; Fridrich *et al*., 2014). On the basis of the results, adequate measures can be taken that include prevention of contamination and systemic disinfection.

The presence of bacteria in drinking water *per se* is not an issue, as long as no pathogenic organisms are present: there are bacteria in drinking water, even in relatively high numbers (10^3 to 10^6 cells/mL), without consequences on human health (Hoefel *et al*., 2005; Hammes *et al*., 2008). Water temperature is an essential factor influencing bacterial growth kinetics and competition processes (Niquette et al., 2001). The temperature oscillates seasonally, even within a single drinking water distribution system. Elevated water temperatures have often been associated with increased bacterial abundance in drinking water distribution systems (Francisque et al., 2009; Liu et al., 2013). The microbiological quality of water is commonly defined as a maximum acceptable number or concentration of bacteria that do not constitute a health hazard (EU, 2020). *E. coli*, intestinal enterococci, coliform bacteria and colony count on 22°C shall be monitored in accordance with the monitoring frequencies. *E. coli* and intestinal enterococci are considered "core parameters". Minimum requirements for parametric values used to assess the quality of water intended for human consumption is 0/100 ml for *E. coli* and intestinal enterococci. In Republic of Srpska (B&H) the limit value for total count on 22°C (TC 22°C) is 100 CFU/ml and for total count on 37°C (TC 37°C) the limit is 20 CFU/ml. Also, coliform bacteria (CB), *Escherichia coli (E. coli)* and intestinal enterococci (EC) must not be detectable in 100 ml sample of water (Official Gazette RS, 2017). Indicator organisms are used to assess the microbiological quality of water. Whilst the presence of coliform bacteria does not always indicate a public health threat, their detection is a useful indication that treatment operations should be investigated (Edberg, 2000). The use of indicator bacteria, in particular *Escherichia coli* (*E. coli*) and the coliform bacteria, as a means of assessing the potential presence of water-borne pathogens has been paramount to protecting public health (Hijnen *et al*., 2000). The presence of *E. coli* in a sample of drinking water may indicate the presence of intestinal pathogens. However, the absence of *E. coli* cannot be taken as an absolute indication that intestinal pathogens are also absent. *E. coli* bacteria are the only biotype of the family Enterobacteriaceae which can be considered as being exclusively faecal in origin (Edberg, 2000; WHO, 2008) and it can represent up to 95 % of the *Enterobacteriaceae* found in faeces. *E. coli* occurs in the faeces of all mammals, often in high numbers (up to 10^9 per gram of faeces) (Edberg, 2000; WHO, 2008). It is incorrect to state that drinking water distribution and delivery systems should be sterile. The active growth of microorganisms is considered indicative of failures in water processing units or distribution (Gottschal, 1992). Water is used in various ways in milk production and dairy industry, thereby becoming part of the food intentionally, inevitably or accidentally. The contamination of the food by water-borne microorganisms occurs directly, much more often, however, indirectly after multiplication of these microorganisms on the cleaned surfaces of the equipment used (Terplan, 1980). Some studies revealed that wash water can be source of bacterial contamination for milk and further compromise the quality and safety of milk or milk products (Kivaria *et al*., 2006; Perkins *et al*., 2009). The water used during handling and processing of milk products can be potential sources of microbial contamination with possible negative consequences on food safety. Especially, the water used in keeping the hygiene of milking and milk storage utensils is crucial to keep the quality and safety of the products. *E. coli* was isolated in 39.20% of samples of water (Amenu *et al*., 2016). In a study by Habes *et al*. (2015) it has been founded that all water samples used in the production of milk and milk products were microbiologically safe. Kalaba *et al*. (2020) found that in the period 2015-2017 of the 584 water samples, 26.20% were unsatisfactory. The aim of this study is to determine the microbiological status of water used in food industry of animal originin Republic of Srpska, in order to identify the risks to food safety.

Materials and methods

The experiment used samples of water from food industry of animal origin from the territory of the Entity of Republic of Srpska (Bosnia & Herzegovina) sampled in the period 2018-2020. A total of 390 samples were examined (122 in 2018, 127 in 2019 and 141 in 2020). Laboratory testing of samples was performed at the Public Institution Veterinary Institute of Republic of

Srpska "Dr Vaso Butozan" Banja Luka. Microbiological examination was carried out according to the Official Gazette RS (2017). This included enumeration of colony forming units (CFU) expressed as total count of bacteria cultivated at 22°C (TC 22°C) and 37°C (TC 37°C) according to BAS EN ISO 6222 (ISBIH, 2003a), coliform bacteria (CB) and *E. coli* according to BAS EN ISO 9308-1/A1 (ISBIH, 2018) and intestinal enterococci (EC) according to BAS EN ISO 7899-2 (ISBIH, 2003b). In our research and in the statistical analysis of the obtained results, we used, as basic statistical methods, descriptive statistical parameters. The research results are presented in tables and figures.

Results and discussion

The territorial and economic organization of the Republic of Srpska (B&H) is conditionally created at the level of six regions: Banja Luka, Prijedor, Doboj, Bijeljina, East Sarajevo and Trebinje. The distribution of water is such that it is not enough where it is most needed (in the northern, most developed part of Republic of Srpska), and flows are most scarce during periods of the year when needs are greatest and when water quality protection problems are most serious. Figures 1 to 4 show the average representation of the samples in relation to the region of origin and the category of samples.

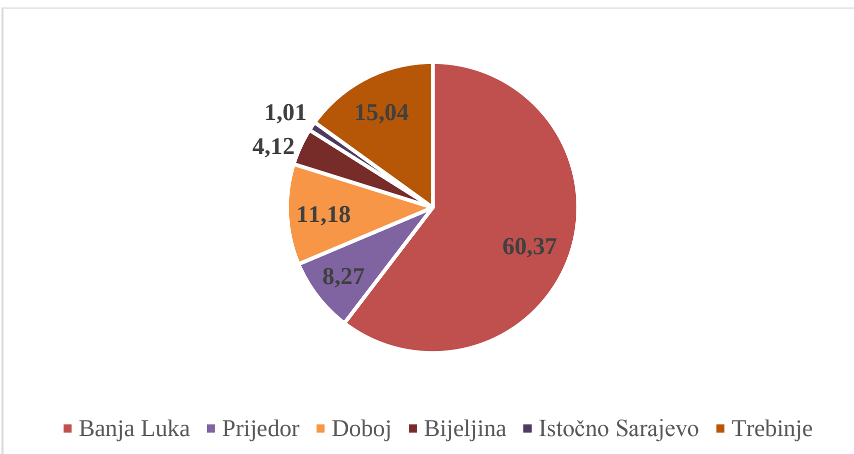

Figure 1. Representation of samples in relation to the region in % for the period 2018-2020

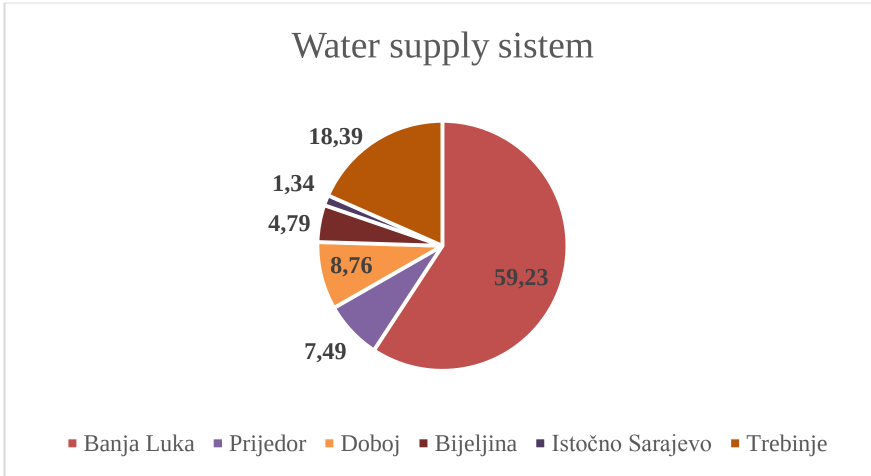

Figure 2. Average regional representation of samples originating from water supply system in % for the period 2018-2020

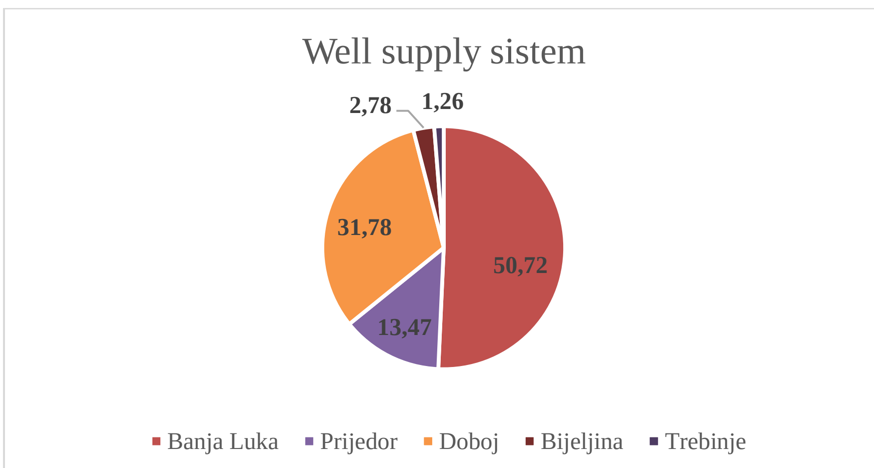

Figure 3. Average regional representation of samples originating from well supply system in % for the period 2018-2020 years.

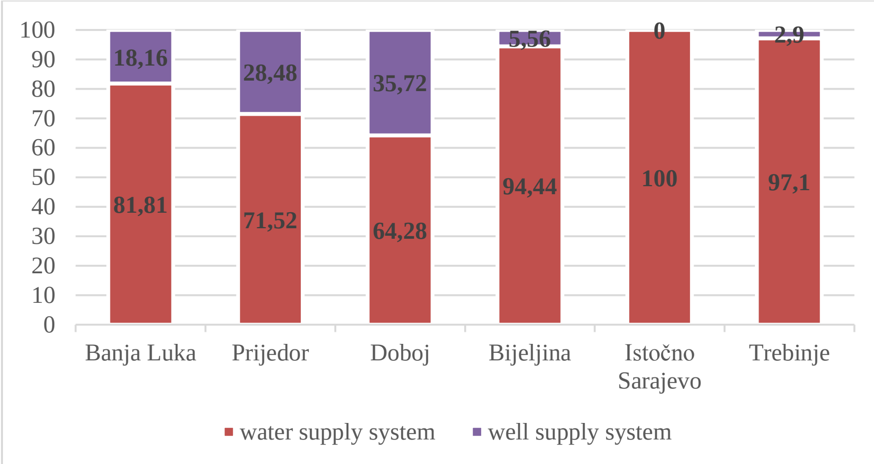

Figure 4. Representation of samples by regions in % in relation to the category for the period 2018-2020

Analysis of the representation of samples by region shows that the most regions predominantly use in the food industry water from water supply system. Most of the analyzed samples, as expected, come from region with the highest concentration of facilities in the food industry (Banja Luka). The analyzed number of samples originating from the region of East Sarajevo is negligibly small, so it was left out of the discussion.

No source of water that is intended for human consumption can be assumed to be free from pollution. All sources have different microbiological qualities and may be subject to natural or manufactured sources of pollution that may result in the deterioration of water quality to the point where treatment is no longer effective in removing all of the contamination. Zero-probability level of microbiological contamination of drinking water does not exist (EU, 2020).

Table 1 shows the test results by region in relation to the total number of samples in % for the period 2018-2020 years, and Table 2 shows the results by region in % in relation to categories for the period 2018-2020 years.

Table 1. Test results by region in relation to the total number of samples in % for the period 2018-2020

Region	Satisfactory	Unsatisfactory
Banja Luka	90.26±7.41	9.74±7.41
Prijedor	86.16±6.26	13.84±6.26
Doboj	86.64±4.28	13.36±4.28
Bijeljina	100	0
Istočno Sarajevo	78.57±25.75	21.43±25.75
Trebinje	79.90±7.12	20.10±7.12

In most regions over four-fifths of the samples were satisfactory. The obtained results, in contrast to the results of Kalaba *et al*. (2020), indicate a much better microbiological status of water.

Table 2. Test results by region in % in relation to categories for the period 2018-2020.

Region	$\bar{x}$±δ			
	Water supply system		Well supply system	
	Satisfactory	Unsatisfactory	Satisfactory	Unsatisfactory
Banja Luka	91.86±6.54	8.14±6.54	64.10±24.43	35.90±24.43
Prijedor	86.51±17.55	13.49±17.55	83.33±28.87	16.67±28.87
Doboj	94.44±9.62	5.56±9.62	70.24±39.82	29.76±39.82

Bijeljina	93.33±11.55	6.67±11.55	33.33±57.74	0
Istočno Sarajevo	83.33±28.87	16.67±28.87	0	0
Trebinje	84.56±11.30	15.44±11.30	0	33.33±57.74

As expected, the microbiological status of water from the water supply system is significantly better than well water, in which one-third of the three regions have unsatisfactory samples.

According to the WHO (2008), *E. coli* are the only true indicator of faecal contamination; they are exclusively of intestinal origin and are found in faeces. Their presence indicates mostly fresh faecal contamination and thus points to serious shortcomings in protection of the specific water source, treatment of water and its hygienic safety. Faecal streptococci represent evidence of faecal contamination and tend to persist for longer in the environment than thermotolerant or total coliforms. Colony counts are enumerations of the general population of heterotrophic bacteria present in water supplies. The enumerations may represent bacteria whose natural habitat is the water environment or those that have originated from soil or vegetation. Two incubation temperatures and times are used for total count, 37°C for 48 h to encourage the growth of bacteria of mammalian origin, and 22°C for 72 h to enumerate bacteria that are derived principally from environmental sources.

Table 3 shows the average test results of the total number of samples by region in % in relation to the test parameter for the period 2018-2020.

Table 3. Test results of the total number of samples by region in % in relation to the test parameter for the period 2018-2020

Region	$\bar{x}\pm\delta$				
	TC 22°C	TC 37°C	EC	*E. coli*	CB
Banja Luka	9.30±6.68	8.02±6.69	1.12±1.95	2.14±0.79	2.57±0.31
Prijedor	13.84±6.26	13.84±6.26	8.59±8.35	5.56±9.62	5.56±9.62
Doboj	4.18±3.64	9.17±2.55	3.92±6.79	0	3.03±5.25
Bijeljina	0	6.67±11.55	0	0	0

Trebinje	13.66±0.62	12.86±8.59	2.97±2.57	4.35±7.53	5.86±6.62

The presence of pathogenic bacteria from water supply system is a particularly worrying fact given that water must be microbiologically correct, which means that it must not contain pathogens (Official Gazette RS, 2017). A possible explanation for this is dilapidation and damage to water supply installations leading to water contamination.

Use of contaminated water in the handling and processing of milk products can cause a higher potential health risk than the risk through direct drinking. This is due to the fact that multiplication of pathogenic micro-organisms can occur in milk and milk products with amplification of the load of the pathogens (Amenu, 2013).

E. coli is a coliform bacteria and it is considered a primary indicator of fecal water contamination. Enterococci include a number of species that occur in the faeces of humans and warmblooded animals. The main reason for their enumeration is to assess the significance of the presence of coliform bacteria in the absence of *E. coli*, or to provide additional information when assessing the extent of possible faecal contamination. As such, they are regarded as secondary indicators of faecal pollution (WHO, 2008).

Tables 4 and 5 show the results of testing water from water supply system and well water by region in % in relation to the test parameter for the period 2018-2020. years.

Table 4. Test results of water from water supply system by regions in % in relation to the test parameter for the period 2018-2020

Region	$\bar{x}\pm\delta$				
	TC 22°C	TC 37°C	EC	*E. coli*	CB
Banja Luka	7.68±5.76	6.05±5.88	1.33±2.31	1.65±1.50	6.34±6.72
Prijedor	13.49±17.55	13.49±17.55	0.56±0.96	0	0
Doboj	2.78±4.81	2.78±4.81	0	0	0
Bijeljina	0	6.67±11.55	0	0	0

Trebinje	10.90±5.32	9.96±11.62	3.10±2.69	1.59±2.75	3.10±2.69

The obtained results are better than the results of the study of testing water from water supply system at milk collection points, were found 20.40% of unsatisfactory samples, of which 10.20% was detected *E. coli* and coliforms, and faecal streptococci in 12.24% (Denžić *et al*., 2013).

Table 5. Test results of well water by regions in % in relation to the test parameter for the period 2018-2020

Region	$\bar{x}\pm\delta$				
	TC 22°C	TC 37°C	EC	*E. coli*	CB
Banja Luka	30.34±21.31	13.67±17.45	0.85±1.48	0.85±1.48	5.56±9.62
Prijedor	16.67±28.87	16.67±28.87	16.67±28.87	16.67±28.87	16.67±28.87
Doboj	0	21.43±25.75	16.67±28.87	0	4.76±8.25
Bijeljina	0	0	0	0	0
Istočno Sarajevo	0	0	0	0	0
Trebinje	33.33±57.74	33.33±57.74	0	33.33±57.74	33.3±57.74

The obtained results indicate that the presence of bacteria, especially pathogenic ones, is significantly higher in well water than in water from water supply system. However, these results differ significantly from the results of analysis of water from milk collection points, originating from wells, where it was found 63.90% (Jaki *et al*., 2010) and 58% (Denžić *et al*., 2012) of unsatisfactory samples, including *E. coli* (20.45%), coliforms (32.55%) and enterococci (41.86%).

Conclusion

Research shows that the microbiological status of water used in food industry of animal origin in Republic of Srpska in the period 2018-2020 differs significantly between individual regions. The analysis revealed a significantly higher number of unsatisfactory samples of well water with presence of intestinal enterococci, coliforms and *E. coli*. Water from water supply system has a better microbiological status, but pathogenic bacteria have also been detected in it, which is of concern because it can affect food contamination during the production process.

Abstract

Maize (*Zea mays* L.) is one of the oldest crops in the world and, as a C4 plant, it shows an incredible increase in biomass. In recent years, a significant number of varieties and hybrids of maize with different tolerance and resistance to diseases and pests have been introduced in Bulgaria. An important pest against which resistance has been created is the European corn borer (*Ostrinia nubilalis* Hb.). The aim of the present work is to monitor the incidence and development of the European corn borer in three maize hybrids in the region of Central Northern Bulgaria. The study was carried out on F1 maize hybrids: ISH714, ISH618, NOSTRANO AGROSUD. Flight dynamic was monitored daily from early May to late September using pheromone traps ZOEKON (ECB-1 capsules). The attack of each hybrid was detected by plant dissection. Damage above and below the cob and the number of larvae in each stem were reported. During the study period 2017-2019, it was found that the hybrids ISH 714 and ISH 618 were attacked equally by the first generation of the European corn borer and there were no proven differences between them. A higher number of larvae were reported in the NOSTRANO AGROSUD hybrid. The ISH 714 hybrid can be defined as the most resistant to the European corn borer, it had the lowest attack and degree of damage, as the differences with the other hybrids ISH 618 and NOSTRANO AGROSUD were statistically proven.

Keywords: *Ostrinia nubilalis, hybrids resistance.*

Introduction

Maize (*Zea mays* Linnaeus, 1753) is an economically important crop and, as a C4 plant, alongside wheat and rice, one of the most important sources of energy in the world. It is attacked by a very large number of insect pests. The European corn borer is a major pest of maize in many European countries, in the Mediterranean region of Africa and in limited areas in southwest Asia. It creates serious problems in maize production in Bulgaria and Europe (Pronko, 2011; Gagnon et al., 2019). In many regions with intensive maize cultivation, 50 to 80% and sometimes up to 100% of the plants are damaged, resulting in a yield loss of 30-40% (Lisowicz and Tekiela, 2004). In recent years, in addition to the use of insecticides, efforts have been made to create varieties and hybrids resistant to very dangerous pests such as cotton bollworm, European corn borer, corn aphids and others through breeding methods. The application of alternative methods to limit the use of plant protection chemicals is an important assignment to be solved by farmers and researchers. An increasing number of maize varieties and hybrids with different tolerance and resistance to diseases and pests are entering Bulgaria. However, it should be considered that insect pests adapt to crop resistance due to their natural evolutionary process, which is a serious problem for agriculture. Achieving higher yields and greater profitability implies systematic observations on the anticipatory adaptation of pests to the new and changing mechanisms of influence on them. Therefore, science is researching new ways and strategies to manage resistance. New plant protection programs must be accompanied by crop resistance monitoring to pests. In this aspect, the following of the density and dynamics of the European corn borer populations in resistant varieties and hybrids is of paramount importance. The aim of the present work is to monitor the occurrence and development of the European corn borer in three foreign maize hybrids in the region of Central-Northern Bulgaria.

Materials and Methods

Geographical location of the experimental areas

The results in the present work are based on carried out field investigations. The experimental area was located on the left bank of the Osam river valley about 30 km northeast of the city of Pleven, Bulgaria (43°50'441"N, 24°99'045" E).

Agrotechnical data for the experimental areas

The study was conducted in the period from 2017 to 2019 on an area of 0.5 ha. Sowing was carried out in the first week of April with hybrids ISH 618, ISH 714 and NOSTRANO AGROSUD at 72120 plants/ha and row spacing 19.8 cm. Maize was sown in this area according to the crop rotation scheme. The plant protection measures applied precluded the use of insecticides during the growing season. Control points were identified from which the necessary data were obtained to assess the resistance of maize hybrids. The values obtained from the three experimental years (2017-2019) were averaged.

Determination of the population density of European corn borer populations

The presence of the first and second generation was predicted based on the effective temperature sums from the date of permanent increase of the average daily temperatures above 10°C resp. 15 °C. Flight dynamics were monitored from early May to late September with Zoekon pheromone traps (ECB-1 capsules). They were mounted on woody vegetation 10 m from the maize crops, at a distance from each other (laterally) 75-100 m and at a height of 1 m above the ground surface. The wild herbaceous vegetation under and around the pheromones was not mowed.

As an auxiliary method to the monitoring with pheromone traps before the start of flight activities of *O. nubilalis*, the plants were observed for the presence of the first groups of eggs.

Monitoring of the flight would be more accurate if light traps were also used, but due to the difficulty of installing them in production experimental fields, the flight of moths was followed only with pheromone traps.

Determination of the infestation by the European corn borer

The infestation degree of each hybrid was assessed in 3 replicates by dissection of 15 plants (5 for each replicate). Damage above and below the cob and the number of larvae in each stem were counted. Due to the impossibility to compare the resistant hybrids with another non-resistant, the resistance was determined by a correlation between the number of the adults of European corn borer and damaged plants.

Characteristics of plant material

The study was carried out on three F1 maize hybrids: The ISH 714 hybrid is a late maturity maize hybrid (FAO 700). It is grown for the production of grain and silage. The hybrid has a good tolerance to *O. nubilalis*, very good to *Helminthosporium* spp. and medium to *Fusarium* spp. The ISH 618 hybrid is a medium-late maturity maize hybrid (FAO 600). Shows excellent yield under different conditions; suitable for silage in a second crop. Has a very good tolerance to *O. nubilalis*, very good to *Helminthosporium* spp. and *Fusarium* spp. The NOSTRANO AGROSUD hybrid is a medium early maturity maize hybrid (FAO 450). It is grown for grain production. Shows very good tolerance to *O. nubilalis*, good to *Helminthosporium* spp. and *Fusarium* spp.

Statistical analysis

The results were analysed using the software package Statistica 13.0 (TIBCO® Statistica™, CA, USA). One- and two-factor analysis of variance (ANOVA) was used to determine the influence of various factors on the studied features.

Results and discussion

Flight dynamics of the the European corn borer

It is known that in the observed area the European corn borer develops two generations per year and depending on climatic factors they are more or less differentiated.

The flight of first-generation was determined by pheromone traps and the presence of groups of eggs. The dynamics of flight for the region and the period 2017-2019 is presented graphically in Fig. 1. An increase in the *O. nubilalis* population was observed in the end of June. The peak of the population was registered in the end of June, when the plants were in the growth stage BBCH 55. The largest number of moths in the pheromone trap was observed between the end of June and the first ten days of July, followed by a clear decline in the population, and in the third ten days of July more moths were caught again.

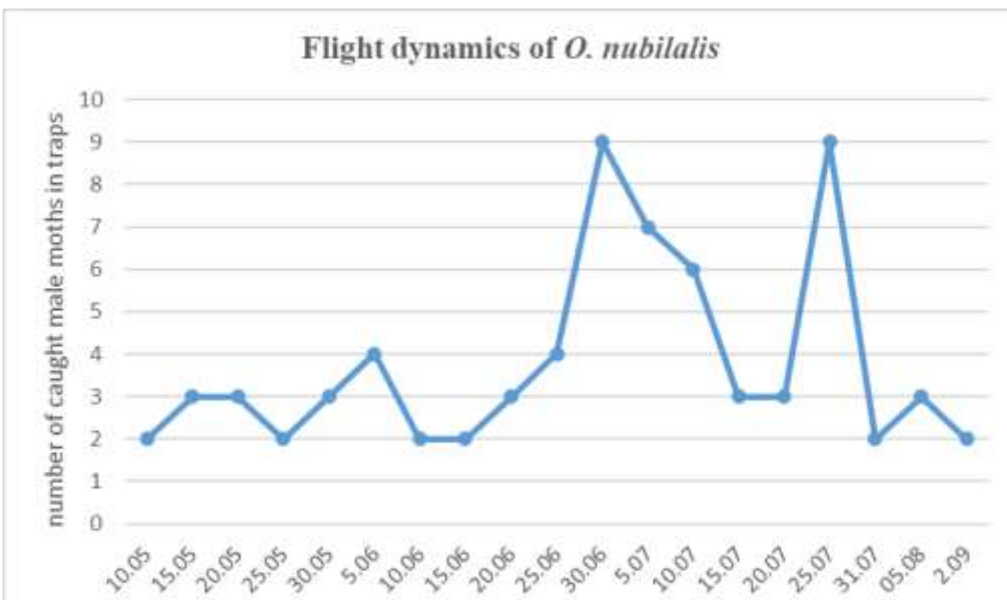

Figure 1. Flight dynamics of the European corn borer moths based on the catch with pheromone traps, 2017-2019, Pleven region (Bulgaria)

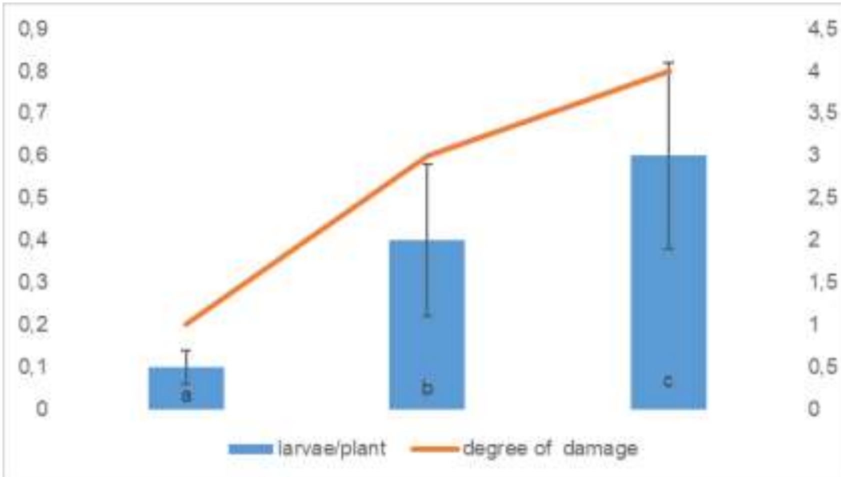
The monitoring carried out during 2017, 2018 and 2019 using pheromone traps showed that male *O. nubilalis* were present in the corn field between May and September. During the flight, two population peaks were observed: the first in the first ten days of June and the second in the second ten days of July. The second peak coincides with the peak of the second generation.

Degree of infestation and damage by European corn borer

The following results were obtained from the processing of European corn borer infestation data: a higher number of larvae (0.68 ± 0.15 larvae/plant) were registered in the studied plants in NOSTRANO AGROSUD hybrid than in the ISH 714 and ISH hybrids 618 (0.29 ± 0.15 larvae/plant resp. 0.38 ± 0.22 larvae/plant) (Fig. 2).



Mean ± SE; different letters = significant differences; P <0.05; -Tukey test

Figure 2. European corn borer infestation in hybrids ISH 714, ISH 618 and NOSTRANO AGROSUD

Despite the presence of larvae, significant damage was not found in all three hybrids. Data from the infestation and damage of second generation showed that the larvae were found mainly in the stems of maize plants. The proportion of larvae in the cobs was relatively low: in INOSTRANO AGROSUD 0.43 ± 0.22 larvae/stem and 0.25 ± 0.03 larvae/cob; in ISH 618 0.36 ± 0.17 larvae/stem as in 0.17 ± 0.01 larvae/cob, while in ISH 714 the number of larvae was 0.05 ± 0.04 larvae/stem, but no larvae were found in the cobs (Fig. 3).

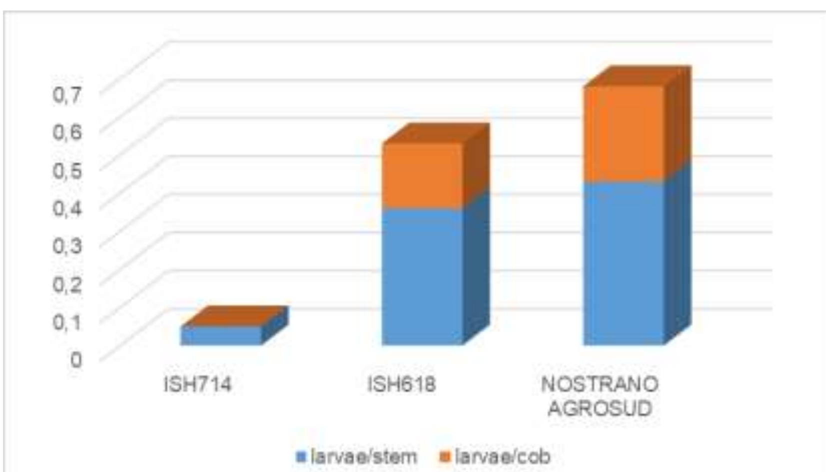


Figure 3. European corn borer infestation (second generation) in hybrids ISH 714, ISH 618 and NOSTRANO AGROSUD

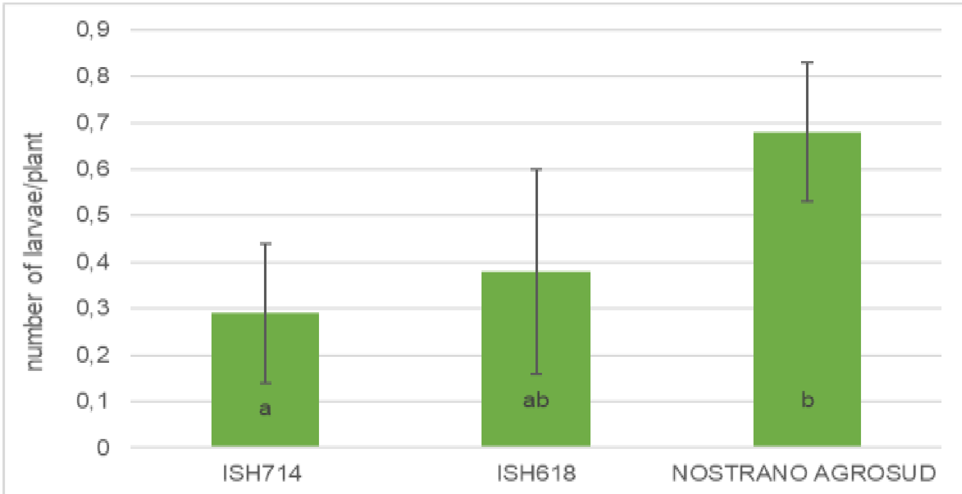
The damage to the cobs was evaluated on a Hudon and Chaing (1991) scale from 1 to 9, with the highest degree of 9. A higher degree of damage was demonstrated for NOSTRANO AGROSUD (4) and ISH 618 (3) compared to ISH 714 (1) (Fig. 4).



Mean ± SE; different letters = significant differences; P <0.05; -Tukey test

Figure 4. Degree of damage by European corn borer in hybrids ISH714, ISH618 and NOSTRANO AGROSUD

Yield measurements were performed and the reported values were as follows: ISH 714: 13.700 t/ha; ISH 618: 14.000 t/ha; NOSTRANO AGROSU: 10.650 t/ha. The yields did not deviate significantly from those indicated in the characteristics of the hybrids. When comparing the number of caught moths with the number of larvae and the established damages, it can be seen that not always the larger number of moths is accompanied by more larvae and damages. For example, in July the average catch was 5.6 moths in a pheromone trap and the larval density was 0,1 ± 0,04 larvae/plant in ISH 714, 0,4 ± 0,18 larvae/ plant in ISH 618 and 0. 6 ± 0.22 larvae/plant in NOSTRANO AGROSUD. The number of reported moths also differs with the degree of damage. After correlation analysis of the data, it was demonstrated that the values of the correlation coefficients between the number of moths and larvae and the degree of damage for the period May-September were very insignificant (R = 0.29). This indicates that low values of recorded flight cannot be used as a criterion for predicting minimal damage or that infested hybrids are resistant to European corn borer. This finding is consistent with previous data of Nikolov and Stoyanova (2003). The authors look for a relation between the catch of European corn borer moths with light and pheromone traps and the damage from larvae on the pepper. They found that the values of the correlation coefficients between the number of moths and the density of the larvae, resp. the damage were insignificant. Similar data were obtained from Maini and Burgio (1999) in sweet corn. The authors found that there is a certain positive correlation (r = 0.75) between the number of caught females and the percentage of damaged cobs, while when reporting males such a correlation was not observed. It should be noted that many biotic and abiotic factors affect the fertility and sterility of adults, the hatching and parasitism of eggs during different years. However, the degree of infestation and damage by European corn borer, which we have observed in the three foreign maize hybrids, is important for more effective control of the pest and for obtaining information on possible pre-early adaptation of plants to new and changing mechanisms of influence.

Conclusions

Results showed that the hybrids ISH 714 and ISH 618 were infested equally by the first generation of the European corn borer and there were no proven differences between them. A higher number of larvae were reported in the NOSTRANO AGROSUD hybrid.
The hybrid ISH 714 can be determined as the most resistant in the conditions of central northern Bulgaria to the European corn borer. It had the lowest infestation and the lowest degree of damage (1), as the differences with the other hybrids ISH 618 and NOSTRANO AGROSUD were statistically proven. A relation between the catch of the European corn borer males with pheromone traps and the damage by larvae on hybrids was not established.

Abstract

Barley production has been constrained by various factors, of which loose smut (*Ustilago nuda*) is the main biotic factor. Molecular and agronomical screening analyses were evaluated to study the similarity levels and marker assisted selection associated with resistance to loose smut among eight barley genotypes using Sequence-Related Amplified Polymorphism (SRAP). Agronomical parameters during two consecutive 2020 and 2021 seasons were studied to identify their reaction to loose smut. The results exhibited significant differences among all studied genotypes for all studied characters, and the highest mean values for all studied traits were detected in Giza 136 and Giza 137. Six SRAP selected primer combinations were amplified and gave 56 total fragments, where primer combination me1+em3 gave the highest polymorphism (100 %) and the highest polymorphic information content of PIC was (0.96). The dendrogram of SRAP markers had clustered all studied genotypes into two main clusters, cluster I include all the resistance genotypes Giza 136, Giza 137, Giza 123, Giza 132, Giza 138 and Line 2. However, cluster II include only Line 1 and line 3 as a susceptible genotypes. Thus, SRAP marker could be efficiently used to assess genetic variation among barley genotypes and useful for barley germplasm management in terms of biodiversity protection and design of new crosses for loose smut breeding programs.

Keywords: *Hordeum vulgare, Loose smut (Ustilago nuda), Sequence-related amplified polymorphism (SRAP), UPGMA cluster analysis.*

Introduction

Barley (*Hordeum vulgare* L.) is a cereal crop that is grown throughout the world and is ranked fifth in world crop production. Barley can be grown in many different climatic regions due to its adaptability to diverse conditions. These climatic conditions include variable growing seasons, temperatures, and precipitation rates (FAOSTAT, 2020).

Barley, like most crops, is attacked by many disease-causing organisms. Some cause only minor damage while others can completely destroy the crops. One of the most devastating diseases is loose smut which is caused by a fungus (*Ustilago nuda*). This fungus can drastically reduce both the yield and quality of crops which has been considered as a common and world-wide seed-transmitted pathogen (Thomas, 2011). The mycelium, that is localized in the embryo, spreads systemically and asymptotically in the developing plant; during flowering, the inflorescence is largely replaced by sari containing the black teliospores of the fungus.

Seeds infected by loose smut produce normal-looking tillers up until the time of ear emergence. Thus, the affected plants compete for light, water and nutrients alongside healthy plants. (Zegeye et al., 2015).

Improvement of resistant cultivars is one of the most effective and economical means of controlling barley loose smut. Identification and incorporation of new and effective sources of resistance are key to the success of barley breeding programs. Molecular markers display an important role and considered as a tool in parallels with conventional breeding for barley improvement. The first step to design breeding program for useful trait is choosing parental genotypes based on its genetic dissimilarity (Mariey et al., 2021).

Sequence related amplified polymorphism (SRAP) is a PCR based marker system as described by (Li and Quiros, 2001*)*. It is simple, discloses numerous co-dominant markers, targets open reading frames (ORFs), and allows easy isolation of bands for sequencing. SRAP markers have been successfully used to measuring the genetic diversity and relationships in barley (Yang et al., 2010; Mariey, 2021*)*. Nonetheless no much works for using SRAP as a marker for genetic diversity in barley for loose smut.

The objectives of the present study were to fingerprint and to determine the relationships among some barley genotypes based on the SRAP markers as the first work for for loose smut associated with loose smut resistance to use them in barley breeding programmers.

Materials and methods

Field Experiments and Plant Materials

Eight Egyptian barley genotypes were used in this study. Their names and pedigree are shown in Table (1). Barley genotypes were grown in the Experimental Research Station of Sakha (Egypt) during two growing seasons 2019/2020 and 2020/2021 with the aim to evaluate the yield and its related traits and loose smut reaction. Randomized complete block design with three replications was used. Plot size was 1.8 m^2 (6 rows x 0.2 m x 1.5 m). Studied characteristics determined in this study included plant height (cm), number of spike m^{-2}, number of grains $spike^{-1}$, grain yield ($t.ha^{-1}$)

Inoculation and disease evaluation

Smutted heads (SMT): (disease incidence): Assessment of 100 randomly selected plants from three central rows of each plot at the time of heading and calculated as percentage of plants showing symptoms**.**

Loose smut incidence (LSI) was assessed in each cultivar according to the method described by Menzies et al. (2009), and was calculated as follows:

$$LSI\ (\%) = \frac{\text{Number of smutted plants}}{\text{Total number of plant}} \times 100$$

Molecular markers assay

The molecular assay was carried out in the Genetics Laboratory of Genetics Department, Faculty of Agriculture, kaferelshikh University, Egypt. Genomic DNA was isolated using CTAB method from fresh leaves of the used eight genotypes of barley according to Doyle and Doyle (1990). The PCR reactions using nine SRAP combinations were used in this study as shown in Table (2). The reactions for SRAP was optimized and mixtures were prepared (in total volume of 25 µl). PCR cycling was carried out as the following program; initial denaturation at 94 °C for 4 min, followed by five cycles comprising 1-min denaturation at 94 °C, 1-min annealing at 35 °C, and 30 s of elongation at 72 °C. In the following 30 cycles, denaturation at 94 °C for 1 min, annealing at 50 °C for 1 min, and elongation at 72 °C for 30 s were carried out, ending with an elongation step for 10 min at 72 °C. The amplified products were stored at 4 °C. The PCR products were separated by electrophoresis using 2% agarose gel in 1 x TBE buffer against 100 bp DNA Ladder as a size marker. Bands were detected with ethidium bromide staining and visualized under UV light, then photographed on Gel Documentation.

Data Analysis

***Agro-Morphological Traits Analysis*.**

Data collected from field experiment were statistically analyzed as a randomized complete block design (RCBD) using analysis of variance (ANOVA) as a combined analysis (Steel et al., 1997).

Molecular Marker Analysis

The amplified bands from SRAP were scored as a binary data under the heading of total scorable fragments, which was determined for each cultivar. The data were used to estimate the genetic similarity on the basis of number of shared amplification products *(*Nei and Li, 1979*)*. Polymorphism information content (PIC) values were done according to (Anderson et al., 1993). Cluster analysis was performed to produce a denderogram using PAST program adapted by Hammer et al. (2001).

Results and discussion

Agro-Morphological Traits Analysis

The results exhibited significant differences among the genotypes for all studied characteristics. This provides an evidence for the possibility to carry out a sufficient selection program on the basis of these traits using the studied cultivars in Table 3. The results significantly varied in plant height clearly indicated that Giza 137 was the tallest cultivar (114.2 cm). However, Giza 132 was the shortest cultivar (85.0 cm). The mean performance of number of grains spike^{-1} indicted that Giza 137 gave the highest no. of grains spike^{-1} (63.5 grains spike^{-1}), however, the lowest no. of grains spike^{-1} was produced by Giza 123, which gave 61.5 grains spike^{-1}. Concerning number of spikes m^{-2}, the means of the cultivars showed that Giza 137 gave the highest number of spikes m^{-2} (513.2 spikes m^{-2}), while the lowest number of spikes m^{-2} was obtained by Giza 138 with value of 450.8 spikes m^{-2}. Regarding grain yield, Giza 137 had maximum value (3.7 t fed^{-1}). However, Giza 132 had the lowest grain yield (2.3 t fed^{-1}). The results were in close agreement with those obtained by (Mariey et 2021*)* who found high genetic variation for most of agro-morphological traits among barley genotypes under normal condition

High loose smut incidence (LSI) was assessed in line 1 and line 3

loose smut was common in all districts surveyed (Zegeye et al., 2015). Infected barleyseeds used for planting purposes in repeated cycles, has lead to the multiplication and distribution of the fungus across large areas of the region. line1 and line3 weren't acted as a potential activator of plant defense responses to biotic stresses. The genetic also helped the plant to become susceptible.

Table 3. Analysis of variances of combined mean values of eight Egyptian barley genotypes for agro-morphological traits and loose smut reaction

Molecular markers analysis

The SRAP marker system is becoming the marker of choice for characterization and genetic diversity studies in a wide range of plants. The study described in the present paper shows that SRAP analysis is a powerful tool also for the characterization of barley genotypes. In our study, the SRAP markers were used for the first time for assessment the genetic diversity among Egyptian barley genotypes for loose smut resistance. The results obtained in this study showed that there were high levels of polymorphism in genotypes under study especially when the genotypes were compared for the loose smut reaction. Total of 56 fragments were amplified with six primer combinations, Results in Table 4 showed the average percentage of polymorphic loci for all primer combinations was 77.67 % and the average band number amplified from each pair of primers was 9.33% bands, of which included 7.5% polymorphic bands, which the maximum band number among the six primers combinations was 13 obtained by primer combination me1+em3 which gave the highest polymorphism (100 %) and highest Polymorphic information content (PIC) (0.96) which generated specific band associated to loose smut with size 550 bp Fig (1) found in the susceptible genotypes (line 1 and line 3), However, primer me1+em2 had the lowest polymorphism (57.4.0%) and lowest PIC value (0.58).

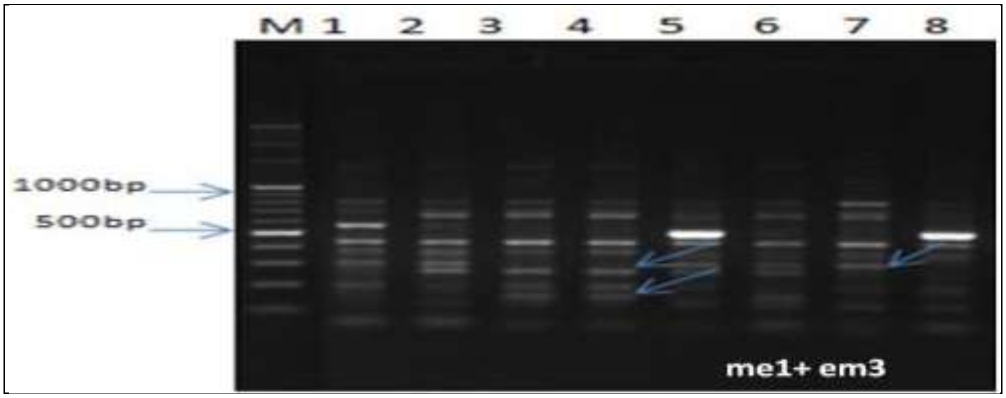

Fig (1) Agarose gel electrophoresis using SRAP primer combinations me1+em3 (A) and me2+em2 (B) in eight barley genotypes. (M) marker, (1) Giza 123, (2) Giza 132, (3) line 1, (4) line 2, (5) line 1, (6) Giza 136, (7) Giza 137 and (8) Line 3.

Table 4. Polymorphism number and rate for six SRAP primer pairs used to amplify genomic DNA templates from eight Egyptian barley genotypes

Primer combination	Number of Total fragments	Number of polymorphic fragments	Percentage of polymorphic fragments	polymorphic information content (PIC)
me1+em2	7	4	57.14	0.58
me1+em3	14	14	100.00	0.96
me2+em1	10	7	70.00	0.71
me2+em3	8	6	75.00	0.68
me1+em2	9	8	88.89	0.83
me1+em1	8	6	75.00	0.76
Average	9.33	7.5	77.67	
total	56	45		

A dendrogram (**Fig.2**) based on the genetic similarity coefficient was constructed using the six SRAP primers. In this dendrogram, all the eight barley genotypes divided in two main cluster, cluster I include all the resistance six barley genotypes Giza 136, Giza 137, Giza 123, Giza 132, Giza 138 and Line 2. However, cluster II include the genotypes Line 1 and line 3 were as a susceptible genotypes with genetics similarity (0.82).

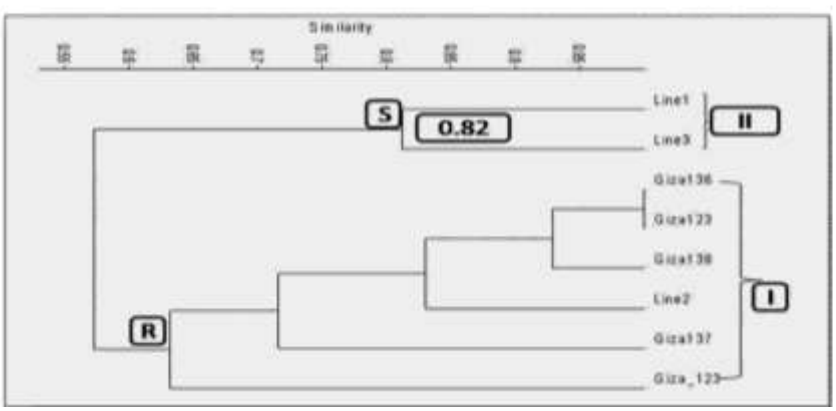

Fig (2): SRAP based dendogram of the eight barley genotypes constructed using Unweighted Pair–GroupMethod with Arithmetic (UPGMA).

In present study, genetic diversity level of Egyptian barley genotypes for loose smut is higher than other genetic diversity studies using different marker systems for loose smut such as such as RFLP (Eckstein et al.,1993), SSR (Cheng-Dao et al., 2001) and SCAR marker for loose smut in wheat (Draz et al., 2021) .SRAP markers mainly targets exons which are expected to be evenly distributed along all chromosomes with GC-rich regions and introns with AT-rich regions (Li and Quiros, 2001). Small and simple barley genome taken into consideration, many intron and exon regions may have influenced the number of excess polymorphic bands. Therefore, using SRAP marker to assessment the genetic diversity among barley genotypes for environment stress will be useful for barley germplasm management in terms of biodiversity protection and design of new crosses for disease resistance to loose smut breeding programs . These results were in a good harmony with (Mariey et al., 2021). They reported that the SRAP marker will be efficiently used to assess genetic variation among barley genotypes and would be useful for barley germplasm management in terms of biodiversity protection and design of new crosses for environment stress breeding program.

Conclusions

This is the first attempt to determine the genetic diversity resistance to loose smut in Egyptian barley genotypes using SRAP markers. The primer combination me1+em3 was (0.96) indicating that this primer combination is highly informative and might be useful tool to determine the genetic differences among barley cultivars for loose smut reaction.

Abstract

Apples are rich in bioactive compounds like antioxidants, polyphenols and other compounds having health promoting properties. The shift of modern-day consumer towards fresh, minimally processed, conveniently prepared food is making minimally processed apples more and more popular. Processing of fruits generates physiological stresses in the live tissues even if it is minimal processing. These stresses lead to quality deterioration and shorter shelf life as compared to fresh intact produces. Use of edible coatings is gaining popularity now a days for packaging of fruits and vegetables but not much information is available regarding the use of gelatin based edible coatings on minimally processed apple cubes. The present research work discusses the effect of edible coatings made of gelatin, citric acid and glycerin. Two different concentrations of gelatin, 8% and 10% were used and their effect was seen on carrots against the control samples (carrot samples having no coating). The concentration of glycerin was 2% and ascorbic acid was 1% in both the coating solutions. Apples were cubed, coating was applied using the dipping method. The control and coated samples were stored in ambient conditions. Total polyphenol content, Percent loss in weight, color values, textural analysis antioxidant capacity of apple cubes were recorded for 5 days. Coatings were proved to be good only for retention of total polyphenols and textural properties. It negatively influenced weight loss percent and browning.

Key words: *freshly cut vegetables, carrots, biodegradable, edible packaging, circular economy.*

Introduction

It has been proven by numerous scientific studies that a good lifestyle and eating habits promote health. Due to the omnipresence of the internet, consumers can access all the information including health-related in a flash of a second. Thus, modern day consumer is much more aware, conscious and demanding. Moreover, the busy lifestyles, new habits, and demand for ready to eat food has resulted in growth of minimally processed fruit and vegetable market [1]. Minimally processed fruits and vegetables are more convenient, have fresh characteristics, and health benefits. Minimal processing can be any of these unit operations- washing, sorting, peeling, coring, slicing, etc. [2]. But in the process, the integrity of fruits and vegetables is altered because of the wounding [3]. Apple is a very popular fruit, consumed all over the world. Apples always remain in the top three produced fruits around the world. The worldwide production of apples in 2020 was 63.9 million tons (World Data Atlas) and is projected to be about 75.9 million tons in 2021 (USDA).

Edible films and coatings are made up of edible biopolymers and food grade additives. The biopolymers can be proteins, polysaccharides, lipids, or their mixture. Edible films are free standing structures and are applied to food after they are made but edible coatings are applied directly to the food stuff [4]. The use of edible coatings for a wide range of food products, including fresh and minimally processed fruit, has received increased interest. Gelatin is natural water-soluble protein obtained by partial hydrolysis of collagen which is found in bones, skins, connective tissues and tendons of vertebrates and invertebrates [5]. Gelatin has very good gelling, thickening and water binding capacity[6].
Not much research has been done to see the effect of gelatin coatings on minimally processed apples. Considering the above, the objective of present work was to develop edible coating based on gelatin, apply it to minimally processed apple cubes and evaluate shelf life of the product based on color, texture, percentage loss in weight, total polyphenol content antioxidant capacity for a period of 5 days at ambient storage conditions.

Materials and methods

Materials

Materials used were gelatin, citric acid, glycerin, apples. Apples were brought from local supermarket in Budapest.

Sample Preparation and Coating

The experiments were performed in the laboratory of Department of Fruit and Vegetable Processing Technology located at Budapest in the month of June. 4 kilogram good quality apples were brought. They were peeled using a hand peeler and cut into cubes using Robert Bosch (Gmbh) FD8904 machine and knife. After cubing they were washed thoroughly in potable running water and then dipped in 0.1% Citric acid for a few seconds. Afterwards, the apple cubes were divided in three different batches. No coating was applied to the first batch, it was called control. The other two were treated with 2 different coatings. For the first coating 8% gelatin was heated with distilled water for 5 minutes. After that, glycerin (2%) and citric acid (1%) were added. The solution was brought to about 35-37℃ temperature. Same method was used to make the second coating, but the concentration of gelatin was 10%. Coatings were applied using dipping method. Each apple cube was coated three times and then observations were taken daily for 5 days. Control and coated apple cubes were stored in ambient conditions.

Analytical methods

Percentage weight loss

Weight of the samples were measured on each day of analysis using a laboratory scale high precision digital A & D company, FX3000i weighing balance with accuracy of 0.01g. Weight loss was then determined and expressed as percentage weight loss using the following formulae:
Weight loss (%) = $(W_i-W_f)/W_i * 100$ [W_i-the initial weight, W_f -measured weight (g) of sample on day of analysis]

Color values

Color measurements were performed by CIE Lab Color Measuring System with Konica Minolta CR 410 manual digital color meter.

Texture Analysis

The texture analysis was performed using Brookfield LFRA Texture Analyser-6514933. A stainless-steel needle probe was used having 1.0 mm diameter and 46 mm length. The penetration depth was 4mm and speed of the probe was 1mm/s.

Total Polyphenolic Content
Total Polyphenol Content (TPC) was determined using the method of (Singleton and Rossi). The spectrometric measurements were carried out with Hitachi U-2900 equipment (Hitachi High-Technologies Europe GmbH, Krefeld, Germany).

Ferric Reducing Ability of Plasma (FRAP)
Antioxidant capacity was determined using Ferric Reducing Ability of Plasma (FRAP) assay using the method of [7] with slight modifications.

Statistical Analysis
All the experiments were done in triplicates/more than triplicates. There were two fixed factors, treatment (edible coating with different concentrations of gelatin) and storage time (number of days). Statistical evaluation was done using IBM SPSS V27 in 95% confidence interval.

Results and Discussion

Weight loss percentage
weight loss occurred in all the apple cubes. It is a natural phenomenon. When fruits and vegetables are exposed to environment, they lose weight [8]. The prime reason for weight loss could primarily be water evaporation facilitated by water vapor pressure gradient along with the loss of carbon (lost during formation of CO_2 during respiration) [9], [10]. Unexpectedly the weight loss % of control samples were less than the coated ones. The results for weight loss of apple cubes are assigned in Table 1.

Table 1. Effect of coating treatment and storage time (days) on weight loss% of the apple cubes. Values represent means of nine replicates and their corresponding standard deviations. Superscripts with small case letters indicate significant differences by time along the rows. Superscripts with the uppercase letters indicate significant differences by treatment along the columns. 8%G, and 10%G represent 8%, and 10% concentrations of the gelatin in the edible coatings. C represents the apple cubes without any coating or treatment.

weight loss% of apple cubes				
TREATMENT	Time (Days)			
	1	2	3	4
10%G	$59.51 \pm 3.32^{a,B}$	$82.63 \pm 9.04^{b,B}$	$86.64 \pm 0.55^{b,B}$	$86.66 \pm 0.59^{b,B}$

Color values
L*, a*, b* color values

Results for the L* color values are expressed in Table 2. Declining trend was seen throughout the storage. Control samples had highest L* values. Coated samples showed higher a* color values compared to control ones. The control samples showed comparatively higher values than the coated samples during the analysis period.

Texture analysis

Hardness, Gumminess, Chewiness

The hardness of coated samples was found to be more than control samples. Treatment had no significant effect on gumminess and chewiness of the apple cubes during the storage period in our study.

Table 3. Effect of coating treatment and storage time (days) on hardness of the apple cubes.

hardness of apple cubes				
TREATMENT	Time (Days)			
	1	2	3	4
10%G	37.89 ± 9.33a,A	97.11 ± 26.27 b,B	114.61 ± 25.37 b,c,B	145.89 ± 59.82 b,A

Conclusion

Results show that the samples coated with new edible coatings performed better in terms of retention of Total Polyphenols. The positive effect of coatings was seen on texture analysis. Based on the results, it can be suggested that the application of coatings made of gelatin, citric acid and glycerin are not good for reducing the water loss percentage of apples. The coatings were not able to retard the browning. The coated samples had more browning than control ones. The FRAP values were affected only by time not by the effect of treatment.

Abstract

The use of agricultural products and their wastes as in the production of edible coatings and films has been developed in recent years. In this study, optimization of the edible coating production was carried out using response surface methodology (RSM) and optimal custom design with 20 treatments. Different levels of acetylated potato starch (APS) (3, 5, and 7 gr), rice bran oil (RBO) (0, 0.5, 1, 1.5, and 2 gr), and ultra-thorax rate (homogenization) (0.35×10^{-3}, 1.53×10^{-3} and 3.51×10^{-3} g) were used. Factors such as weight loss, stability, and *aw*, as the responses of experimental design were considered for investigation. Emulsion gel consisting of 6.57 gr of the acetylated potato starch and 2 gr of the rice bran oil produced at 0.35×10^{-3} g homogenization rate was selected as the best combination of edible coating. The effect of the emulsion gel based on acetylated potato starch, rice bran oil was studied on some of the grape's chemicals (TA, TSS, pH, weight loss, and spoilage percentage) and sensory properties. Consisted Edible coating of the rice bran oil and acetylated potato starch increased acidity and brightness, but reduced pH and TSS during storage.

Keywords: *Edible coating, Rice bran oil, Acetylated potato starch, Grape*

Introduction

Fruits are suitable environments for microbial growth due to the high content of sugars and other nutrients as well as high humidity (Tournas and Katsoudas, 2005). "Grape" (it was scientifically named *Vitis vinifera*) has been considered as an important fruit among its producing countries. Its preservation is difficult due to its perishable nature. Post-harvest fungal contamination causes a lot of waste of the grape. Therefore, manufacturers seek alternative approaches to maintain the quality of the grape. In the past, to increasing the shelf life of this product was being mainly used sulfur dioxide (Smilanick et al., 1990; Mustonen, 1992; Karabulut et al., 2003).
The edible coating is a thin layer of materials (mostly Biopolymers) that extend the shelf life of foods by protecting them against the transport of gases, water vapor, soluble solids, and mechanical damages (Baldwin, 2006). Various materials including hydrocolloids (polysaccharides and proteins), lipids (fatty acids, glycerides, and waxes) have been used to produce the edible coatings (Mariniello et al., 2003). Starch is one of the most important polysaccharides that has made good films. The starch-based films often are transparent or semi-transparent without odor, taste, and color. Potato starch produces gels with high viscosity due to its high phosphorus content (Rajabian, 2018). "Acetylated starch" reduces gelatinization temperature and increases transparency, viscosity, and freezing stability of the gel (Luallen, 1985; Rogals, 1986; Luallen, 1988; Schierbaum and Kettliz, 1994). Previous studies indicated the effectiveness of starch-based coatings on storage life and control the decay of the red grape and strawberry fruits (Maria et al., 1998; Farayde et al., 2015). Adding lipids to hydrocolloid compounds has improved their moisture-barrier properties due to the hydrophobic properties of lipids (Debeaufort et al., 2002). "Bran" is the by-product of rice processing (Grist, 1985). Its oil

increases the shelf life of fruits by reducing weight loss, transpiration, and respiration which are major agents of their spoilage in the refrigerator (Sala et al., 2009).
In this study, optimization was performed on the production of edible coating based on rice bran oil (RBO) and acetylated potato starch (APS) at different homogenization rates. Then, the effects of the produced coating on some quality characteristics of grape were investigated.

Materials and Methods

Grape (Asgari cultivar) was obtained from Kashmar (Khorasan Razavi) with characteristics such as much sweet taste and high storage capacity. The berries were uniform in size and color (light-green). Clusters were washed with brine and dried at ambient temperature for 2 hours just before the experiments. Then, the clusters which were free from any disease, insect, injury, or machine damage were selected for further study.
Acetylated potato starch- produced under the protection of Denmark- was purchased from Arsha Pouyeh Company (Tehran-Iran). Edible refined rice bran oil was prepared by Saman Oil Company (Khorasan Razavi-Mashhad) with a purity of 99.99 %.
Response surface method and optimal custom design were used for the optimization of 20 treatments and two repetitions under three independent variables including acetylated potato starch at three levels (3, 5, and 7 gr), rice bran oil at five Levels (0, 0.5, 1, 1.5 and 2 gr) and homogenization rate at three levels (0.35×10^{-3}, 1.53×10^{-3} and 3.51×10^{-3} g) (g is relative centrifugal force or RCF). Weight loss of coated grapes (percentage), the stability (percentage), and a_w of emulsion gels (percentage) parameters were considered as test responses to investigate the effect of different levels of treatments on them. The weight loss of 20 treatments belonging to the optimization stage was also calculated as a percentage with three repetitions every two weeks. The edible coating was prepared by continuous mixing a certain amount of acetylated potato starch in 100 ml of distilled water through gelatinization of starch into a hot water bath at 90 °C for 5 min (Riku, 2007). After cooling (for 30 min), the resulting gel was homogenized by adding a certain amount of rice bran oil (gr) and 2 % Tween 80 as emulsifier under a certain rate of Ultraturex (rpm) for 5 min (T25 digital, Made in Germany) (Shaw, 2002).
To measure the stability of emulsion gels, a certain amount of every sample was poured into a falcon and centrifuged for 30 min under 1999.52 g at ambient temperature (D72- Made in Germany). The separated phase was removed from the container by reversing the falcon on filter paper. The stability was calculated as a percentage based on the ratio of the secondary weight of the falcon containing emulsion gel to its initial weight (Baliga & Madaiah, 1970).
To determine a_w of gels was used a water activity meter (HYGROLAB-3, Made in Swiss). Thus, a certain weight of every coating sample was poured into a device (at the temperature of 20 °C). After establishing equilibrium, the amount of water activity was calculated based on the ratio of equilibrium respective humidity to 100 (Iranian National standard, 1992).
Coated treatments were weighed by digital Scale with the accuracy of 0.001 ± 1 gr (Ouauz GT 2100, Made in the USA) before and after storage in the refrigerator. Their weight loss was reported as a percentage through the ratio of the difference between the initial weight of the cluster and its initial weight (Parvaneh, 1986). To determine the total soluble solid (TSS) of the samples, a Refractometer (PAL-3, Made in the USA) was used at three repetitions (Hassani et al., 2010). The titratable acidity (TA) was measured using 5 ml of grape juice filtered in 95 ml of distilled water, 0.1 N NaOH, and Plenolphthalein reagent to an end-point of pH 8.1 at three repetitions (Shirin & Asgar, 2014). Grape extracted juice pH value was measured by a pH meter

at three repetitions (CP-744, Made in England) (Abdollahi, 2008). The CIE Laboratory color scale was used to determine the parameters L* (Black to White), a* (Red to Green), and b* (Yellow to Blue). All measurements were performed at three repetitions (Ebrahimi et al., 2018). The coated grapes were judged by 7 panelists to evaluate the sensory characteristics and general acceptance (in the terms of odor, color, flavor, appearance, texture, and overall acceptability) every two weeks. To study the mentioned parameters, the 5-point Hedonic ranking method was used. The scores 5 and 1 were considered for a very good and bad attributes, respectively.
Design-Expert software (10.0.3.0-x64-Softcozar.com.msi) in the form of optimal custom design with 20 treatments, 3 measured variables, and 3 responses were used to evaluate the results and determine the optimal conditions for the production of edible coating based on acetylated potato starch and rice bran oil. On the other hand, SPSS version22 software was used for statistical analysis. Duncan's multiple range tests (DMRT) with the maximum acceptable error of 5% were used to measure significant differences between samples, analysis of variance (ANOVA).

Results and Discussions

The Results of Optimization

As it can be seen from figure 1, weight loss decreased and then increased with increasing the concentration of APS. This difference in result can be due to the inherent moisture loss of the fruit during storage, its weight was reduced. In the following, the environment slowed down the process of weight loss of grape by keeping fruit moisture; it even increased the weight of samples. Also, an increase in the concentration of RBO had a significantly effect on the weight loss so that the lowest percentage of weight loss was observed in the high concentrations of both the independent variables. Therefore, rice bran oil has been able to prohibit moisture loss of grape during storage by preventing the transmission of its.

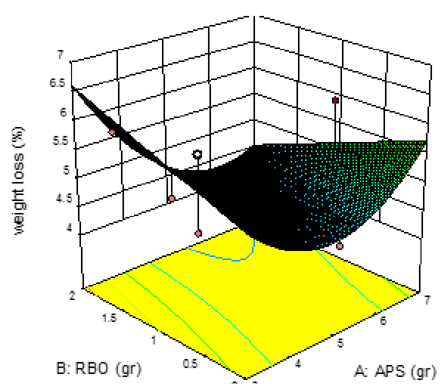

Fig.1. The effect of different levels of Acetylated Potato Starch and Rice Bran Oil on the weight loss of the clusters.

According to figure 2, the stability went through an upward trend with increasing the concentration of APS. The highest stability obtained at the highest level of acetylated potato starch. But none of the values of RBO and homogenization rate had any effect on the stability of emulsion gel. The reason for this case could be the more and better strength of gel due to filling the maximum of empty spaces between two continuous and diffused phases. Also, uniform and more mixing the components of the coating increased its stability the gelling agent (acetylated potato starch) was the effective parameter of this flow.

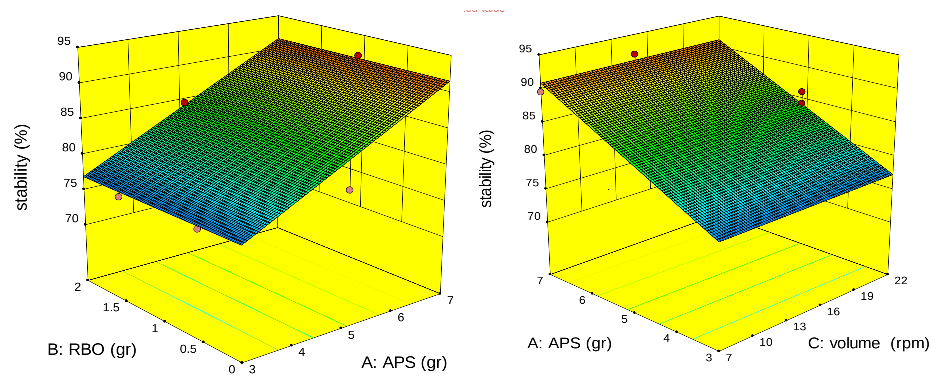

Fig. 2. The effect of different levels of Acetylated Potato Starch, Rice Bran Oil, and the rate of homogenization on the stability of the emulsion gel.

Figure 3 shows clearly the effect of different levels of acetylated potato starch, rice bran oil, and stirring speed on water activity. Increasing the concentration of both acetylated potato starch and rice bran oil had a very significant effect on the changes in water activity parameter. The effect was impressive to some extent that the highest and lowest a_w were obtained at the minimum (0 gr) and maximum (3 gr) of RBO, respectively. But in the case of APS, results were significantly opposite obtained; thus, the water activity of emulsion gel increased with the use of the high levels of starch. Also, the different levels of X_3 did not affect the water activity of the gel. Consequently, it can be concluded that a desirable water content (less than 0.8 %) is going to create for the emulsion gel by increasing the level of consumption of rice bran oil as a plasticizer in the composition of the edible coating.

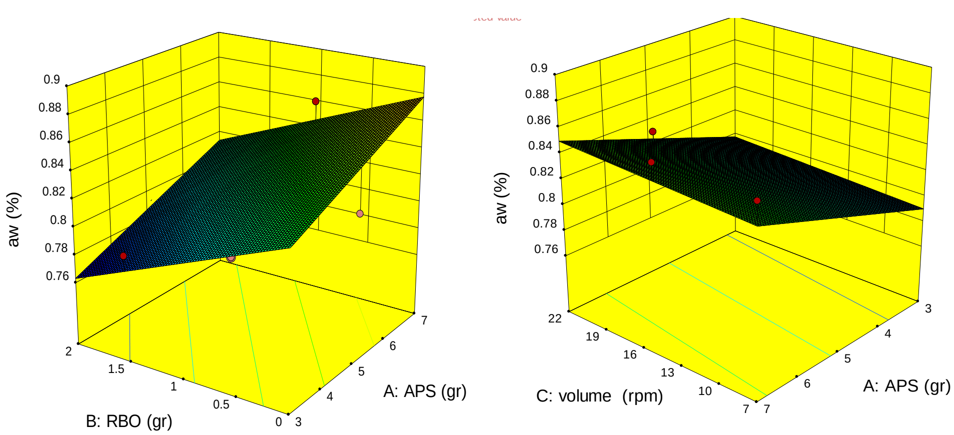

Fig. 3. The effect of different levels of Acetylated Potato Starch, Rice Bran Oil, and the rate of homogenization on the amount of aw emulsion gel.

The results obtained from the effect of emulsion gels were produced (20 samples of edible coating) on the design responses (weight loss, stability, and a_w) is inserted in Table 1.

Observations	APS (gr)	RBO (gr)	Homogenize speed (g)	Weight loss %	Stability %	a_w %
1	7	1	10^{-3} 1.53 ×	5.44	88.6	**0.8**
2	7	2	10^{-3} 3.51×	4.94	93.6	**0.81**
3	7	0	10^{-3} 3.51×	18.21	76.75	**0.84**
4	7	1	10^{-3} 1.53 ×	5.9	91.94	**0.86**
5	7	0	10^{-3} 0.35 ×	6.17	91.46	**0.9**
6	7	2	10^{-3} 0.35 ×	6.83	66.52	**0.77**
7	7	0	10^{-3} 3.51×	5.67	74.29	**0.83**
8	7	0.5	10^{-3} 0.35 ×	5.11	72.25	**0.81**
9	3	0	10^{-3} 0.35 ×	5.17	80.26	**0.82**
10	3	2	10^{-3} 3.51×	2.47	78.73	**0.78**
11	7	0	10^{-3} 3.51×	5.11	91.85	**0.89**
12	7	1	10^{-3} 0.35 ×	4.5	89.61	**0.86**
13	3	1.5	10^{-3} 1.53 ×	6.1	76.26	**0.79**
14	3	0.5	10^{-3} 1.53 ×	6.3	69.52	**0.81**
15	5	1	10^{-3} 3.51×	4.3	86.15	**0.83**
16	3	0.5	10^{-3} 1.53 ×	5.046	76.56	**0.81**
17	5	2	10^{-3} 1.53 ×	4.054	84.54	**0.78**
18	5	0	10^{-3} 1.53 ×	4.52	80.21	**0.82**
19	7	2	10^{-3} 0.35 ×	2.44	90.69	**0.79**
20	5	1	10^{-3} 3.51×	4.2	84.34	**0.80**

Therefore, it can be predicted that using 2 gr rice bran oil, 6.57 gr acetylated potato starch and 0.35×10^{-3} g homogenization rate led to the formation of optimal emulsion gel with the most stability (90.075%), the least a_w (0.80%), and weight loss (4.403%) (Table1)

The results of Chemical parameters

A significant percentage of soluble solids in fruits contains sugars and a small portion of them, amino acids, organic acids, vitamins, and minerals. The amount of soluble solids increases with fruit ripening (Hassani et al., 2010).

Figure 4 shows (effect of different levels of APS, RBO, and Volume on the TSS parameter in the second week of storage), on the second week of storage, the highest TSS was obtained at the maximum oil concentration, 2 gr. Also, with increasing homogenization rate (Volume) and APS, this parameter decreased with a slight slope. Its maximum value was observed in 3 gr of starch. An increase in the soluble solids during storage occurs due to decrease product moisture and the decomposition of compound sugars into simple sugars. At the end of storage, by increasing starch levels, TSS decreased with a large slope; but, the effect of the RBO parameter did not change. During this period, the homogenization rate factor showed an inverse effect so that the maximum soluble solid was obtained at 3.51×10^{-3} g (Figure 5). These results were consistent with reports of kiwi fruit, Ghezel Ozum grape, and fresh strawberries (Hassani et al., 2010; Asghari & Ahadi, 2012; Emamifar, 2014). This difference in Brix changes in the two storage periods can be attributed to the moisture changes in grape.

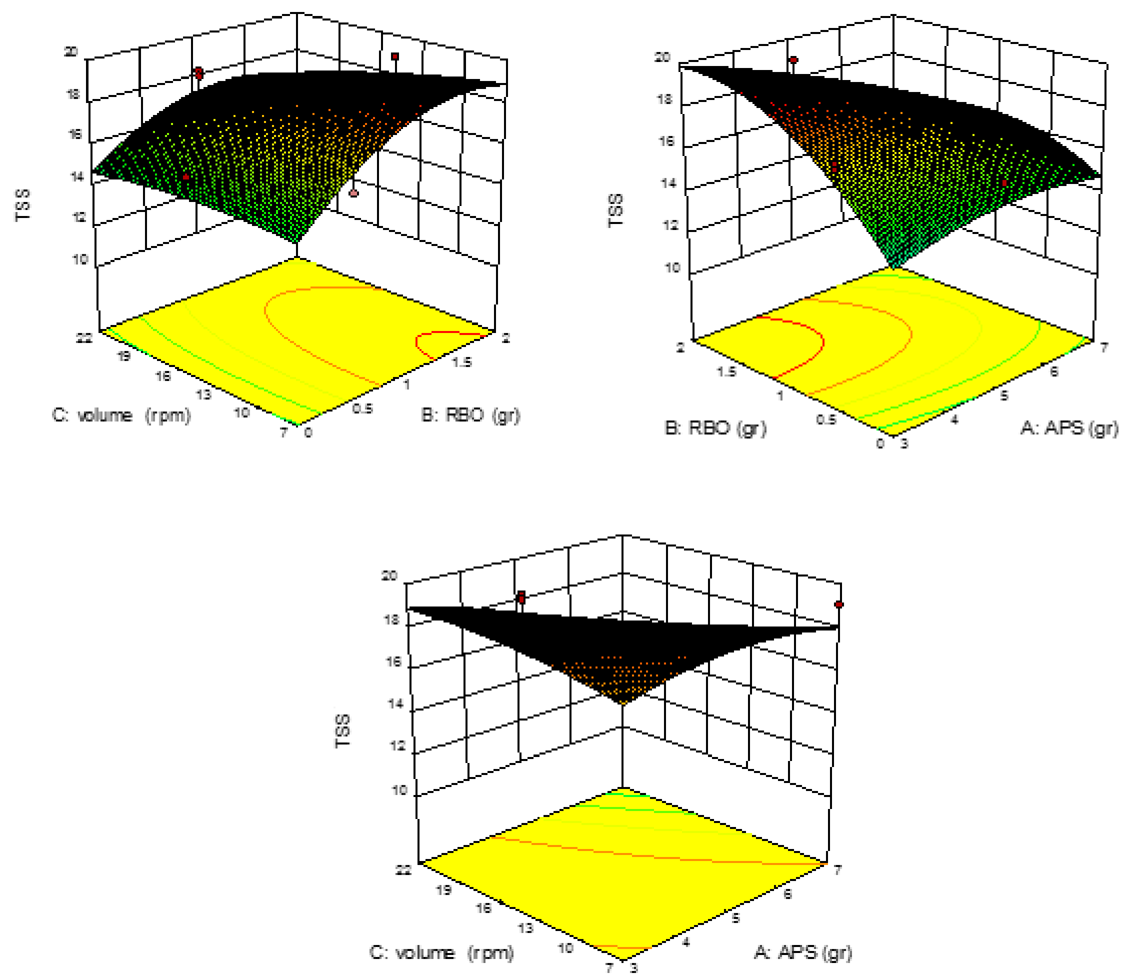

Fig. 4. The effect of different levels of APS, RBO, and Volume on the TSS parameter in the second week of preservation.

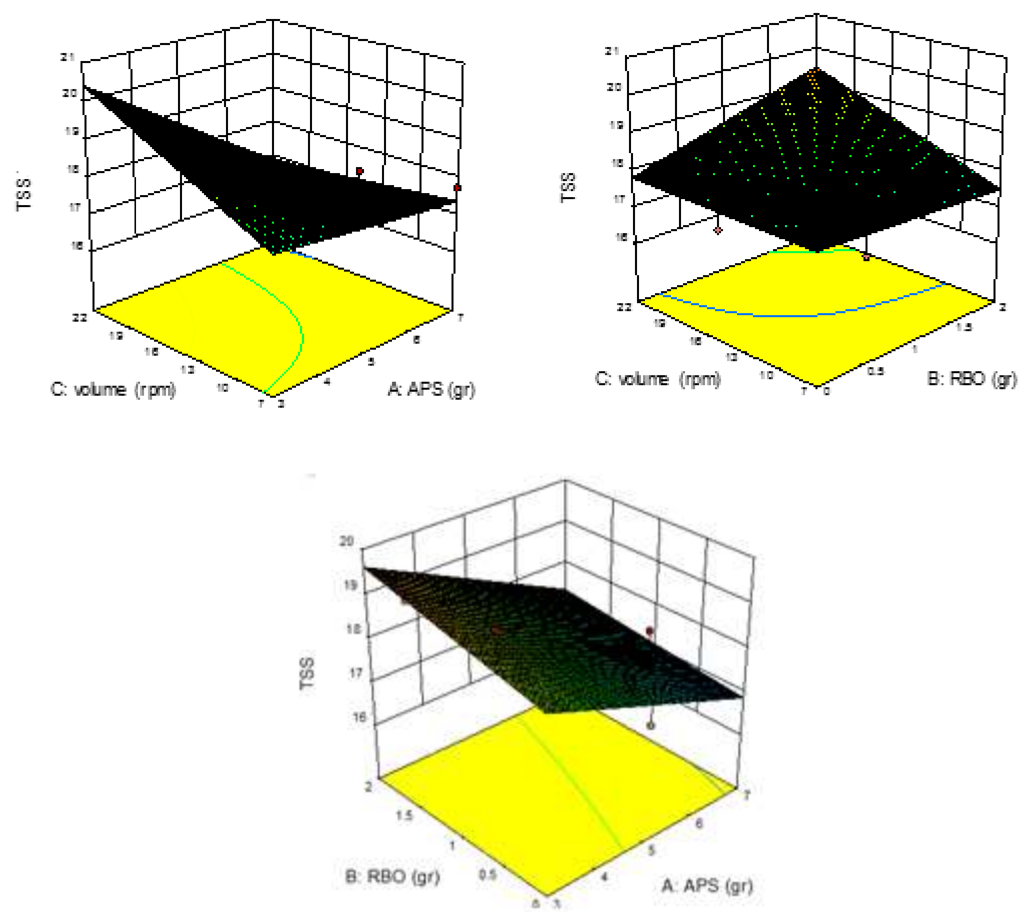

Fig. 5. The effect of different levels of APS, RBO, and Volume on the TSS parameter in the Fourth week of preservation.

The amount of titratable acids (TA) depends on the ripeness of the fruit, so that when ripe, the amount of organic acids, and the sour taste in the product decrease. The amount of these acids in the harvest period depends on the content of soluble solids and the rate of decomposition of acids (Hassani et al., 2010).

Figure 6 shows that with increasing starch concentration and rate of homogenization, acidity decreased and the highest amount of TA obtained at the lowest levels of these two variables, 3 gr and 0.35×10^{-3} g. But in the fourth week of storage, different results obtained so that with increasing APS and volume, there was an upward trend in acidity (Figure 7).

A decrease in the acidity occurs due to the decomposition of organic acids during the refrigeration period following a drop in humidity and increases the soluble sugar content of the fruit. This reason justifies the reduction in acidity in the first period of storage. In the last two weeks, due to rehydration of the sample from the environment, fruit TSS decreased during this period and the acidity of the product increased. These results are consistent with the reports of researchers to increase the shelf life of fruits such as kiwi, peach, and apricot. They stated that organic acids decrease as they mature and increase metabolic activity within the crop; however, edible coatings maintain the more and better titratable acidity by reducing the rate of fruit respiration, (Hassani et al., 2010; Galvis-Sanchez et al., 2003; Gerossi et al., 2009).

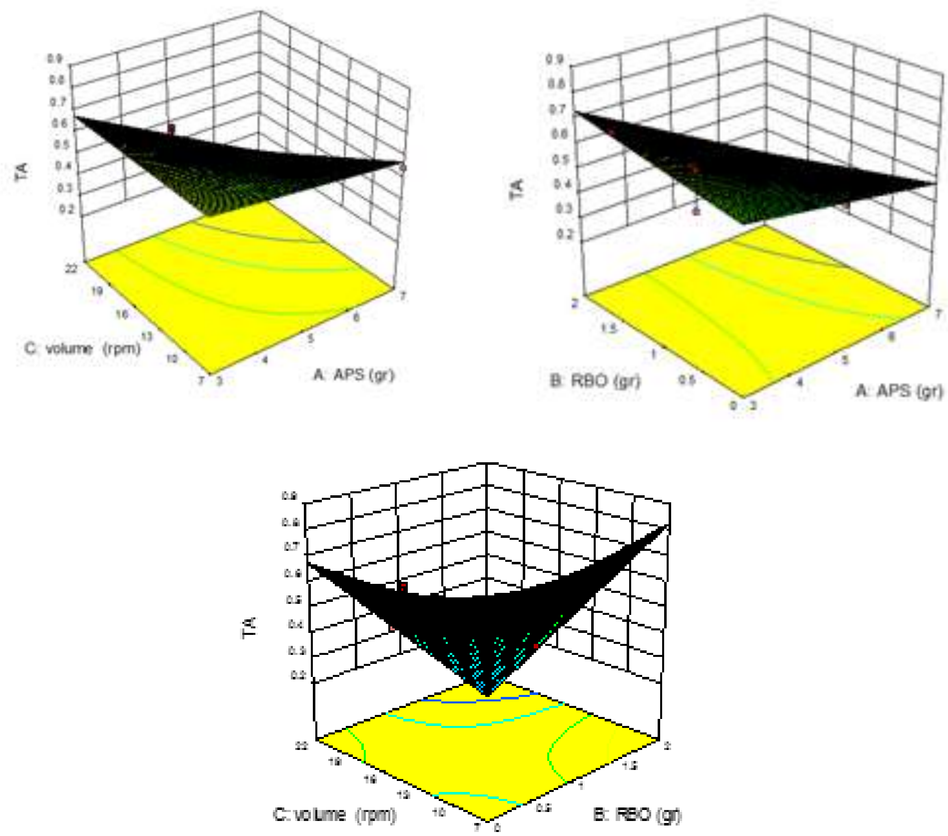

Fig. 6. The effect of different levels of APS, RBO, and Volume on the TA parameter in the Second week of preservation.

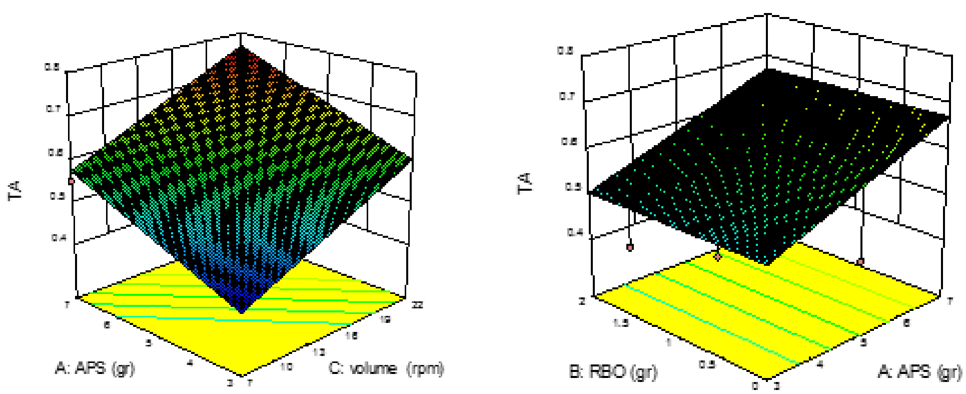

Fig. 7. The effect of different levels of APS, RBO, and Volume on the TA parameter in the Fourth week of preservation.

The pH increased and decreased by increasing APS and RBO, respectively. But the rate of homogenization did not affect this parameter (Figure 8). This increase in pH is due to the increase in sugar content and decrease in grape acidity. In the fourth week of storage of samples, the highest pH level was evaluated at the highest level of bran oil consumption, 2 gr; because it preserves as much moisture as possible and consequently prevents the decrease of acidity and increase of fruit sugar. In contrast, the maximum amount of this parameter was calculated in 3 gr of starch (minimum concentration) (Figure 9). The above discussion is consistent with the results obtained from studies on the use of edible coatings for peach and grape products (Ochoa-Velasco et al., 2014; Asghari & Ahadi, 2012).

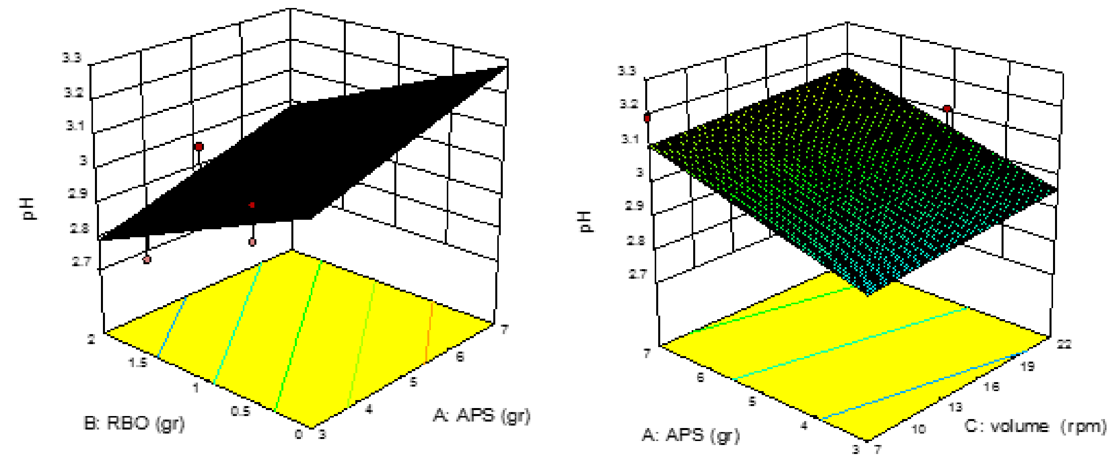

Fig. 8. The effect of different levels of APS, RBO, and Volume on the pH parameter in the Second week of preservation.

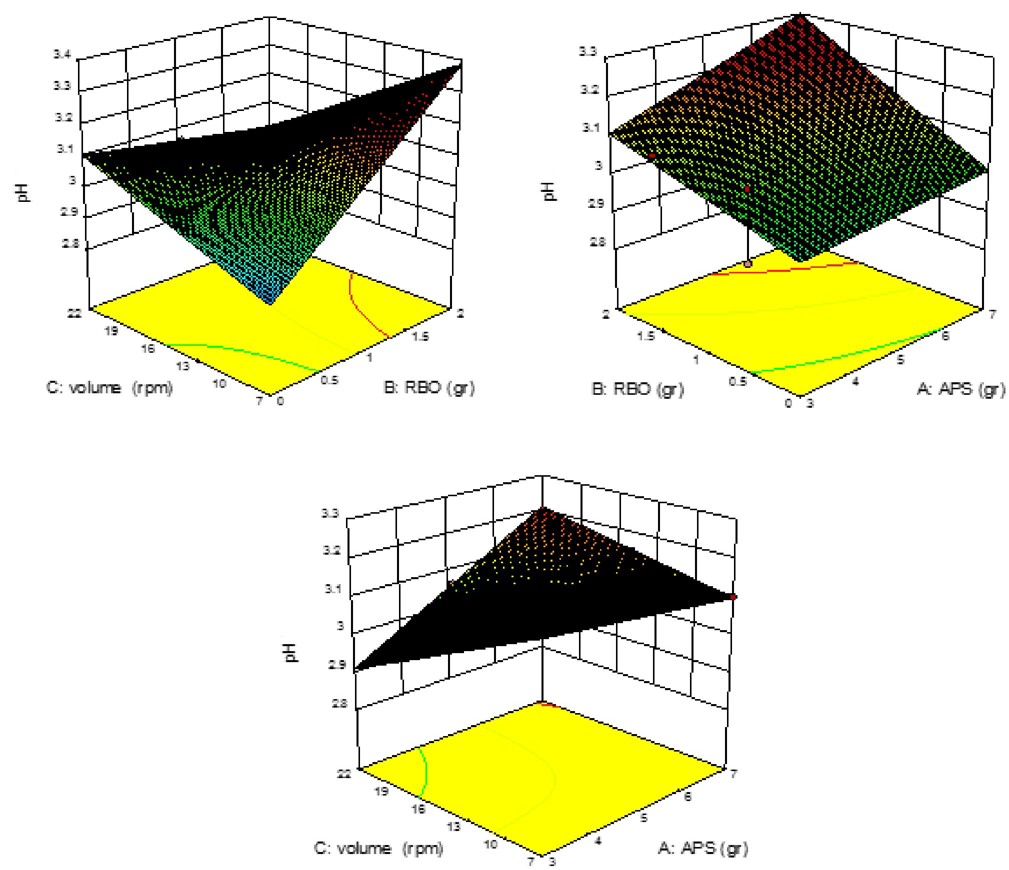

Fig. 9. The effect of different levels of APS, RBO, and Volume on the pH parameter in the Fourth week of preservation.

According to Figure 10, with increasing starch level, the amount of green color increased and with increasing oil concentration, the parameter a* of gel decreased. On the other hand, the X1X2 interaction reduced the vegetables in the edible coating.
With increasing X1, X2, and X1X2, the amount of blue decreased and yellowing increased, but with increasing the rate of homogenization, the color of the gel tended to blue (Figure 11).
From Figure 12 it can be concluded that the coatings containing the highest level of starch and oil consumption provided the most transparency. The luminosity of the coated clusters depends on the phosphate monoesters present in the potato starch structure, the amount of which is very high in this plant source. High results are according to Basiak et al. (2013) and Semigen et al (2018).

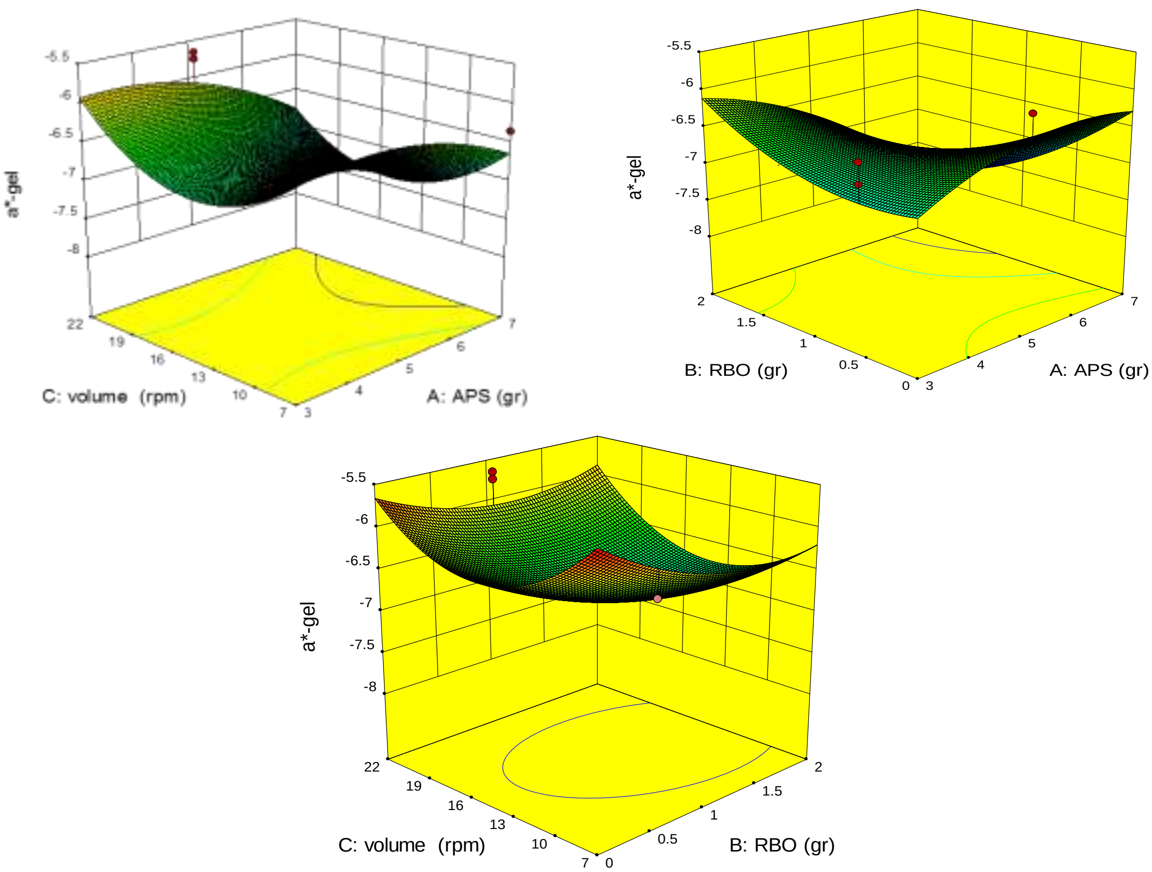

Fig. 10. Effect of different levels of Acetylated Potato Starch, Rice Bran Oil, and Ultratorex speed on the color parameter a* of Gel.

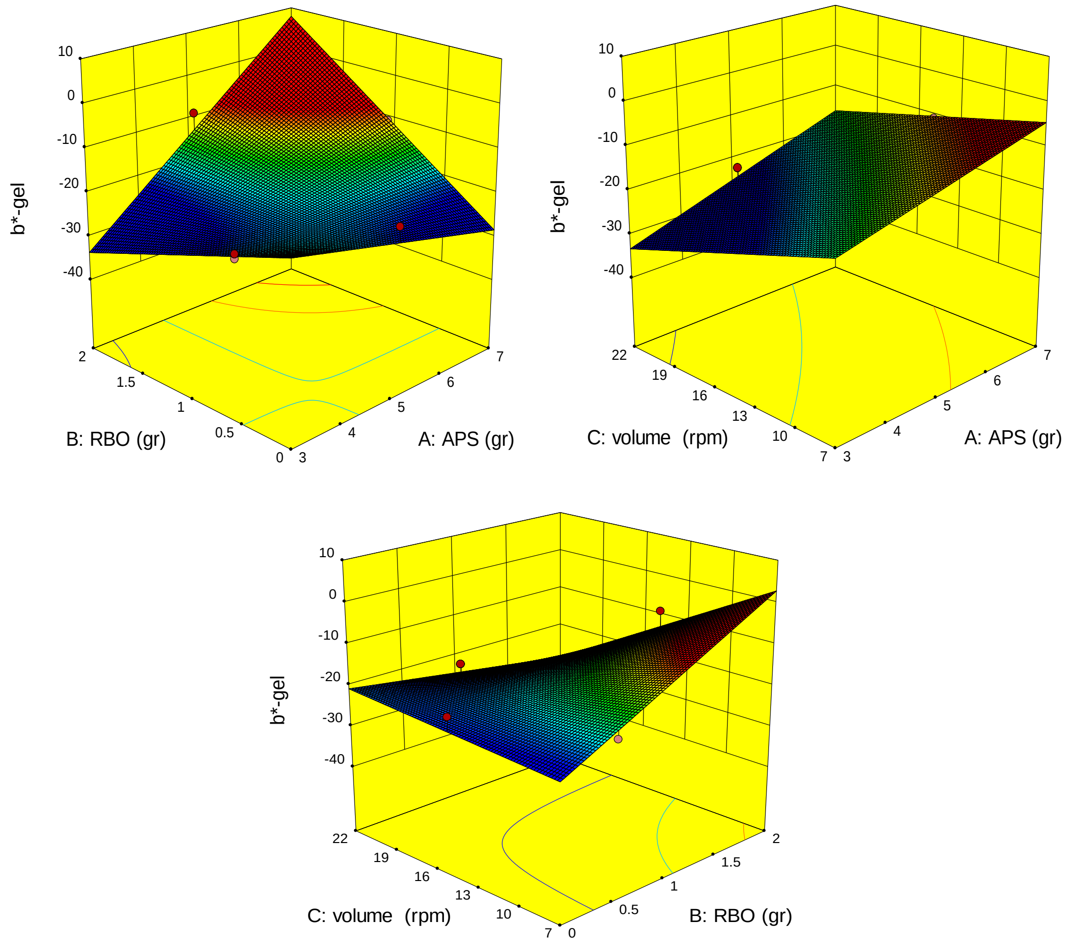

Fig. 11. Effect of different levels of Acetylated Potato Starch, Rice Bran Oil, and Ultratorex speed on the color parameter b* of Gel.

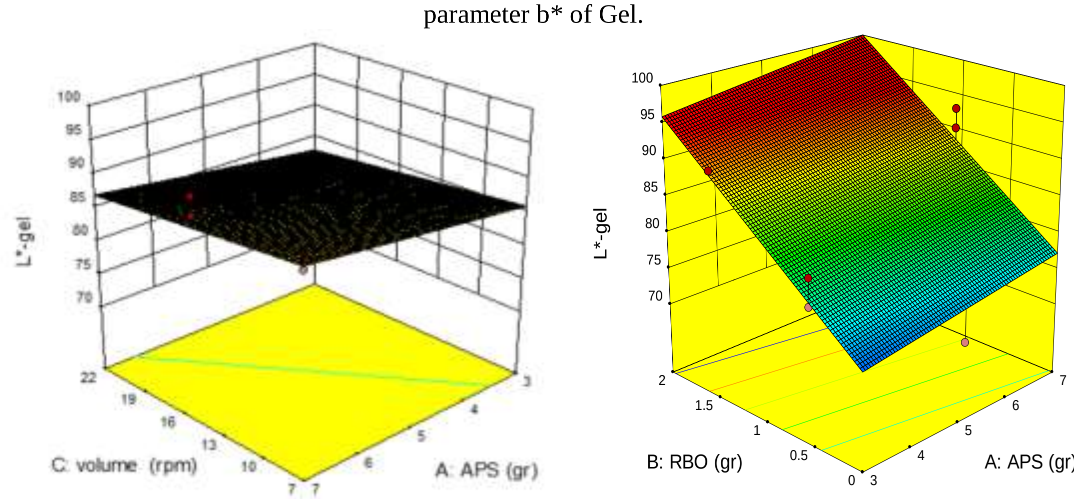

Fig. 12. Effect of different levels of Acetylated Potato Starch, Rice Bran Oil, and Ultratorex speed on the color parameter L* of Gel.

The enzymatic browning is one of the effective factors in changing the color of fruits and vegetables during storage. On the other hand, edible coatings, by reducing the contact of oxygen with the tissue of products, prevent or delay the progression of this reaction (Akbarian, 2012).
Potato starch concentration factor had the greatest effect on the amount of a*. As you can see, with increasing the concentration of starch in the edible coating, the amount of grape' a* decreases with a sharp slope (Figure 13).
According to Figure 14, as the amount of variables X1 and X3 increased, the yellowness of the grape clusters underwent a decreasing trend, which was steeper for starch. As the amount of starch consumed and the rate of homogenization in the edible coating increased, the luminosity of the coated samples during 28 days of storage followed an increasing path (Figure 15).

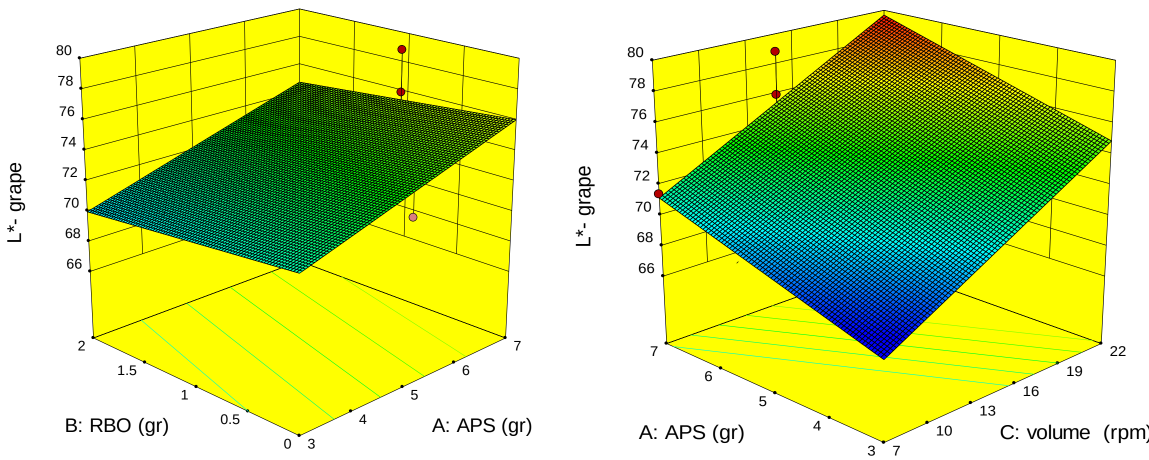

Fig. 15. Effect of different levels of Acetylated Potato Starch, Rice Bran Oil, and Ultratorex speed on the color parameter L* of grape.

Results of Sensory Test

In the first two weeks, no significant difference in flavor was observed between the control and coated samples. In the last two weeks of storage, there was a significant difference between all treatments, and the control cluster had an unfavorable taste along with samples 18 and 5. Also, the best taste belonged to the clusters with a small amount of starch and oil.

In terms of appearance, in the first 14 days of storage, there was no significant difference between the coated and uncoated clusters. Low homogenization rate due to the production of porosity and the prevention of bubbles that make the appearance of the gel unpleasant, as well as emulsion gel with a low amount of starch, which causes less thickness on the grape clusters and faster absorption by the shell.

At the end of refrigeration period, a very significant difference was seen between all treatments in terms of appearance, and samples 16 and 4 were selected by the evaluators as the most desirable and worst clusters in terms of shape, respectively.

The best fruit texture was attributed to samples 13 and 16 (lower starch content and medium oil) and the worst to samples 2 and 5 (highest starch concentration). But no significant difference was observed between control and coated clusters in the first two weeks of maintenance.

But in the last two weeks, there was a very significant difference between the control sample tissue and the coated samples. In terms of texture, the samples of 16 and 13 were determined as the best and the worst treatments, respectively. The results indicate that the use of starch with lower concentration and oil with a medium level in the composition of the coating reduces the moisture loss and consequently the optimal preservation of fruit texture during storage.

There was no significant difference between control and coated clusters in terms of overall acceptance in the first two weeks of storage. Sample 7 had the highest and treatments 2 and 12 had the lowest overall acceptance percentage from the evaluators' point of view. After 28 days of storage, samples containing less starch and oil with moderate concentration were more desirable than the control cluster and other coating compounds for the evaluators.

All the sensory parameters in question, through the edible coating, were able to induce a favorable feeling to the consumer when eating fruit. As for the flavor parameter, the evaluators felt better taste than other treatments only when consuming samples containing less oil and starch.

Table 2. The effect of edible coating on the sensory parameters of grape clusters.

Sensory parameters	Color		Odor		Flavor		Appearance		Sensory Texture		Overall Acceptance	
	Time (day)		Time (day)		Time (day)		Time (day)		Time (day)		Time (day)

Conclusion

Edible coatings due to the use of biodegradable, recyclable, and edible in their production have become a useful alternative to synthetic films and coatings. Using the combination of 2 gr rice bran oil, 6.57 gr acetylated potato starch, and stirring speed of 0.35×10^{-3} g was selected as the best treatment because it was led to the coating with the highest stability and the least a_w and weight loss. Moreover, it improved the chemical properties of grapes by reducing oxygen transfer and controlling moisture diffusion. Also, it increased the shelf life (more than 2 weeks) and the marketability of grape samples. It was also showed that the employment of the edible coating based on the APS and RBO increased the brightness as well as the acidity of the grape cluster while their pH and TSS were decreased during four-week storage. Moreover, the coated Samples with higher levels of Oil and less Starch scored higher in terms of all sensory parameters except taste and were more desirable from the point of view of evaluators.

RADIATION LEVELS IN SAMPLES OF DICALCIUM PHOSPHATE (DCP) WITH A GAMMA SPECTROMETRY METHOD

Abstract

Radioactive contamination of living organisms and body tissues primarily depends on the level of contamination of the food they consume, and to a lesser extent on drinking water and inhalation. The aim of this study was to determine the level of radioactivity present in dicalcium phosphate (DCP) samples used as a feed additive. DCP is used as a major source of phosphorus and calcium because it strengthens the skeleton and accelerates the growth of the animal. It is therefore important to familiarize yourself with these levels as part of this radioactivity is likely to be transmitted to humans through the food chain. Measurements were made in order to determine the risks that those quantities may bring. Radioactivity levels are measured using a standard spectroscopic system with a high-resolution HPGe detector. The mean values for the measured activities in the DCP samples were 5.27Bq.kg-1 for 226Ra, 2.87 Bq.kg-1 for 228Th. The mean value measured for 40K was 22.26 Bq.kg-1, respectively. From the results obtained for DCP, it can be seen that the activity of 226Ra is significantly lower than the activity of 228Th, while the value measured for 40K in the samples does not pose a risk to human health, even to animals, because potassium is an essential mineral for living organisms. Considering that the radioactive contamination of the tissues of the animal body originates primarily from the level of contamination of the used animal feed, as well as from the water used for irrigation of the animals, a preventive measure is to control the radioactivity of the feed in their use, i.e. the concentration of radioactive isotopes should be as low as possible, ensuring that they do not pose a threat to the animal organism.

Key words: *DCP, gamma spectrometry, feeds.*

Introduction

Minerals are unavoidable elements in daily animal nutrition, which should be offered in quantities by following animal's requirements. In the same time, the fact that minerals e.g. phosphorus play an important part in environmental contamination should be taken into consideration. Therefore, animal nutritionist should balance animal's daily diet by using high quality phosphorus and in the same time by limiting the excess amount of phosphorus into the environment.
There is a significant need for radiological analysis in the environment, i.e. the soil, food for humans and animal feed. For radioecology, the study of the migration of radionuclides in the soil as a basic resource in agricultural production is of particular interest. In most cases the radionuclides in the soil are tightly bound, however the root of the plant can still absorb them.

Since the first discovery of radioactivity, there has been concern about the damage it can cause to humans, living things and the environment. Many studies have been devoted to monitoring the amount of activity of radionuclides in food and dietary supplements, especially those related to human nutrition, in order to determine the risks that those amounts may bring (Tchokossa et. Al., 2013; Zagato et al., 2007).
The process of artificial fertilizer production distributes radionuclides into the environment and in the same time incorporates them into final products and intermediate products (Saueia et al., 2005). The phosphate rock that is usually used for phosphate fertilizer production, contains natural radionuclides from U and Th series (Mazzilli et al., 2000). Phosphoric acid is a starter material for production of: triple superphophate, simple mono superphosphate, monoamonia phosphate and diamonia phosphate, Nitrogen-Phosphorus-Potassium fertilizer and dicalcium phosphate.
Phosphate-based products, such as dicalcium phosphate (DCP) and monocalcium phosphate (MCP) contain approximately 20% phosphorus, and for this reason they are important in the modern production of live raw materials. These compounds are most commonly used in the diet of cattle, pigs and poultry (Arruda et al., 1997), as well as as a dietary supplement in humans. Normally, animal feed is developed on an organic basis and is intended to provide the most complete nutrition possible. In order to increase the nutritional value, elements that can actually increase the amount of radionuclide activity in animal feed are increasingly added, which was discussed by Arruda et al., (1997). It should be noted that phosphorus is one of the elements often added to food, as it is one of the most important minerals for living organisms, including humans. It is an essential element for all living cells and a key element for the cellular energy transportation (Roessler, 1990). It affects several important biological processes, such as osmotic pressure and all metabolic reactions (Casacuberta et al., 2007).
In this study, radioactivity was measured in a representative number of DCP samples, wherewith specific activities of certain natural radionuclides were calculated, compared with other studies and calculated doses.

Materials and Methods

Sampling
The samples were placed in 0.5 l Marinelli beakers which were fully filled, sealed and stored in order to establish a balance between ^{226}Ra and ^{222}Rn before the measurements are performed. (6) Eighteen samples of DCP were analyzed, which were being used as a feed additive. The measurements were performed at intervals and the background spectrum of the acquisition system is checked on a weekly basis. The process of homogenization of these samples was performed according to the international standard protocol to ensure homogeneity. All studied samples of animal feed were from different farms in the Republic of Macedonia.

Instrument
The samples were measured on an instrument-gamma spectrometer (Canbera Packard) with a high purity germanium detector. The measurement was carried out in beakers that were hermetically sealed so that ^{222}Rn produced by the decomposition of ^{226}Ra would not result in gas leakage. After ensuring a time balance between the successors of the ^{238}U and ^{232}Th series, these sealed samples were prepared for analysis. GENIE 2000 software was used for data acquisition and analysis. The specific activity of ^{226}Ra is calculated for the energy line of 186.1 (keV) and

^{232}Th through its decay descendant ^{228}Ac (second in the decay chain), i.e. through its three gamma decay energy lines which occur at 338.4; 911.07 and 968.9 (keV).
The activities of ^{40}K were determined from its γ-line of 1460 keV, while the activities of ^{137}Cs were determined by means of an estimation of the γ-line at 661.66 (keV). The time interval for calculation (counting) was 108000 seconds.

Activity calculation
The specific activity (A) is determined according the equation

$$A = \frac{\frac{N}{t} - \frac{N_0}{t_0}}{\varepsilon \cdot \gamma \cdot m} \quad (\mathrm{Bq \cdot kg^{-1}})$$

Where, N is clean surface of peak accumulated from a specific radionuclide in analysis of a specific sample (number of readings), N_0 is clean surface of peak accumulated from the spot of a specific radionuclide without an analysis of sample (number of readings), t is live time of accumulation of the sample spectrum (s), t_0 is live time of accumulation of the phone spectrum (s), ε is detector efficiency for a given energy (for a specific peak), γ is intensity of gamma transition in radioactive decay for a respective radionuclide (%), and m is sample mass (kg) (Garcia-Talaver, 2007).

Radium equivalent activity Ra_{eq}
The calculation of the radium equivalent activity (Raeq) is a value for comparing the specific activities of the samples with different contents of ^{226} Ra, ^{232}Th and ^{40}K. The uniformity with respect to radiation exposure was defined in terms of the radium equivalent activity (Raeq) in Bq/kg in order to compare the specific activity of the materials containing different amounts of ^{226}Ra, ^{232}Th and ^{40}K. It is assumed that 370 Bq/kg of ^{226}Ra, 259 Bq/kg of ^{232}Th and 4810 Bq/kg of ^{40}K produce the same gamma-ray dose rate. It is calculated by using the following ratio (Beretka and Methew, 1985).

Ra_{eq}(Bq/kg)= $A_{Ra}+1.43A_{Th}+0.07A_k$

A_{Ra}, $A_{Th,}$ A_k - specific activiites (Bq/kg) of ^{226}Ra, ^{232}Th and ^{40}K, respectively. The value of the radium equivalent activity of 370 Bq/kg corresponds to the maximum allowed dose for a population of 1 mSv.

External and internal hazard index
In order to assess the equivalent average of the annual effective dose imposed to the residents of each area, the external hazard index for the soil samples was calculated.
$H_{eks} = A_{Ra}/370 + A_{Th}/259 + A_k/4810 \leq 1$
A_{Ra}, $A_{Th,}$ $A_{k\,-}$ specific activities (Bq/kg), ^{226}Ra, ^{232}Th and ^{40}K, respectively (Kurnaz et al., 2007)

Results and discussion

The different radionuclide activities in DCP samples could be derived from two causes: the geological characteristics of the phosphate rock; and the industrial manufacturing processes used for its production. According to the obtained results in regard to DCP, it is observable that the activity of ^{226}Ra is higher than the activity of the thorium series. The mean value for ^{226}Ra was

(5.27) Bq.kg-1, while the value for ^{232}Th reached (2.87) Bq.kg-1. According to Silva et al., (2001), ^{226}Ra is the biggest source of radioactivity in phosphogypsum and can enter living organisms because it follows the same biological pathway of calcium. However, the activity for ^{40}K was (22.26) Bq.kg -1, i.e. with the highest value in all samples of DCP, since K is an essential element for living organisms, therefore the radioactivity of ^{40}K cannot be avoided (Abbady et al., 2005). Thus, the results regarding the activity for this radionuclide in this research and for the DCP samples comply with the expectations and do not create any additional concern.

Arruda Neto (1997)	/	/	/

The mean value of the radiation risk index H_{eks} is minimum and it amounts to 0.03, and its value is lower than the maximum allowed value which is <1 for H_{eks}. The value of the radium equivalent activity Ra_{eq} is below the maximum recommended limit, i.e. 370 Bq kg^{-1} and it amounts to 10.93 Bq.kg^{-1}.

The specific activity values and the calculated radiation risk index (H_{eks}) and radium equivalent (Ra_{eq}) obtained in this study also did not exceed the safety limits, noting the negligible radiation hazard arising from naturally occurring terrestrial radionuclides.

Conclusions

The activity concentrations of natural radionuclides, ^{40}K, ^{226}Ra and ^{232}Th, were assessed in this study, in different samples of DCM used in the Republic of Macedonia. The results were also compared with other similar studies in other parts of the world. However, the values of the concentrations of the tested radionuclides are within the permissible values, i.e. the transmission of such levels to animal feed and, ultimately, to humans, through the radionuclide pathway, will not pose a threat when humans eventually consume poultry meat, poultry products and eggs from poultry fed with this food. However, it would be necessary to establish radionuclide monitoring systems in the main food in order to reduce human exposure to radiation through the consumption of animal products. Prevention would be the best manner to reduce radioactive contamination in animals and further in consumers as well. Monitoring the level of natural and artificial radionuclides in animal feed in order to mitigate the amount of radioactive substances that can reach the human body through the trophic chain is the basis for radiological contamination.

Abstract

The bacteria *Bacillus* species were described as inducers of plant systemic resistance in relation to their antagonistic activity. The objective of this study was to evaluate the effect of selected strain of *Bacillus amyloliquefaciens* (I3) on inducing systemic resistance in *Arabidopsis thaliana* as a model for plant molecular genetics. The microorganisms were identified and confirmed for their antagonistic potential *in vitro* and *in vivo* in previous studies. In order to explore this mechanism, two mutants of *A. thaliana* carrying a *PR1* promoter (a conventional marker of salicylic acid (SA) pathway) and *LOX2* promoter (a marker triggering jasmonic acid (JA) pathway activation) were analyzed after inoculating antagonists. Transgenic reporter line analysis demonstrated that *B. amyloliquefaciens* I3 induced *A. thaliana* defense pathways by activating SA and JA at a high level compared to lines treated with chemical elicitors of reference~~s~~ [acibenzolar-*S*-methyl; Bion 50 WG, SA, and methyl jasmonate]. The efficacy of *B. amyloliquefaciens* I3 in inducing the defense mechanism in *A. thaliana* was demonstrated in this study.

Keywords: *seed treatment, Bacillus amyloliquefaciens I3, salicylic acid, jasmonic acid, β-glucuronidase.*

Introduction

Among the biological control alternatives to the extensive use of chemical pesticides, the application of non-pathogenic bacteria living in association with plant is promising. Treatment with these microorganisms was in many cases associated to the reduction of plant diseases severity. As bacterial treatment at the root level confers protection against foliar or systemic pathogens, has been termed induced systemic resistance (ISR) (Kloepper *et al.*, 1992). ISR is effective against a broad range of diseases, the potential to activate ISR is assigned to antagonistic microorganisms (van Loon *et al.*, 2006) or to their secondary metabolites (Ongena *et al.*, 2007). The plant defense mechanism is typically related to ISR activation (Mejri *et al.*, 2017; van Wees *et al.*, 2008), the signaling pathways of which depend on cultivars, pathogen, and microorganism inducer (Leeman *et al.*, 1995; van Wees *et al.*, 1997). *Bacillus amyloliquefaciens* I3 isolated from wheat leaves in Morocco demonstrated high antagonistic potential against *Zymoseptoria tritici in vitro* and in greenhouse conditions (Barakat *et al.*, 2018). Also, it was demonstrated that surfactine extracted from *B. amyloliquefaciens* strain S499 triggers ISR in wheat against *Z. tritici* (Le Mire *et al.*, 2018).

In this study, the objective was to evaluate the potential of *B. amyloliquefaciens* I3 to induce and activate defense pathways in *Arabidopsis thaliana* by seed treatment. This property was described *in vitro* and *in vivo* using mutant lines of *A. thaliana* which report the activity of gene promoters *PR1* and *LOX2*, markers of salicylic acid (SA) and jasmonic acid (JA) defense pathways, respectively.

Materials and Methods

Biological Material

Mutant lines pPR1::GUS and pLOX2::GUS (N6357 and N57953, respectively) were used as reporter lines for SA and JA activity, respectively. These lines were provided by Nottingham *Arabidopsis* Stock Center.

In-plant analysis of β-glucuronidase (GUS) activity in *Arabidopsis* lines, genetically transformed by transcriptional fusions of the *UIDA* gene with promoters of the *PR1* (PR1 line) and *LOX2* (LOX2 line) genes allows the activation of these promoters already described as markers of induction of the SA and JA pathways, respectively (Millet *et al.*, 2010; Jensen *et al.*, 2002).

Preparation of Antagonist Inoculum

B. amyloliquefaciens I3 inoculum was prepared in Luria Bertani (LB) Agar (Luria et Burrous, 1957) and incubated 72 h at 27 °C in the dark.

Arabidopsis Seedling Preparation

Ten milligrams of seeds (6000 *Arabidopsis* seeds) were stirred in 1 mL of sterilizing solution (ethanol 70%, sodium hypochlorite 10%) for 10 min, subsequently rinsed three times with ethanol 70%, and dried up using Whatman papers disinfected with ethanol.

Arabidopsis was cultivated *in vitro* and *in vivo* for studying its different early growth stages (germination, cotyledons, leaf production, and rosette production); also, on late growth stages (flowering and silique ripening). *In vitro* seedlings were grown in Murashige and Skoog basal salt mixture agar media in petri plates of 90 mm in diameter. *In vivo* seedlings were sown in pots of 7 × 7 × 8 cm, with three seeds in each pot.

Seeds were stratified at 4 °C in the dark before adding the antagonist suspension. Afterwards, 10 µL of the antagonist suspension (10^9 colony-forming units (cfu)/mL) were added on the top of each seed in *in vitro* conditions. In the *in vivo* conditions, the substrate was inoculated with 8 mL of the antagonist suspension (10^9 cfu/mL). Both plates and pots were transferred to a growth room kept at long-day conditions.

In this study, four controls were made: a negative control in which seeds were treated with sterile milliQ water, and positive controls where seeds were treated with acibenzolar-*S*-methyl at 925 µM (Bion 50 WG), SA at 140 µg/mL which induced *PR1* activity, and methyl jasmonate (MeJa) at 60 µM which induced *LOX2* activity in reporter cell lines. All plants in controls were treated using foliar spray 24 h before being stained with GUS solution.

Histochemical Staining

Ten plants were used to study every growth stage modality cultivated *in vitro*, and three plants were used to study in vivo growth modality in pots. Plants were dipped in GUS mixture for 12 h and incubated in the dark at 37 °C while stirring for 150 rotations per minute. Tissues were then washed with ethanol 70%. Stained tissues were studied with a binocular loupe, and the ratio of surface area stained over total surface area of each plant was estimated using ImageJ software. This assay was repeated three times.

Statistical Analysis
SPSS 21 statistic software was applied for histochemical data analysis. Statistical analyses were established at two-factor level; the first corresponded to treatments (*B. amyloliquefaciens* I3, Bion 50 WG, SA, MeJa, and negative control) and the second factor indicated the growth stages (germination, cotyledons, leaf production, rosette, and flowering). ANOVA analysis was applied for analysis of mean data variation, while the Duncan test was used for the comparison of means at p = 0.05.

Results and discussion

The antagonist inoculation in transgenic *Arabidopsis* (*PR1* and *LOX2* reporter lines) demonstrated the induction of SA (*PR1* line) and JA (*LOX2* line) pathways. Results of β-glucuronidase (GUS) staining in both reporter lines (Figures 1 and 2) whose seeds were treated by *B. amyloliquefaciens* I3 revealed the effective activation of both *LOX2* and *PR1* promoters and, thus, the induction of SA and JA pathways. Similar GUS staining results were shown in lines treated with chemical elicitors (Bion 50 WG, MeJa, and SA) at different growth stages (germination, cotyledons, leaf production, rosette, and flowering).

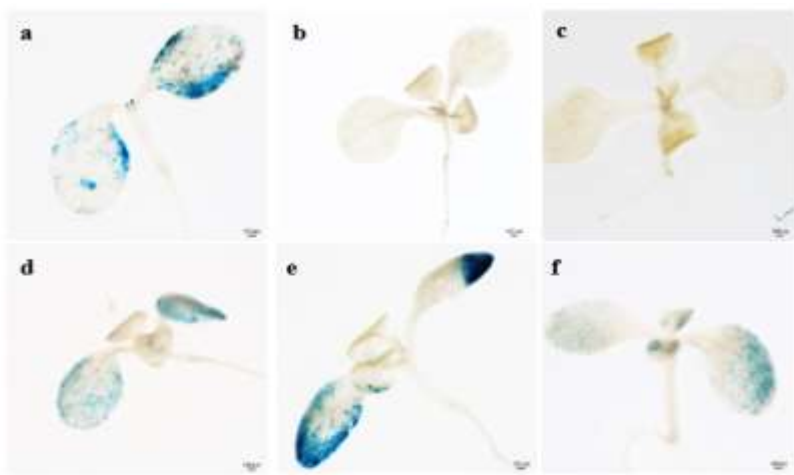

Figure 1. β-Glucuronidase (GUS) activity in pPR1::GUS (**a, d, e**) and pLOX2::GUS (**b, c, i**) lines of *A. thaliana* at cotyledon stage: (**a, c**) seeds treated with *B. amyloliquefaciens* I3; (**d**) treatment by Bion 50 WG; (**e**) treatment by SA; (**b**) treatment by milliQ water; (**f**) treatment by MeJa.

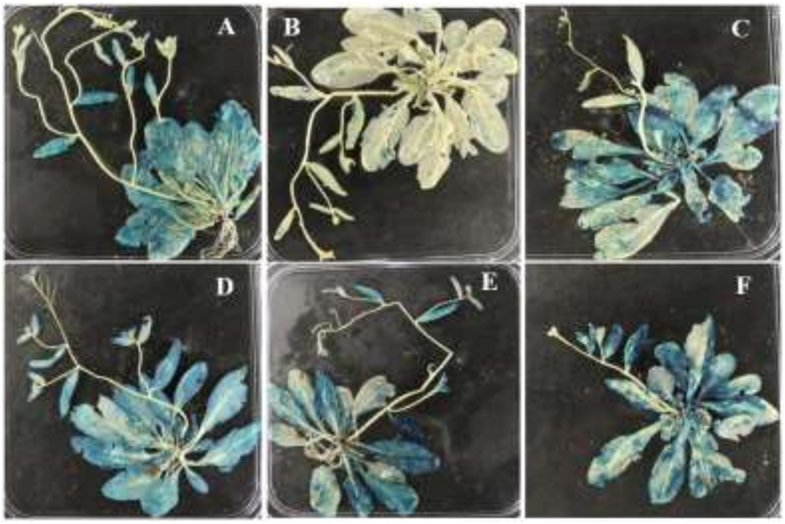

Figure 2. β-Glucuronidase activity in pPR1::GUS (**A, D, E**) and pLOX2::GUS (**B, C, F**) lines of *A. thaliana* at flowering stage: (**A**,**C**) seeds treated with *B. amyloliquefaciens* I3; (**D**) treatment by Bion 50 WG; (**E**) treatment by SA; (**B**) treatment by milliQ water; (**F**) treatment by MeJa.

GUS staining pattern in the germination stage of transgenic *Arabidopsis* lines carrying pPR1::GUS was observed in treated plants with the two positive controls, Bion 50 WG and SA. Plants inoculated with *B. amyloliquefaciens* strain I3 developed an intense histochemical staining which was dependent on the developmental stage. The former ranged from 51% in the cotyledon stage to 91% in the flowering stage. *Arabidopsis* lines carrying pPR1::GUS and treated with *B. amyloliquefaciens* I3 showed a very high GUS stain pattern compared to those observed in plants treated with water at different growth stages. GUS staining covered at the most 3% of the plants in the flowering stage treated with water (Figure 3).

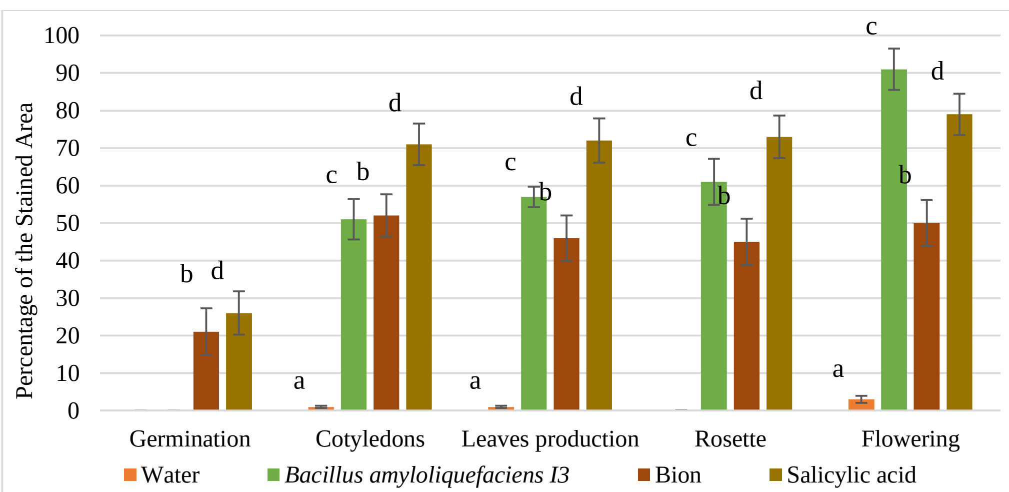

Figure 3. GUS stain pattern surface for each treatment and growth stage in the pPR1::GUS line. Bars correspond to standard errors of means. Letters denote homogeneous groups in the Duncan test at p = 0.05.

The transgenic *Arabidopsis* line carrying pLOX2::GUS, planted *in vitro,* did not show any GUS stain pattern when treated with both antagonists during all the studied developmental stages (germination, cotyledon, leaf production, rosette). On the other hand, when this line was treated with methyl-jasmonate, the GUS stain patterns ranged from 79% in germination to 81% in the rosette stage (Figure 4). Plants presented highly significant GUS stain differences in all the treatments in the flowering stage. The GUS stain patterns covered 84% of the leaf surfaces when plants were treated with *B. amyloliquefaciens* I3. The GUS stain patterns covered 82% of the leaf surfaces when treated with MeJa. On the other hand, the negative controls were stained on less than 2% of the total surface (Figure 4).

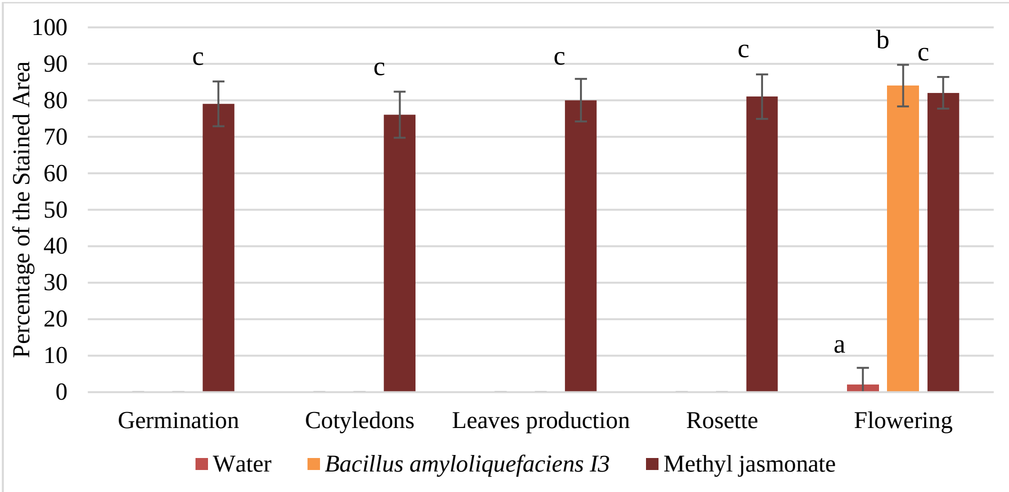

Figure 4. GUS stain pattern surface for each treatment and growth stage in the pLOX2::GUS line. Bars correspond to standard errors of means. Letters denote homogeneous groups in the Duncan test at $p = 0.05$.

In the present study, the induction of SA and JA pathways by *B. amyloliquefaciens* I3 from the cotyledons to the flowering stage was demonstrated using GUS staining patterns (Figures 1 and 2). The GUS staining pattern in the plant surface was significantly higher ($p = 0.05$) when plants were treated with antagonist at the flowering stage compared to the percentage of GUS dyes in plants treated with the commonly tested chemical references, Bion 50 WG and SA (Figure 3). There was no visible GUS staining in pLOX2::GUS lines observed in in vitro cultivated plants; however, in the flowering stage, the GUS staining was observed. On the other hand, the GUS staining pattern was very high in plant leaves treated with *B. amyloliquefaciens* I3, which demonstrate the potential of strains I3 in inducing the JA pathway (Figure 4). It is important to note that both transgenic plants exhibited a positive GUS staining and were also induced in the flowering and the silique ripening stages, while the antagonist inoculation was established in the substrate during the early developmental stages (Figure 2).

Our results are in agreement with the study conducted by Niu *et al.* (2011), who demonstrated that *B. cereus* AR156 induces ISR in *A. thaliana*, by simultaneously activating SA and JA pathways. Similarly, van Wees et al. (1997) proved that strain WCS417r of *Pseudomonas fluorescens* induces ISR in tomato and *A. thaliana* against *Pseudomonas syringae* pv. *tomato* and *Fusarium oxysporum* f. sp. *raphanin*, respectively. Ryu *et al.* (2004) also demonstrated that different plant growth-promoting rhizobacteria (PGPR) (*Serratia marcescens* 90–166, *Bacillus pumilus* SE34, *P. fluorescens* 89B61, *P. fluorescens* 89B27, *B. amyloliquefaciens* IN937, and *B. subtilis* IN937) induce SA and JA pathways in cucumber. However, it is important to note that surfactines and fengycines, which are lipo-peptides produced by the genus of *Bacillus*, may interact with plant membrane cells and disturb them (provoking stress), leading to a similar defense reaction in the plant that may be confused with ISR induction (Ongena *et al.*, 2007).

Conclusion

Our results demonstrated the potential of *B. amyloliquefaciens* to systemically induce SA and JA pathways in *A. thaliana.* According to the biocide effect, the antagonists may offer more sustainable plant protection in field conditions using the treated seeds with *B. amyloliquefaciens* I3.

INTERFERENCE COMPETITION BETWEEN LADYBIRD BEETLE ADULTS (COLEOPTERA: COCCINELLIDAE) ON PRICKLY PEAR CACTI PEST *DACTYLOPIUS OPUNTIAE* (HEMIPTERA: DACTYLOPIIDAE)

Mohamed EL AALAOUI*, Mohamed SBAGHI

National Institute of Agricultural Research, Morocco
*Corresponding author: mohamedelaalaoui@gmail.com

Abstract

The outbreaks of mealybug, *Dactylopius opuntiae* (Cockerell) (Hemiptera: Dactylopiidae) have created problems to Prickly Pear crops in Morocco in recent years. The native ladybird *Hyperaspis campestris* (Herbst 1783) (Coleoptera: Coccinellidae) and introduced ladybird *Cryptolaemus montrouzieri* (Mulsant, 1853) (Coleoptera: Coccinellidae) were used to control this menace. Petri dishes were used to determine the minimum number of *D. opuntiae* females that females of the introduced ladybird beetle *C. montrouzieri* require per day to achieve maximum fecundity and to assess the effects of interference competition from conspecific and heterospecific [*Hyperaspis campestris* (Herbst 1783)] adult ladybirds on its growth and reproduction. The number of *D. opuntiae* females at which females of *C. montrouzieri* ate most, and achieved maximum reproduction was 30. The presence of *H. campestris* does not significantly affect the reproductive numerical response of *C. montrouzieri* females. The presence of a conspecific or heterospecific (*H. campestris*) did not significantly affect the mean number of clutches laid by *C. montrouzieri* females. Also, mean clutch size and number values were significantly increased as prey density increased from 3 to 25 and does not significantly change from 25 to 30 density. The mean number of clutches laid by *C. montrouzieri* females was independent of the presence or sex of another lady beetle. Based on these results we suggest that the population abundance of *C. montrouzieri* will not be affected by the native ladybird *H.campestris.*

Keywords Coccinellidae, *Dactylopius opuntiae*, *Hyperaspis campestris*, Interference competition.

Introduction

The prickly pear cactus is a weed in some contexts but is also exploited for its fruit and cladodes as a vegetable source for humans, fodder for livestock, and as a barrier hedge. In Morocco, cactus was introduced in 1770 and it is now well represented throughout the national landscape. As a result of drought, the cactus area has evolved significantly in the past two decades: from 50 000 ha in 1998 to > 150 000 ha in 2014 (Paolo *et al.*, 2017). The modernization of Moroccan agriculture (Green Morocco Plan) encourages cactus plantation as an alternative crop in less favorable regions. Each year, over 4 000 ha are planted in the center and south of the country (Ait Hamou, 2007). Since 2016 *Dactylopius opuntiae* (Cockerell) (Hemiptera: Dactylopiidae) a possibly introduced mealybug has been causing severe damage to prickly pear crops in Morocco. *Dactylopius opuntiae* establish and spread more easily than many other insect species due to: a waxy coating on their dorsal side, which protects them from insecticides, a high reproductive rate, and the propensity to spread quickly through natural carriers such as plant products, wind,

water, rain, birds, human beings, and farm animals (khan *et al.*, 2012). Mealybugs suck sap through phloem tissues causing chlorosis and premature dropping of cladodes and fruits. Severe infestations (>75 % of the cladode surface) can result in death of the plant (Mann, 1969; Vanegas-Rico *et al.*, 2010, 2015). They also seem to be able to become dormant on inert material for considerable periods of time under unfavorable conditions (Khan *et al.*, 2012). Furthermore, problems with insecticide resistance and non-target effects on natural enemies make chemical control a less desirable control option to combat *D. opuntiae*. Therefore, to reduce insecticide use, there is a need to establish an integrated pest management program (Van den Bosch *et al.*, 1982) for *D. opuntiae* by introduction of some natural enemies. Arthropod natural enemies associated with *D. opuntiae* and other Dactylopiidae include only predators (Mann, 1969; Zimmermann *et al.*, 1979; VanegasRico *et al.*, 2010) of which the Coccinellidae *Chilocorus cacti L*. and *Hyperaspis trifurcata* Schaeffer are the most abundant in Mexico and the USA (Mann, 1969; Gilreath and Smith, 1988; Badii and Flores, 2001; Rodríguez-Leyva *et al.*, 2010; Vanegas-Rico *et al.*, 2010, 2015). Besides *C. cacti L*. and *H. trifurcata* Schaeffer, *Cryptolaemus montrouzieri* is also known as a generic predator of mealybugs and scales, and it has been used in 50 countries for control of several mealybug species (Srinivasan and Babu, 1989; Olivero *et al.*, 2003; Al-Khateeb and Asslan, 2009; Rosas-Garcia *et al.*, 2009). *Cryptolaemus montrouzieri* is not a common predator in Morocco, so morocco has had to import the beetle from different countries where its use as a biological control agent of mealybugs. In addition July 2017, *Hyperaspis campestris* (Herbst 1783) was also observed in cactus crop feeding on *D. opuntiae* in the state of Zemamra locality (32°37'48" N, 8°42'0" W) in the Sidi Bennour region (120 km north-west of Marrakech), Morocco. The combination of predators produced varying degrees of success, both in fields and greenhouses. Failures may be the result of unfavorable environmental factors, incompatible pest management practices, and antagonistic interactions among the biological control agents (khan *et al.*, 2012). *Cryptolaemus montrouzieri* has the potential of interfering with the biological control of the mealybug (Sengonca and Yanuwiadi, 1994).
This study aimed to determine (1) the minimum number of *D. opuntiae* females that females of *C. montrouzieri* need per day to maximize their fecundity; (2) the effect of the presence of the adults of conspecifics and the heterospecific *Hyperaspis campestris* on the growth and reproductive capacity of *C. montrouzieri* females.

Materials and methods

Insects

Adult of *Hyperaspis campestris* were collected from prickly pear plantations from Zemamra (32°37'48" N, 8°42'0" W) and immediately identified. The ladybird was maintained on Cladodes infested with *D. opuntiae* nymphs in the laboratory at 27°C. The *C. montrouzieri* colony was established from adults imported by the laboratory of entomology at INRA (National Institute of Agricultural Research). Adults were placed in entomological cages (80-80-80 cm) comprised of a wooden frame covered by a mesh fabric to allow ventilation. Access to water was provided via a cotton wick inserted into a 25 ml glass vial of water. Cladodes infested with *D. opuntiae* were introduced into the cages to provide food and substrates for *C. montrouzieri* oviposition. Infested cladodes were withdrawn weekly and *C. montrouzieri* larvae transferred to another cage with the same characteristics to complete their development.

Effect of *D. opuntiae* females density on biological features of *C. montrouzieri* females

Cryptolaemus montrouzieri adult females were (15 days old) were placed individually in Petri dishes (14 cm in diameter) and provided by different densities of *D. opuntiae* females. 20 replicates randomly distributed were used for each combination of predator and prey density. Each of the 20 replicates contained seven treatments, defined by the density of the prey they would subsequently be offered. These densities were, 3, 5, 10, 15, 20, 25, and 30. All experiments were carried out at 27°C. *Dactylopius opuntiae* females were replaced daily for 3 days. Each set of *D. opuntiae* females was weighed before being presented to the predators. The females' voracity and reproductive capacity (measured as the number of eggs laid per female per day, number of eggs laid per clutch per female per day, and number of clutches laid per female per day) were recorded over the final 24 h of the 3-day experimental period.

Daily voracity (V0) was estimated using the equation of Soares et al. (2003): $V0 = (A- a_{24})* ra_{24}$. where V0 is the number of prey consumed, A is the number of prey offered, a_{24} is the number of prey alive after 24 h, and ra_{24} is the proportion of prey alive in the absence of a predator after 24 h. Another measure of voracity is the biomass of prey ingested (mg) per unit of time, the so-called relative consumption rate (RCR). RCR was evaluated according to Soares et al. (2004): $RCR_{(mg)} = (W_i/N)*V_0*PUC$. Where RCR (mg) = relative consumption rate, Wi = total weight of insects provided, N = number of insects provided, V0 = number of insects eaten and PUC = prey utilization coefficient. In a separate experiment, the PUC of *C. montrouzieri* females was estimated to be 61.44 ± 9.35% using the following model (Schanderl, 1987) $PUC=[(W_0-W_1-(W'_0-W'_1)/W_0]*100$. where W_0 = body weight of one *D. opuntiae* female provided, W_1 = *D. opuntiae* female carcass weight, W'_0= initial body weight, and W'_1= final bodyweight of one *D. opuntiae* female in the control treatment.

Effect of the presence of conspecific and heterospecific adults on the growth and reproductive capacity of *C. montrouzieri* females

In this study, *C. montrouzieri* adult females (15 days old) were placed individually in Petri dishes (14 cm in diameter) and provided with 15 *D. opuntiae* gravid females (egg production stage). At the end of the second day, one conspecific (treatment 1) or one heterospecific (treatment 2) beetle was also released in the experimental setup. All experiments were carried out in the same conditions 27°C, and all adults used in this experiment were reared under the same conditions. On the third day, the reproductive capacity of *C. montrouzieri* females was recorded. In the replicates with two females of *C. montrouzieri*, results for reproductive capacity were compared and presented per female. 20 replicates randomly distributed (ten females and ten males) were used for each treatment.

Statistical analysis

The data of voracity, relative consumption rate, reproductive capacity, the mean number of eggs laid, the mean number of eggs laid per clutch per female and mean number of clutches laid per female kept alone, with a conspecific or a heterospecific were analyses using ANOVA followed by a multiple comparison test (LSD test) with the software package SPSS ver. 18.0 (SPSS, 2012).

Results and discussion

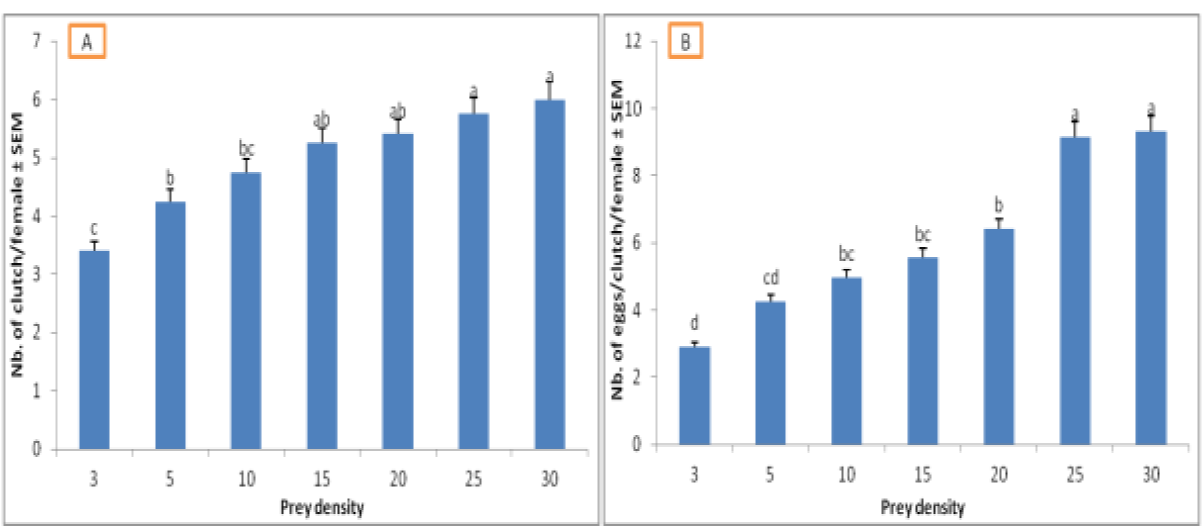
Effect of *D. opuntiae* females density on biological features of *C. montrouzieri* females

Daily voracity of *C. montrouzieri* females against *D. opuntiae* females was significantly increased (ANOVA, F = 178.854, df = 6, P < 0.0001) and reached maximum values when 30 mealybugs were provided. Biomass ingested was also significantly increased (ANOVA, F = 156.658, df = 6, $P \leq 0.0001$) to reach maximum values when 20 mealybugs were provided (Table 1). Fecundity varied significantly with treatment (ANOVA, F = 41.868, df = 6 , P < 0.0001). Number of eggs laid by *C. montrouzieri* females significantly increased as prey density increased from 3 to 20 and does not significantly change from 20 to 30 density (Fig. 1A). Mean clutch size differed significantly with treatment (ANOVA, F = 42.407, df = 6, P < 0.0001). It significantly increased as prey density increased from 3 to 25 and does not significantly change from 25 to 30 density (Fig. 1B). The number of clutches differed significantly with treatment (ANOVA, F = 24.840, df = 6, P < 0.0001). Clutch number increased significantly as prey density increased from 3 to 25 and does not significantly change from 25 to 30 density (Fig. 1C).

Table 1. Mean voracity (mean number of *Dactylopius opuntiae* females eaten ± SE and relative consumption rate (milligrams of biomass ingested ± SE) of *C. montrouzieri* female, provided with different numbers of *D.opuntiae* females

Number of *Dactylopius opuntiae* females provided	Daily Voracity	Relative consumption rate
3	2.17±0.49 e	27.76±6.32 d
5	3.13±0.50 d	40.72±6.83 c
10	4.20±0.78 c	55.54±10.25 b
15	4.53±0.91 c	60.43±12.06 b
20	4.95±0.75 b	66.11±9.97 a
25	5.35±0.71 a	65.90±9.05 a
30	5.55±0.75 a	66.08±8.97 a

Bars with different letters are significantly different according to Tukey's protected LSD test (alpha = 0.05).



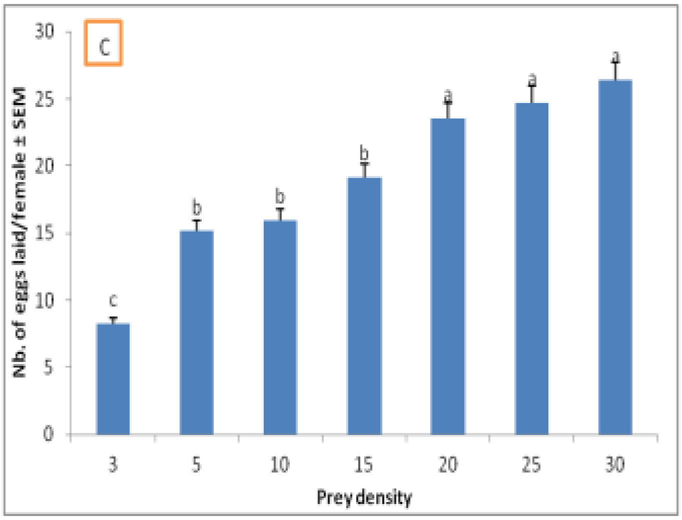


Fig. 1. Reproductive capacity [A clutch number (mean number of clutches per day per female ± SE), B clutch size (mean number of eggs per day per clutch ± SE) and C fecundity (mean number of eggs per day per female ± SE)] of *C. montrouzieri* females in 24 h on seven different prey densities. Bars with different letters are significantly different according to Tukey's protected LSD test (alpha = 0.05).

Effect of the presence of conspecific and heterospecific adults on the growth and reproductive capacity of *C. montrouzieri* females

Fecundity of *C. montrouzieri* females was not significantly reduced in both treatments. In the presence of conspecifics (ANOVA, F = 0.549, df = 3, P = 0.652), and also in the presence of heterospecifics ladybird (ANOVA, F = 1.52, df =3, P = 0.225). The mean number of eggs laid by *C. montrouzieri* female was not significantly affected by the presence of another lady beetle species independent of its sex (Fig. 2). The presence of heterospecifics ladybird did not significantly affect the clutch size of *C. montrouzieri* (ANOVA, F = 1.510, df = 3, P = 0.228), but clutch size was significantly lower in the presence of male conspecifics (ANOVA, F = 3.458, df = 3, P = 0.026). Mean clutch size was not significantly affected by the sex of the heterospecifics (Fig. 2). The presence of a conspecific or heterospecific did not significantly affect the mean number of clutches laid by *C. montrouzieri* females (ANOVA, F = 2.475 , df = 3 , P = 0.077; ANOVA, F = 2.376, df = 3, P = 0.086, respectively). The mean number of clutches laid by *C. montrouzieri* females was independent of the presence or sex of another lady beetle (Fig. 2).

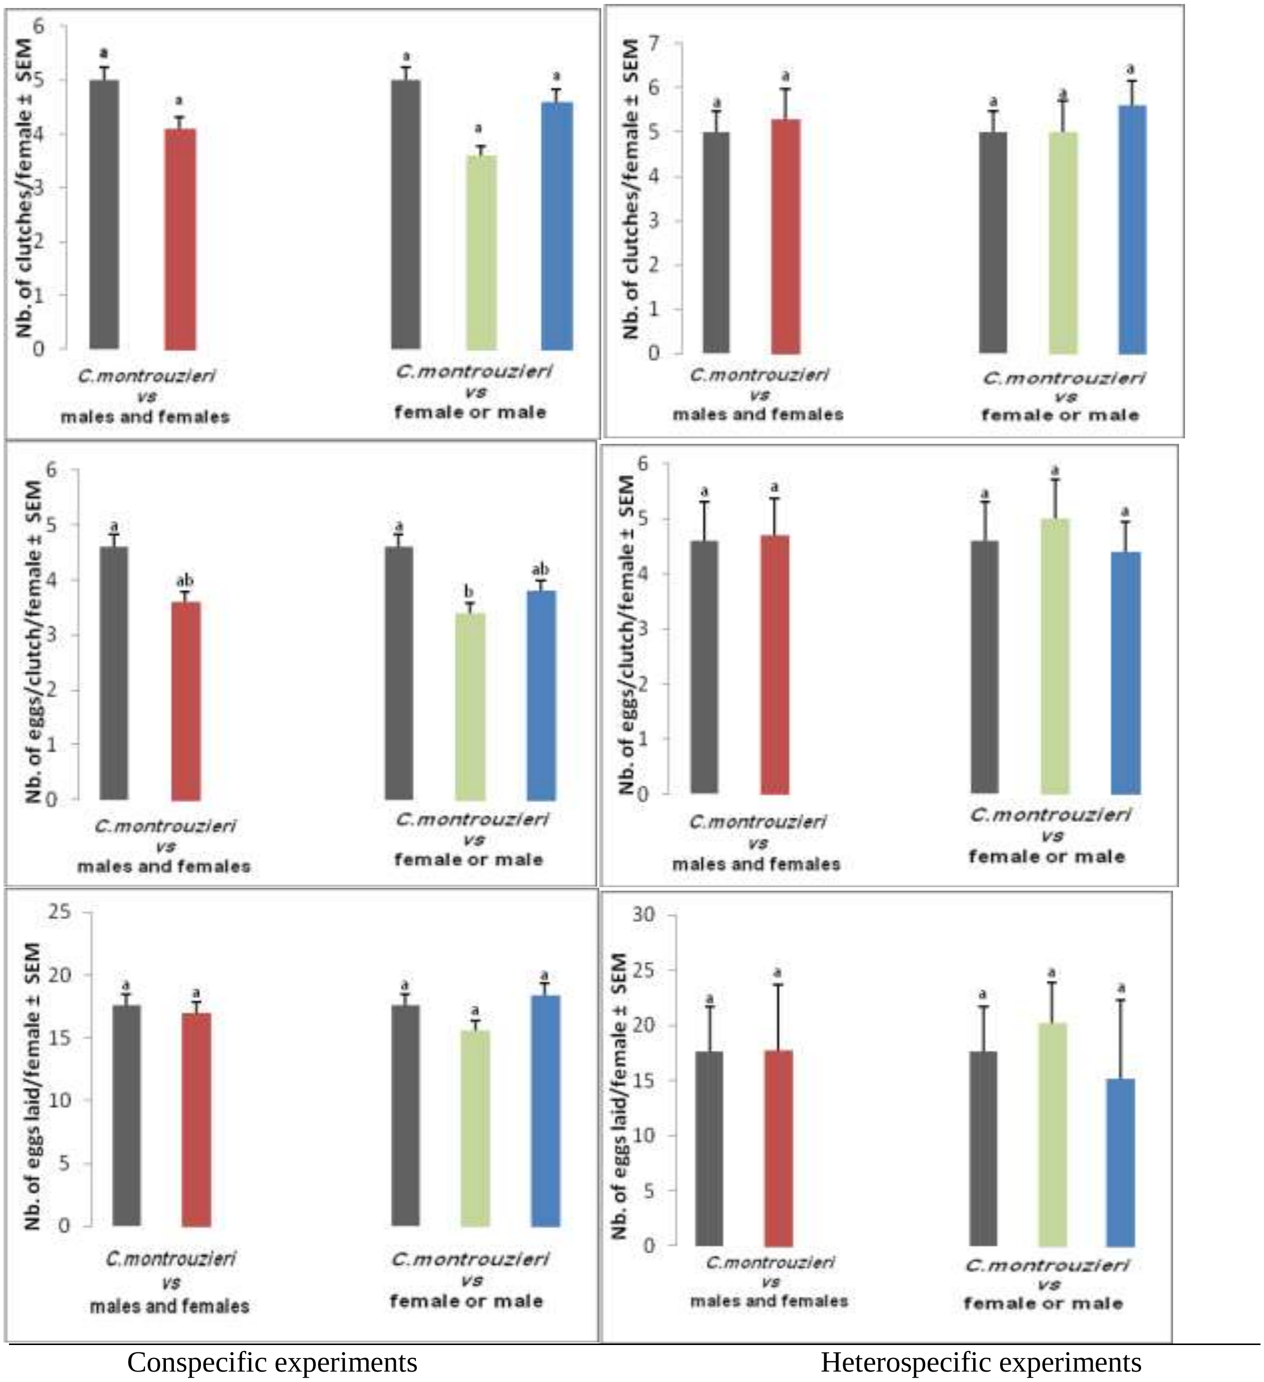

Fig. 2. Mean changes in mean number of eggs laid, number of eggs per clutch per female, and mean number of clutches per female of *C. montrouzieri* females in the presence of ladybird beetles *H. campestris.* Histograms within the same subgroup of experiments having the same letter are no significantly different (P < 0.05; Tukey's protected LSD test). Black bars *C. montrouzieri* females kept alone; brown bars *C. montrouzieri* females in the presence of conspecifics or heterospecifics; green bars *C. montrouzieri* females in the presence of a male conspecific or heterospecific; and bleu bars *C. montrouzieri* females in the presence of a female conspecific or heterospecific.

The results of this study showed that there was a significant difference among the number of prey consumed and reproductive capacity of *C. montrouzieri* females at different prey densities. The maximum consumption and reproductive capacity were recorded at high prey densities, and they were significantly higher than those obtained at the lowest densities. The voracity and reproductive capacity of coccinellids depend on prey density. The increase in prey density results in the increase of number of prey eaten and its reproductive numerical response (Hodek and Honêk, 1996). Over the range of 3–30 *D. opuntiae* females provided per day, the mean number of eggs per clutch increased significantly. These results suggest that *C. montrouzieri* females maximize their fitness by laying large clutches. Our results reported that The presence of heterospecifics ladybird did not significantly affect the reproductive capacity of *C. montrouzieri* females. *Cryptolaemus* has the potential of interfering with the biological control of mealybugs (Sengonca and Yanuwiadi, 1994). Since clutch size was significantly lower in the presence of male conspecifics. The mechanism for this lower clutch size is not clear. However, one of the possible explanations is that *C. montrouzieri* females expended some time and/or matter and/or energy on competition or avoiding competition, and then there was less of these resources available for larging theirs clutches. The combination of predators produced varying degrees of success, both in the fields and greenhouses. Failures may be the result of unfavorable environmental factors, incompatible pest management practices, and antagonistic interactions among the biological control agents (Khan *et al.*, 2012). Our results suggest also that both predators show strong predatory potential against *D.opuntiae*, with *C. montrouzeiri* being the most ravenous feeder. From a biological control point of view, this study shows that *H. campestris* could not endanger the population abundance and/or induce competitive displacement of *C. montrouzieri*, Thus the combination of the two predators can reduce more significantly *D. opuntiae* population.

Conclusion

The laboratory results presented here suggest that the local polyphagous ladybug (*H. campestris*) is not able to negatively impact the reproductive parameters of the introduced beneficial ladybug *C. montrouzieri*; however, an extrapolation of these results to the field will not be entirely accurate. Therefore, a direct field assessment of the impact that this local ladybug species (*H. campestris*) may have on introduced beneficial ladybugs such as *C. montrouzieri* is needed.

THE INFLUENCE OF POLYOLS USED AS OSMOTIC AGENTS IN OSMOTIC DEHYDRATION PROCESS

Magdalena CHĄDZYŃSKA*, Malgorzata NOWACKA

Abstract

Osmotic dehydration (OD) is a technique used in food technology for the partial removal of water from plant tissues that often precedes different preservation treatments, especially drying. The OD process can improve the food product quality and reduce energy consumption in the next processes allowing to create new products. It positively affects retention of flavour, colour and nutrients and causes a reduction of both water content and water activity of a dehydrated material. Many factors have an impact on the efficiency of OD (e.g., temperature, time, solution type and concentration, the ratio of the mass of the dehydrated product to the mass of the solution, the sample geometry, the material structure). For the OD process, different types of agents might be applied. One of the most common osmotic agents is sucrose solution. However, because of the worldwide epidemic of obesity, there is an increasing demand for its less-caloric alternatives. In recent years, the use of polyols as the osmotic agents is widely investigated due to their low energy value and a comparable sweetness to sucrose. The aim of this study is to discuss the applicability of chosen substances from the polyol group as the osmotic agents. The sugar profiles, kinetics parameters and sensory properties of dehydrated food products with the use of polyols are analysed. Literature review points out that some substances from the polyol group can successfully be alternatives to sucrose in the OD process. Erythritol and xylitol is the most studied and promising osmotic agents of sugar alcohols.

Keywords: *osmotic dehydration, polyols, sugar alcohols, plant tissue.*

Introduction

Food preservation involves delaying the growth of microorganisms and inhibiting biochemical reactions. Its aim is to prevent foods from spoiling and therefore to minimize wastage (Sridhar *et al.*, 2020; Yadav and Singh, 2014). Although the concept of food preservation was introduced in ancient times, it is constantly evolving. With increasing demands of quality and safety of foods, preservation techniques have been improved and modernized (Amit *et al.*, 2017; Sridhar *et al.*, 2020). One of the techniques that enables to obtain a high nutritional and organoleptic quality product is osmotic dehydration (OD).

OD can be used as a technique for obtaining minimally processed food products (Tappi *et al.*, 2017) or as a pre-treatment before other processes, e.g., freezing (Dadan *et al.*, 2020) or drying Assis *et al.* (2017). In the latter case, it causes energy saving as well as increases retention of nutritional value, colour, flavour and texture of dried fruits and vegetables (Yadav and Singh, 2014). OD is a process used for partial dewatering of plant tissues such as fruits and vegetables by immersing in hypertonic solution. During OD, a counter-current transfer of mass occurs through the transfer of water from the food tissue to the osmotic solution, and at the same time the osmotic substance goes into the dehydrated material. Additionally, the food's solutes, i.e., vitamins, minerals, organic acids, saccharides, or colourants are leached out of the tissue. This transfer is quantitatively negligible compared with the first two types but it also affects the change in the chemical composition of the product. The driving force for mass flow is the chemical potential difference across a semi-permeable membrane between the material and the solution (Ahmed *et al.*, 2016; Akbarian *et al.*, 2014; Nowacka *et al.*, 2021). The efficiency of the OD process is influenced by several factors such as type and concentration of the osmotic solute, food structure, maturity level, shape, and size of the raw material, ratio of the osmotic solution to the product, as well as the process parameters (time, temperature, pressure, agitation) (Ahmed *et al.*, 2016; Ciurzyńska *et al.*, 2016; Yadav and Singh, 2014). The osmotic dehydration process is also affected by solubility, molecular weight, physicochemical properties, and the ionic state of the solute. A low molecular weight osmotic agent can more easily penetrate the cells of plant tissues as compared to a high molecular weight osmotic agent (Gribova *et al.*, 2021). Furthermore, the solute cost, harmlessness, organoleptic compatibility with the food product and additional preservation effect by the solute should be considered when choosing osmotic agents (Akbarian *et al.*, 2014). The most used osmotic agent for fruits is sucrose (Chandra and Kumari, 2014). However, its high consumption might cause negative consequences on human health (Codella *et al.*, 2016). Therefore, it is important to find alternative osmotic agents to sucrose. Various substances that enable to achieve products with desirable nutritional, functional, and organoleptic properties were recently proposed, for example fruit juice concentrates (Lech *et al.*,2017; Samborska *et al.*, 2019), steviol glycosides (Nowacka *et al.*, 2018) and polyols (Cichowska *et al.*, 2018; Mendonça *et al.*, 2017).

Polyols (polyhydric alcohols or sugar alcohols) are low digestible carbohydrates, which are obtained by substituting an aldehyde group with a hydroxyl one. They are naturally present in certain kinds of fruits, vegetables, or mushrooms. Sugar alcohols have lower caloric value (from 0.2 to 2.7 kcal/g) compared with sucrose (4 kcal/g) and relative sweetness of around 30-100 % compared with sucrose (Grembecka, 2015). The use of sugar alcohols during pre-treatment can reduce sugar content in the product, resulting in the reduction of calories (Cichowska *et al.*, 2019a).

This study aims to analyse the possibility of use of selected polyols as the osmotic agents. Certain parameters, including water activity, mass transfer kinetics, sugar profiles, colour changes, sensory properties depending on the type of sugar alcohol are described.

Material and Methods

This paper is based on a literature review of journal articles and book chapters. The presented conclusions were drawn from the analysis and synthesis of current information on the research topic. The information was gathered from the main online scientific databases including Science Direct, Elsevier, and Google Scholar.

Results and Discussion

The present review focuses on the effect of the use of the chosen sugar alcohols such as maltitol, xylitol erythritol and sorbitol as osmotic agents. Those substances were chosen as their applicability in the OD is the most studied substances among all polyols so far.

Maltitol is a disaccharide polyol that consists of glucose and sorbitol in equal parts. Although it is characterized by a pleasant sweet taste, the insulin response associated with its ingestion is significantly reduced due to its slow absorption. Maltitol characterizes with properties the most resembling the ones of sucrose among sugar alcohols. Its sweetness amounts up to 90% of the one attributed to sucrose, but its caloric value is lower (2.1-2.4 kcal/g). Maltitol causes laxative effect when consumed in amounts exceeding 25-30 g/kg body weight per day (Grembecka, 2015). The molecular weight of maltitol amounts 344.31 g/mol and it is similar to the molecular weight of sucrose (342.30 g/mol). Kowalska *et al.* (2019) stated that maltitol caused comparable mass exchange rate to sucrose when both substances were used in the same concentration. However, the mass transfer kinetics of the OD of yacon with maltitol was less effective in relation to the other polyols as xylitol, erythritol, sorbitol. This result can be attributed to its significantly higher molecular weight (Mendonca et al., 2016). The changes of water activity in the OD are related to water content of dehydrated product. Therefore, the influence of maltitol on decrease of water activity is not significant compared to sucrose (Cichowska *et al.*, 2018). The OD in maltitol solution may significantly increase the content of this substance in the dehydrated tissue. It was observed by Cichowska *et al.* (2019b), where significant increase of colour intensification was noted but the total colour difference after the OD was quite small. Furthermore, the OD in polyols solutions as a pre-treatment before convective drying was studied by Bialik *et al.* (2020). It was demonstrated that the utilization of maltitol at 30°C improved the retention of the carotenoids. Moreover, the use of maltitol at 30°C shortened the drying time compared to pre-treatment in sucrose or without pre-treatment.

Xylitol is a 5-carbon polyol. It characterizes with the same sweetness as sucrose (with one-third fewer calories), so it is the sweetest among all polyols. Human tolerance of xylitol amounts to 100 g per day (Grembecka, 2015). Kowalska *et al.* (2019) demonstrated that the OD process in xylitol solution is more efficient than in sucrose solution. It is caused by the low molecular weight of xylitol (152.15 g/mol). For the same reason, the difference between water activity of fresh sample and dehydrated in xylitol is bigger than the difference between the fresh sample and the sample dehydrated in sucrose. Furthermore, the study showed that colour changes of apples dehydrated in xylitol and sucrose solutions were similar. Additionally, the contents of sucrose, fructose and glucose in the samples decreased and the content of xylitol increased during the whole OD process, compared to the fresh material. It is worth mentioning that the absolute changes in sugar profiles were stronger when xylitol was used compared to sucrose and maltitol due to the higher osmotic pressure which is the driving force of sugars' diffusion (Kowalska *et al.*, 2019). The efficiency of mass transfer kinetics and decrease of water activity when xylitol is the osmotic agent were confirmed also for kiwiberries (Bialik *et al.*, 2020), apples (Cichowska *et al.*, 2019a; Cichowska *et al.*, 2018) and yacon (Mendonça *et al.*, 2017).

In the experiment performed by Cichowska-Bogusz *et al.* (2020), an impact of OD with sugar alcohols on drying was analysed. It was found that the OD with xylitol shortens the drying time in both convective and vacuum-microwave drying compared to drying without the OD. Moreover, convective drying was shorter when xylitol was used as osmotic agent compared to sucrose and erythritol. According to this study, no negative effect on taste was observed when xylitol was used in the production of dried apples. In addition, it enabled to obtain a noticeable cooling/refreshing effect felt in the mouth. The use of xylitol enabled the production of dried snacks with lower calorific value, compared to dried apples obtained by the same method without initial OD. Xylitol residues in the dried product were at a level that guaranteed consumer safety, understood as not exceeding the dose resulting in gastric problems. The safety of the level of xylitol residues in dried apples was confirmed by Kowalska *et al.* (2019). However, it was highlighted that the dried fruit should be considered as a snack and consumed in the amount of 20-60 g a day, i.e., in portions that are available on the market for other dry snacks.

Erythritol (1,2,3,4-butanetetrol) is a stable compound that does not decompose in either acid or alkaline environments. Due to its small molecular size, erythritol has a high level of digestive tolerance in comparison to other polyols. As the molecular weight of erythritol (122.12 g/mol) is almost three times lower than sucrose's molecular weight (342.20 g/mol), it could be an alternative osmotic agent to sucrose (Cichowska *et al.*, 2019a). During OD of apples in 30% (w/w) solutions (a solution/fruit mass ratio was 4:1) at 40°C Kowalska *et al.* (2019) showed that the use of erythritol causes stronger mass exchange effect than the use of sucrose, xylitol and maltitol as well as it decreases the value of water activity the most. Moreover, erythritol caused stronger diffusion of sugars from the tissue to the solution than other substances due to the higher osmotic pressure. Additionally, Cichowska *et al.* (2019b) stated that during OD of apples in erythritol solution, there is an increase of brightness which is considered as a positive. The brightness could be higher due to sugar coating, which appeared as a result after a process of OD. This substance has a high crystallization capacity. Cichowska-Bogusz *et al.* (2020) also observed that the microwave-vacuum drying time was shorter when apples were dehydrated previously in erythritol or sucrose solution (their efficiency was the same). However, the OD in erythritol as pre-treatment was not effective in case of convective drying. The use of erythritol similarly to the use of xylitol in production of dried apples causes a noticeable cooling/refreshing effect felt in the mouth and it is good in taste. It might be a safe and healthy snack with reduced calorie, when is consumed in recommended amount. Moreover, dried apples that were previously osmo-dehydrated in erythritol characterized by the best hygroscopic properties among tested polyols. This results in the best storage stability of the dried product, due to the low ability to absorb water from the environment.

Sorbitol is a 6-carbon sugar alcohol and that is the polyol mostly found in nature. Sorbitol has low calorie (2.4 kcal/g) and the sweetening power up to 70 % of the sweetness of sucrose (Brochier *et al.*, 2015). A molecular weight that equals 182.17 g/mol. A lower molecular weight of the solute results in a greater driving force for the process (Mendonça *et al.*, 2017). Therefore, sorbitol is a good alternative to replace the sucrose as the osmotic agent in OD which has been shown in studies conducted by Assis *et al.* (2017) and Hui *et al.* (2017). The low molecular weight of sorbitol resulted also in the reduction of water activity of pineapple osmo-dehydrated in sorbitol in comparison to the OD in sucrose, which is important in extension the shelf life of the product (Hui *et al.*, 2011).

Assis *et al.* (2017) studied the effect of the OD with sorbitol on convective drying. The authors found that the use of sorbitol as osmotic agent did not affect the water loss rate in the hot air-drying process, in comparison to sucrose. However, sorbitol was more effective in reducing the air-drying time and water activity of dried products. It may be explained by the fact that osmotically dehydrated samples with sorbitol solutions presented already lower values of water activity before the hot air drying than the samples osmotically dehydrated with sucrose solutions.

The sensory analysis conducted by Sritongtae *et al.* (2011) showed that partial replacement the sucrose solution with sorbitol at 10 or 15% (w/v) did not cause a significant difference in sample's colour and get worse the quality of the obtained dried products. However, in the study of Vilela *et al.* (2016), in which sensory profiles of three types of candied fruits (pineapple, orange peel and citron) were analysed, the use of sorbitol in the previously conducted OD resulted in significant differences of the textural and sensorial properties of the final products when compared to the traditional process. The sensory evaluation was ambiguous as some characteristics were considered as positive but others can be depreciated by consumers, so consumer tests should be conducted.

Conclusions

The solutions of polyols as maltitol, sorbitol, xylitol and erythritol could be alternatives to the solution of sucrose in the OD process. The mass transfer rates are satisfactory for all the substances when the same solution concentrations are compared. The molecular weight is an important parameter that determines the efficiency of mass transfer kinetics as well as the reduction of water activity and the sugar diffusion to the plant tissue. The molecular weights of erythritol, xylitol, sorbitol and maltitol amount 122.10, 152.15, 182.17, and 344.31 g/mol, respectively. Therefore, erythritol was the most efficient osmotic agent, then xylitol, sorbitol and maltitol, respectively. The use of polyols in the OD process before drying might positively affect the drying time or retention of bioactive compounds in the plant tissue. The replacement of sucrose with erythritol or xylitol results in a noticeable cooling/refreshing effect felt in the mouth, the lower calorific value, and the safe level of polyols in the final products.

Abstract

Maize is the most commonly consumed cereal in the world. Its various compounds are associated with nutraceutical properties and health-promoting benefits. Therefore, maize seeds are considered to be functional food with high antioxidant activities. The drying conditions have a huge impact on maintaining the seed quality. This study aimed to evaluate the effect of temperature on the antioxidant activities of white and red maize (*Zea mays* L.) cultivars. A drying time of 1 h at a temperature of 45 °C was tested. The antioxidant activity expressed in percentages was evaluated as radical scavenging activity using the DPPH (2,2-diphenyl-1-picrylhydrazyl) reagent. The results revealed that the antioxidant activity of the dried white seeds (74.08 %) was not significantly different ($p>0.005$) with respect to the un-dried seeds used as control (72.6 %). Contrary, drying at 45 °C caused a significant ($p<0.005$) rise of antioxidant activity in the red-coloured seeds' being 85.95 % and 92.25 % before and after the treatment, respectively. The obtained results show that the antioxidant activity may be a reliable indicator for the estimation of the cereal seeds' quality, which is useful in the food industry and agriculture.

Introduction

Maize (*Zea Mays* L.) is a principal cereal crop cultivated worldwide and one of the major food sources. High diversity exhibited in cultivated maize is recognized phenotypically by different seed colours, shapes, and sizes, as well as differences in the cob and plant characteristics (Martínez-Martínez et al., 2019). The quality of pigmented grain could be correlated to the antioxidant activity (AA%). Secondary metabolites, phenolics, and carotenoids found in pigmented maize are attributed to the high antioxidant properties of their seeds. The most commonly present phenolic compounds in the seeds are flavonoids, which are responsible for the different coloration of plants, and phenolic acids (Žilić et al., 2012). The color of purple corn is due to anthocyanin which has been using for coloring beverages, jellies, candies (Vilcacundo et al., 2020).

Health promotion benefits of edible plants are correlated to biologically active compounds, called antioxidants, that protect the cells from the harmful effect caused by active oxygen species and prevent the development of various diseases (Harakotr et al., 2014; Zargoosh et al., 2019). Beneficial health effects of nutrients that feature high antioxidant capacity are considered to be functional food ingredients.

Drying cereal seeds is a method of preservation common in the food industry used also to produce food with desired characteristics. During this process, retained moisture is evaporating up to a certain level, while the storage period of dried products is increased (Hihat et al., 2017).

Effects of drying of seeds were investigated experimentally in several separate research studies and the obtained conclusion was that increasing drying temperature reduces nutraceutical properties. Other studies reported the effects of different drying techniques on the antioxidative activity of seeds (López-Vidaña et al., 2017).

In the present work, the effect of drying temperature on antioxidant activity of different coloured maize seeds (white and red) was investigated. The impact of drying was evaluated using DPPH assay. The difference in antioxidant activity between treated (dried at 45 °C) and untreated (control) seeds of two different coloured maize variants was detected.

Material and Methods

Sample preparation

The seed material was supplied by the Maize Research Institute (Zemun Polje, Serbia). Experimetns were carried out at the Institute for Multidisciplinary Research, University of Belgrade. Half of the maize seeds (both white and red coloured) were dried for 1 h at 45 °C in an oven (Daihan Scientific, South Korea) while the other half was stored at room temperature (25 °C) to be used as control. After the heat treatment, maize seeds were homogenized. The seeds were grinded in a mill, followed by further powdering with liquid nitrogen in a mortar with pestle, and used for detection of antioxidant activity with DPPH assay.

DPPH Assay

Antioxidant activity (AA) of different coloured maize seeds, before and after drying, was measured by employing a 2,2-diphenyl-1-picrylhydrazyl (DPPH, Sigma-Aldrich, St. Louis, MO, USA) assay. DPPH was dissolved in 96 % ethanol to a final concentration of 0.4 mM. Freshly prepared DPPH solution was stored in the dark at 4 °C until use. The samples of powdered maize seeds were immersed in 3 ml of ethanol (70 % v/v) and shaken on a vortex mixer for a few seconds. After extraction, 1 ml of 0.4 mM DPPH solution was added to each sample to a final concentration of 0.1 mM. The reaction was carried out while the mixture was constantly shaken and incubated for 30 minutes in the dark. Absorbance was measured at 517 nm on a UV-VIS microplate reader (Tecan Infinite M Nano+, Switzerland). Pure deionized water was considered as a blank while the control consisted of 0.1 mM DPPH in 96 % ethanol solution. Antioxidant activity was calculated as a percentage of depleted reagent and the results were presented as a mean value of four replicates (n=4) and the standard error. The Mann-Whitney U nonparametric test has been used for tested the means values.

Results and Discussion

Obtained results of the antioxidant activity of the two analyzed maize seeds dried at 45 °C compared to the control (untreated) seeds are presented in Figure 1. Drying treatment (1h at 45 °C) of red coloured seeds significantly (P<0.05) increased their AA to 92 % as compared to AA of 86 % recorded in control samples. Contrary to the red pigmented seeds, there is no significant difference (P>0.05) in AA between treated (74.08 %) and control (73 %) seeds of white coloured maize seeds.

Red pigment of the maize seed is attributed to a high content of a class of flavonoids called anthocyanins, with high antioxidant and antiradical activities, located in aleurone layer or pericarp (Žilić et al., 2012). These compounds may contribute to an increase in antioxidant activity in red pigmented seed after exposure to temperature treatment at 45 °C. These red pigmented seeds might be used for producing of the sprouts which have attracted the interest of the food industry for the nutritional value of their components and their biological properties such as the antioxidant activity.

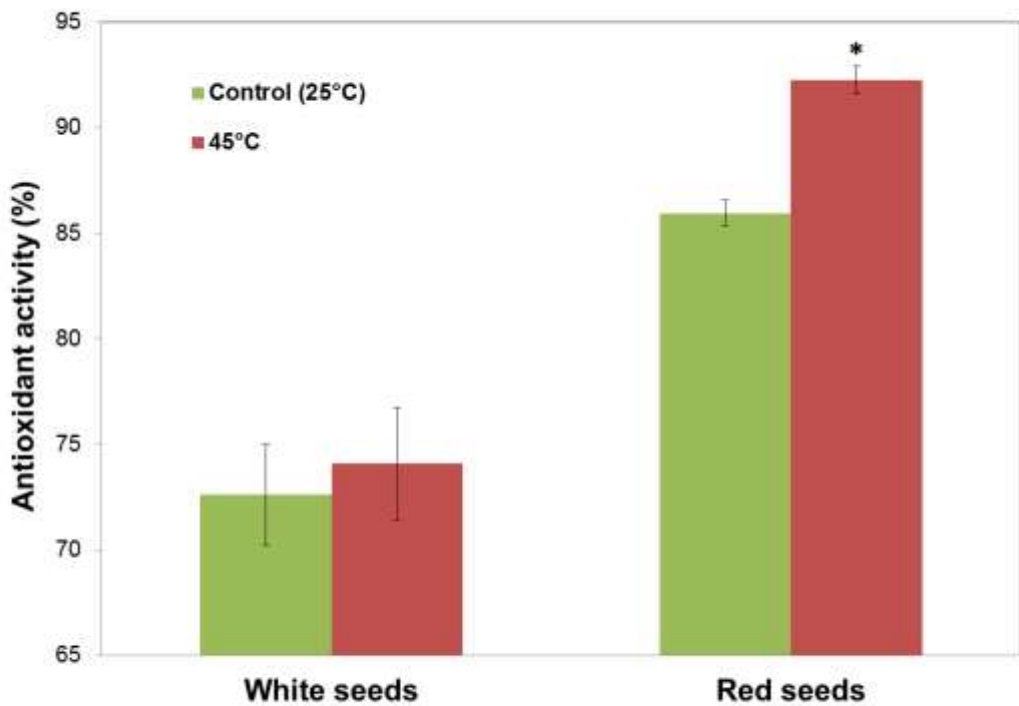

Figure 1. Antioxidant activity of white and red maize seeds after 1 h drying at 45 °C compared to the control (seeds stored at room temperature, 25 °C). Values are given as the mean percentage ± SD (n=4). Asterisk (*) indicates a significant difference at $p<0.05$.

Conclusions

Our results indicate that the heat treatment of the maize seeds (1 h-drying at 45 °C) increased antioxidant activity compared to the control samples. The difference is statistically significant ($p<0.005$) only for red pigmented maize. The two different coloured maize types have different phytochemical profiles, therefore corresponding antioxidant activity differs significantly between the two seed types.

DISSIPATION DYNAMICS OF ANTHRANILIC DIAMIDE INSECTICIDES IN SOME FRUITS

Sanja LAZIĆ, Dragana ŠUNJKA, Slavica VUKOVIĆ, Antonije ŽUNIĆ, Dragana BOŠKOVIĆ, Aleksandra ALAVANJA

Abstract

Nowadays for the control of a wide range of insects pests, different chemical groups of insecticides are available on the market, but in spite of that inappropriate agricultural practice often leads to pest resistance development, as well as various harmful effects on human health or the environment. To overcome these, a few relatively new class of insecticides, as spinosines and anthranilic diamides, are developed. However, even if they are applied in accordance with good agricultural practices, the pesticides may leave residues, and cause side effects on human health. Due to this, it is very important to evaluate the persistance of pesticides in the agroecological conditions where they are applied mostly. In this paper behavior and the fate of the anthranilic diamides, chlorantraniliprole and cyantraniliprole, in peach, sweet cherry and pear fruits were evaluated. Field trials were conducted at different localities in Vojvodina, Serbia. Products based on cyantraniliprole and chlorantraniliprole were foliar applied at the recommended rate, for the control of main peach, sweet cherry, and pear pests. The extraction procedure of insecticides involved a widely used QuEChERS-based method, while residues were analyzed by HPLC-DAD. Methods were validated according to SANTE criteria. The half-life (DT_{50}) of cyantraniliprole in peach and sweet cherry fruits obtained in this study was 2.5 and 3.0 days, respectively. Furthermore, chlorantraniliprole dissipated rapidly in peach and pear fruits, with half-lives of 3.15 and 2.76 days. This study suggests that chlorantraniliprole and cyantraniliprole could be safely used in peach, sweet cherry and pear orchards, with an important role in the control of insecticide resistance.

Keywords: *anthranilic diamide, dissipation dynamic, peach, sweet cherry, pear.*

Intoduction

Contemporary agricultural production, with high, satisfactory yields is almost impossible without the use of plant protection products (PPP) and suitable agrotechnical measures. On the market, currently are available different chemical groups of insecticides, but in spite of that, unsuitable agricultural practice often leads to pest resistance development, as well as various harmful effects on human health or the environment. Nowadays, a few relatively new class of insecticides, as spinosines and anthranilic diamides, with the potential to replace insecticides such as neonicotinoids and pyrethroids in pest management are developed (Schmidt-Jeffris and Nault, 2016). Anthranilic diamides, with a novel mode of action, are highly effective in pest control, which is especially important for reducing pest resistance. The ryanodine receptor is the target site of action of these compounds. They intensely activate this receptor, by releasing stored calcium from the sarcoendoplasmic reticulum, which causes a disorder in the regulation of muscle contraction (Cordova et al., 2006). Active ingredients chlorantraniliprole,

cyantraniliprole, flubendiamide, cyclaniliprole and tetraniliprole belong to this class. Chlorantraniliprole and cyantraniliprole, second-generation anthranilic diamide insecticides, are two active ingredients that are currently registered for use in many crops. The systematic activity and residual control make them ideal for controlling a wide range of pests in many different crops. Anthranilic diamides are also considered to be fairly selective, with low toxicity to many non-target and beneficial insects (Schmidt-Jeffris and Nault, 2016). These two insecticides are used in very low application rates for controlling rangde of pests belonging to Lepidoptera order and some other insects belonging to different orders. They act contact and digestive, with ovicidal, larvicidal activity on all larval stages, as well as adulticidal activity. In Serbia, cyantraniliprole and chlorantraniliprole based insecticides are registered for the control of *Grapholita molesta*, *Anthonomus rubi*, *Rhagoletis cerasi*, *Cacopsylla pyri*, *Lobesia botrana*, *Clysia ambiguella*, *Cydia pomonella*, *Lithocolletis blancardella*, *Delia antique*, *Pieris rapae*, Thysanoptera order, *Helicoverpa armigera*, *Trialeurodes vaporariorum*, *Tuta absoluta*, *Leptinotarsa decemlineata* in peach, raspberry, sweet cherry, pear, grape, apple orchards and, onion, cabbage, cucumber, paprika, tomato, and potato crops (Plant Doctor, 2021).
However, even if they are applied in accordance with good agricultural practices, the pesticides may leave residues (Lazić et al., 2012). This is especially important for the fruits and vegetables consumed mostly fresh. Factors such as climate, soil, application rates, etc., strongly influence pesticide fate in the environment and agricultural products, thus it is important to evaluate persistence under agro-ecological conditions where they are applied. In this paper, authors were evaluated behavior and the fate of the anthranilic diamides, chlorantraniliprole and cyantraniliprole, in peach, sweet cherry and pear fruits.

Material and methods

Field experiment in peach orchards. Field trials were set up at the localities Čerević and Mala Remeta, Serbia, during 2017. The experiments were conducted according to the standard EPPO methods for the experimental design, data analysis, insecticide efficiency, and phytotoxicity (2014, 2015). Products based on cyantraniliprole (100 g a. i./l, SE) and chlorantraniliprole (200 g a. i./l, SC) were foliar applied at the rate of 0.6 and 0.2 l/ha, respectively with water consumption of 1000 l/ha. The orchards were 5 years old with the peach cultivar Royal gem. The treatment was conducted for the control of the first generation of the *G. molesta*. At the time of the treatment, the peaches were in the BBCH 74 phenophase. The experiment was set up in four replications, with the layout of the basic plots according to a randomized block system. To evaluate the cyantraniliprole and chlorantraniliprole residues in the peach fruits, fruit samples were randomly picked from each repetition and delivered to the laboratory. For the determination of cyantraniliprole residues, the fruit samples were taken 1 h after the pesticide application and, during the next 7 days starting from the first, while for the determination of chlorantraniliprole residues, samples were taken 1 h after the application and after 1, 3, 5, 7, 9, 11, 13 and 15 days.

Field experiment in sweet cherry orchard. For the dissipation dynamic analysis of insecticide cyantraniliprole in sweet cherry fruits, the experiment was set up in 2018 at the locality Čerević in Vojvodina Province, Serbia. The trial was created according to EPPO methods, due to the fruit phenophase and biology of treated pests. Insecticide based on cyantraniliprole (100 g/l, SE) was applied at the recommended rate of 0.75 l/ha, with 1000 l water/ha, for the control of *R. cerasi* in sweet cherries. Randomly picked fruit samples were taken right after the drying deposit and every next day, for seven days.

Field experiment in pear orchard. To determine the residues and dissipation dynamics of the insecticide chlorantraniliprole in pear fruits, the experiment was set up according to standard EPPO methods, at the locality of Kula (Vojvodina, Serbia) in 2019. The treatment was performed foliar with water consumption of 1000 l/ha when the pears were in the phenophase BBCH 74. The plot was under the pear cultivar Williams and treated with PPP (45 g/l chlorantraniliprole, 18 g/l abamectin), at a concentration rate of 0.1%. Sampling was performed one hour after the treatment, and after 1, 2, 4, 6, 8, 10, 12, and 14 days.

In all experiments, 500 g of fruit samples were collected and transported to the laboratory, and stored at a temperature of -18 ºC until the analysis. Also, the untreated samples were collected and used as a control for the validation of the methods.

Extraction and determination. The extraction procedure of insecticides involved a widely used QuEChERS-based method (EN 15662) (Anastassiades et al. 2003), while residues were analyzed by high-performance liquid chromatography (HPLC) with a diode-array detector (DAD) (Figure 1). Methods were validated according to SANTE/1183/2017 and SANTE/12682/2019 criteria.

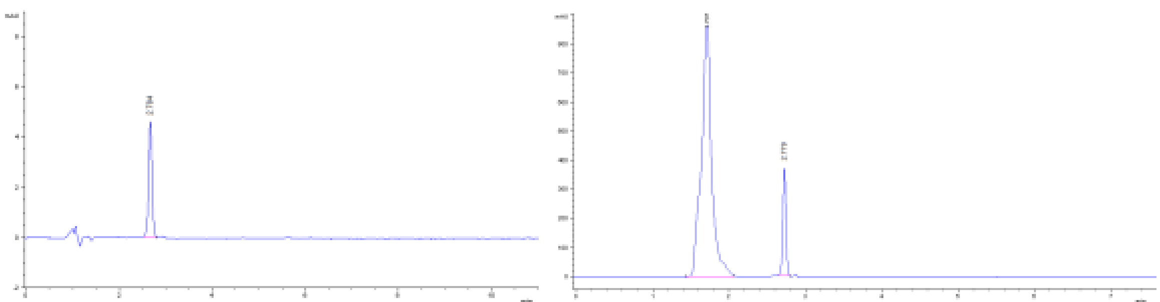

Figure 1. Chromatogram of cyantraniliprole standard solutions in acetonitrile and sweet cherry sample

Results and Discussion

For the analysis of the cyantraniliprole and chlorantraniliprole residues in the fruits, the methods validated in accordance with the requirements of the SANTE/1183/2017 and SANTE/12682/2019 standard were applied.

Table 1. Half-life of the cyantraniliprole and chlorantraniliprole in peach fruits

Insecticide	**Regression equation**	**Correlation coefficient**	**Degradation constant**	**Half life, DT_{50} (days)**
Cyantraniliprole	$y=1.46e^{-0.28x}$	0.28	0.965	2.5
Chlorantraniliprole	$y=2.32e^{-0.22x}$	0.22	0.961	3.15

The concentration of cyantraniliprole in the peach fruits was at the EU MRL (Commission Regulation EU 2018/832) of 1.5 mg/kg, immediately after the drying of the deposit (1.46 mg/kg), while at the end of pre-harvest interval (PHI), cyantraniliprole concentration was 0.19 mg/kg. Using these results, the calculated half-life (DT_{50}) of cyantraniliprole in peach fruits was 2.5 days (Table 1).
After the application of chlorantraniliprole, the maximum level of the residues in the peach fruits was determined after drying the deposit and it was 2.32 mg/kg. The study established that the level of chlorantraniliprole was below the MRL of 1 mg/kg seven days after the application. During the research, it was found that the chlorantraniliprole content in the samples was progressively decreasing. After the PHI of 14 days, the level of chlorantraniliprole was 0.12 mg/kg, which is significantly below the allowed level. The half-life of chlorantraniliprole, calculated based on the residue content, with the use of chlorantraniliprole in the amount of 0.2 l/ha, was 3.15 days.
Over the past few years, a number of studies were conducted with the aim of assessing the behavior of cyantraniliprole and chlorantraniliprole in crops, but none of them were conducted in peach fruits. Hong-Mei et al. (2014) established that the half-life of cyantraniliprole in paprika ranged from 9.2–11.2 days. Also, Sun et al. (2012) reported that the half-life of cyantraniliprole ranged from 2.9–6.4 days in the pak choi. In tomatoes, the half-life of cyantraniliprole was 2.6 days, with a PHI of 3 days, after treatment at the recommended dose (Malhat et al. 2018). According to Hu et al. (2013), the DT50 values of cyantraniliprole were 1.1 and 2.7 days in watermelons. The cyantraniliprole half-lives determined in rice straw at three localities were 3.2, 4.4 and 6.3 days (Zhang et al. 2013). According to the available literature, this was one of the first research of cyantraniliprole and chlorantraniliprole dissipation dynamics in peach fruits. Based on the obtained results, it can be concluded that cyantraniliprole and chlorantraniliprole in the peach fruits decrease rapidly and have low half-life values. Therefore, it is recommended to use cyantraniliprole and chlorantraniliprole-based insecticides for control the of *G. molesta* in peach orchards.

Table 2. Half-life of the cyantraniliprole in sweet cherry fruits

Insecticide	**Regression equation**	**Correlation coefficient**	**Degradation constant**	**Half life, DT_{50} (days)**
Cyantraniliprole	$y = 4.57e^{-0.23x}$	0.23	0.960	3.0

After drying the deposit, the amount of cyantraniliprole residues in sweet cherry fruits was 4.75 mg/kg (Table 2). In sweet cherry fruits, the initial concentration of cyantraniliprole residues was below the EU MRL of 6 mg/kg (Commission Regulation EU 2018/832). Analysis has shown a decrease in the amount of residues, with 0.80 mg/kg of cyantraniliprole in the fruit sample collected last day of the sampling period. The performed study proved that insecticide cyantraniliprole half-life in sweet cherries, was 3 days. The PHI of 7 days was correctly prescribed, however very fast cyantraniliprole degradation allows the use of this product, if needed, even shortly before harvesting, without the risk of the high level of residue content.
Lee et al. (2019) conducted an experiment about the dissipation of cyantraniliprole and its metabolite IN-J9Z38 in proso millet during cultivation. There was a 91.1 and 89.1% decrease in cyantraniliprole residues in grain and straw, respectively, from the initial residues (14-7 days) to

the final plot (40-30 days before harvest). The calculated half-life of cyantraniliprole was 11.3 and 9.4 days for grain and straw, respectively.

Table 3. Half-life of the chlorantraniliprole in pear fruits

Insecticide	Regression equation	Correlation coefficient	Degradation constant	Half life, DT_{50} (days)
Chlorantraniliprole	$y = 4.95e^{-0.25x}$	0.25	0.988	2.76

Since the use of chlorantraniliprole is also allowed in control of pear orchards against *C. pyri*, the method for the determination of its residues in pear fruits was validated. The maximum level of chlorantraniliprole residues in pear fruits was detected after drying the deposit and it was 4.95 mg/kg (Table 3). By analyzing samples collected during the 14 days, a gradual decrease in residue concentration was observed. In Serbia and EU prescribed PHI for chlorantraniliprole in pear orchards is 14 days, while the MRL in pear fruits is 0.5 mg/kg. During this experiment it was determined that the level of this insecticide was below MRL after six days from the day of application. At the end of the PHI the level of chlorantraniliprole in pear fruits was 0.16 mg/kg, which is significantly below the MRL. At the end of the research, the half-life for chlorantraniliprole in pear fruits was calculated, and it was 2.76 days.
Vijayasree et al. (2013) conducted research about chlorantraniliprole residues in cowpea fruits. It was concluded that the concentration of chlorantraniliprole dissipates rapidly in this crop. The calculated half-life was 1.31 days. Kar et al. (2013) conducted an experiment with three applications of chlorantraniliprole at the recommended dose and with a doubled recommended dose. The deposits were found to be less than MRL, which is 2 mg/kg. Residue concentration dissipated below the limit of quantification (0.1 mg/kg) after 3 and 5 days at recommended and double doses respectively. The calculated half-life was 1.36 days following application at the recommended dose while the prescribed waiting period was 1 day. A study about the dissipation of chlorantraniliprole, chlorpyrifos-methyl and indoxacarb in apples was conducted by Szpyrka et al. (2017). The half-lives of chlorantraniliprole, chlorpyrifos-methyl and indoxacarb were 16–17, 4–6 and 20–24 days, respectively. The initial residue levels declined gradually and reached the level of 0.01 mg/kg in 1 month for chlorpyrifos-methyl, 2 months for chlorantraniliprole and 2.5 months for indoxacarb, while MRL was 0.01, 0.5 and 0.5, respectively. By monitoring the degradation dynamics of chlorantraniliprole in grapes in Egypt, a half-life of degradation of 2.7 days was determined (Malhat, 2012).
Based on the available literature, there are no data related to the half-life of degradation of chlorantraniliprole in pear fruits, as well as its degradation dynamics in this fruit species.

Conclusions

This study indicates that anthranilic diamide insecticides, chlorantraniliprole and cyantraniliprole, could be safely used in peach, sweet cherry and pear orchards in the recommended dose in our agroecological conditions. Chlorantraniliprole and cyantraniliprole insecticides dissipated rapidly, with half-lives between 2.5 and 3.15 days. This study suggests that anthranilic diamide insecticides, chlorantraniliprole, cyantraniliprole could be safely used in peach, sweet cherry and pear, with an important role in the control of insecticide resistance.

Abstract

Good microbiological quality of irrigation water has a great importance for health-safety agricultural production. In order to avoid microbiological contamination of crops, the microbiological quality of the water supplying the crops should be monitored. The aim of this paper is investigation of the microbiological quality of the water from 5 channels and one pool from the municipality of Surcin which can potentially be used for irrigation, as well as determination the microbiological quality of the vegetables which are irrigated from the pool. Microbiological parameters of water and vegetables quality are determined by the standard methods prescribed by the Rulebook on parameters of surface waters (MPN method) and Rulebook of food hygiene of production of Republic of Serbia. The values of the tested parameters in one of the five investigated channels, Surcin channel water, were higher in relation to the limit values of the Rulebook. The increased levels of total and fecal coliforms, *Escherichia coli*, *Salmonella,* and *Shigella* were found. The Surcin channel water requires appropriate treatment before its use for crop irrigation. The values of other tested waters did not go beyond the limit values prescribed by the Rulebook, but for the safer agricultural production their treatment is recommended. Microbiological analyzes of vegetables were also done. The total and fecal coliform bacteria, as well as *E. coli*, *Salmonella* sp. and *Shigella* sp., were not detected in the tested vegetable samples.

Key words: *microbiological quality of irrigation water, coliform bacteria, E. coli, Salmonella sp.*

Introduction

Consumption of fresh fruits and vegetables is essential for healthy nutrition and prevention of various diseases The World Health Organization (WHO) underline necessary for consumption at least 400 g of raw fruits and vegetables daily. However, these products could be microbiologically contaminated and pose a risk for human health. Based on that, it is necessary to take care about microbiological safety of fresh vegetables and fruits. It implies the absence of human pathogens, because consuming raw vegetables that are microbiologicaly contaminated can cause many health problems and sometimes can even lead to death. Human pathogens could be associated with gastrointestinal diseases and cause many health diseases such as dysentery, hepatitis, hemolytic uraemic syndrome, typhus (Halablab et al., 2011).

Microbiological contamination of fresh vegetables can occur at any point of production chain and the sources of contamination could be numerous, but one of the most common is contaminated irrigation water or faecal contamination from humans or animals (Halablab et al., 2011). The surface waters are used for irrigation but they are very often polluted (Uyttendaele et

al., 2015) and that contamination comes from runoff, animal faeces, sewage (Gemmell and Schmidt, 2013).
Irrigation water is the good environment for many human pathogens such as viruses (adenovirus, norovirus, enterovirus, rotavirus), human pathogen bacteria (*Campylobacter sp*., *E. coli*, *E.coli* O157: H7, *Bacillus cereus*, *Salmonella sp*., *Shigela sp*.) (Ahmed et al., 2014). These microorganisms are able to colonize vegetable plant tissue through irrigation water and contaminate edible parts of plants because plant root niches are a good environment for their survival. Thus, irrigation water from two rivers in Norway had higher level of *E. coli* compared to national regulatory standard (Paruch et al., 2015). The research of Mcheik et al., (2018) showed huge microbiological contamination in the 33 well water samples taken from 5 sites. All water samples were contaminated with total coliforms and most of them with fecal coliforms, *E. coli* and *S. aureus*. These waters were used for irrigation which caused negative effect on microbiological safety of vegetables. The high microbial loads of coliforms and *S. aureus* were noticed at lettuce, mint, dandelion, spinach, coriander and radish. Such a large number of bacteria on mentioned leafy species of vegetables is a consequence of the larger surface area exposed to contaminated irrigation water. Also, the reason for this is entrance and penetration human pathogen bacteria in plant inner tissues, root and leaves (Kljujev et al., 2018a; Kljujev et al., 2018b). Also, there is evidence that surface of leafy vegetables could be a host for potential human pathogens (Dees et al., 2015). The enteric-bacterial-contaminated irrigation water has impact on the microbiological safety of vegetables. The large number of coliforms and *E. coli* in channel irrigation water leads to contamination vegetables. The high number of coliforms and *E. coli* was at spring onion, cabbage, carrot and tomato (Douti et al., 2021).
It is very important to take care about microbiological quality of irrigation water (Jeong et al., 2016; De Pascale et al., 2011), especially those which is used for irrigation of vegetables that are eaten in raw. It is necessary to regularly control these waters in order to enable safe vegetable production.

Materials and methods

Sampling of water and vegetables for microbiological analysis was done on the territory of the Surcin, municipality near Belgrade in Serbia. The microbiological analysis included 6 water samples and 3 vegetable samples. Out of 6 water samples, 5 samples were originated from channel water and another one was from pool used for irrigation. The locations for water samples were: Channel ”Surcin”, Channel ”Donje polje”, Channel between P.S ”Donje polje” and P.S Petrac”, Channel ”Petrac”, Channel ”Galovca”, Pool ”I.S.C.”. The lettuce sample was taken from open field but hot peppers and cucumbers samples were taken from greenhouse. Analyzed vegetables are irrigated with water from Poll ”I.S.C.”.
The channel "Galovica" covers an area of about 70 000 ha and its capacity is 24 m^3 of water per second. It flows into the river "Sava" near the settlement of New Belgrade and it brings water to the "Galovica" pumping station. The channel "Petrac" covers an area of 8 000 ha, it has capacity 8 m^3 water/sec. and its length is 24 496 m. Both channels ("Galovica" and "Petrac") run in parallel at a distance of 65 m from each other and they are interconnected by a connecting side channel for water inlet and outlet. The water in these channels represents an excess of water and has a important role in irrigation especially in summer. There are two big companies (PKB Corporation A.D. Belgrade and Farm "July 7"-Jakovo) which use waters of Channel "Donje polje'' and Channel between P.S ''Donje polje'' and P.S ''Petrac'' for irrigation their fields with

corn, sunflower and other mainly industrial plants during the summer. Also, the water sample was taken from the pool of the agricultural farm "Iceberg Salat Center". This company uses water from well of 25 meters depth for irrigation.

The microbiological quality of lettuce (*Lactuca sativa*), hot pepper (*Capsicum annuum*) and cucumber (*Cucumis sativus*) was examined. Vegetable samples were taken from the agricultural areas of the company "Iceberg Salad Center". Lettuce was grown in the open field and hot peppers and cucumbers were grown in greenhouses.

Microbiological analysis included determination of: aerobic heterotrophs (psychrophilic and mesophilic), total and fecal coliforms, *Escherichia coli*, *Salmonella* sp., *Shigella* sp. Determination of indicator microorganisms (their presence and number) was done inoculated appropriate nutrient media by direct and diluted samples. The number of heterotrophs was determined on Nutrient Agar (Torlak, Serbia). The water samples were diluted in Peptone Water (Torlak, Serbia) and after medium inoculation, incubation was done at 26°C, 5-7 days (mesophiles), 22°C, 5-7 days (psychrophiles). After incubation, colony counts were done.

The detection of total, fecal coliforms and *E.coli* was done using MPN method. A series of test tubes with MacConkey Broth (Torlak, Serbia) and Durham tubes were inoculated with 1 ml of samples diluted in peptone water, and it was done in triplicate. Incubation was done at 37°C for 48 hours. The tubes with changed medium color and bubbles in Durhams were taken as positive. Based on the number of positive tubes, the most probable number of coliform bacteria in 100 ml of water is determined using the MPN table. The confirmation test using EMB agar (Biomerieux, France) was done. The detection of *Salmonella* sp. and *Shigella* sp. was done using Selenite Broth (Biomerieux, France) for enrichment and SS Agar (Biomerieux, France) for confirmation. Incubation was done at 37°C for 24^{h}. The appearance of typical black colonies is confirmed as *Salmonella sp*. and uncolored and colonies were estimated as *Shigella sp*. The vegetable samples were tested to presence of aerobic heterotrophs, total and fecal coliform bacteria, *E. coli*, *Salmonella sp*. and *Shigella sp*. The 20g of vegetable pieces was homogenizated with Peptone Water on a shaker 250 rpm for 30 min. The 1 ml of dilution was used for inoculation of Nutrient Agar and selective media MacConkey Broth, Selenite Broth, SS Agar, EMB Agar. Incubation was done at 22°C, 37°C and 44°C for $24 – 48^{h}$. The number of bacteria is represented as cfu/ml and MPN/100 ml for water samples and cfu/g DM and MPN/gDM (DM- Dry Matter) for vegetable samples. The obtained results were interpreted according to Rulebook on parameters of ecological and chemical composition of surface waters and parameters of chemical and quantitative status of groundwater ("Official Gazette of RS", no. 74/2011) and Rulebook on general and special conditions of food hygiene at any stages of production, processing and trade ("Official Gazette of RS", No. 72/10).

Results and discussion

Aerobic heterotrophic bacteria are indicators of water status and quality. Their presence in large numbers indicates that the water is loaded with biodegradable organic pollutants. Our results showed that the number of total aerobic heterotrophs depends on the sampling location and the highest number was detected in Channel "Surcin".

Table 1 . The number of aerobic heterotrophs in water samples

Location	Unit	Temperature (t^o)	
		22^{o}C	37^{o}C
Channel "Surcin"	cfu/ml	551	368
Channel "Donje polje"	cfu/ml	14	14
Channel between P.S "Donje polje" and P.S "Petrac"	cfu/ml	338	99,5
Channel ''Petrac''	cfu/ml	24	36
Channel ''Galovca''	cfu/ml	12	9,5
Pool ''I.S.C.''	cfu/ml	24,5	18.5

The number of psychrophilic bacteria was 551 cfu/ml, and mesophilic was 368 cfu/ml which indicate that water is loaded with organic matter. The smallest number of heterotrophic bacteria was noticed in Channel "Galovica" (12 cfu/ml and 9.5 cfu/ml.) (Table 1). The results of the tested vegetable samples showed the high number of aerobic heterotrophs at lettuce (103 cfu/g DM and 54 cfu/g DM) (Table 2).

Table 2. The number of aerobic heterotrophs on vegetable samples

Vegetable sample	Unit	Temperature (t^o)	
		22^{o}C	37^{o}C
Lettuce	cfu/g DM	103	54
Hot pepper	cfu/g DM	14,5	0
Cucumber	cfu/g DM	9	5

Determination of total coliforms (TC), fecal coliforms (FC) and *E.coli* is important for microbiological quality of irrigation waters and vegetables. The coliform bacteria indicate to fecal contamination. The highest number of coliform bacteria (total and fecal) was detected in water of Channel "Surcin", more that 1 100 000 (MPN/100 ml) and according to the Rulebook on parameters of ecological and chemical composition of surface waters and parameters of chemical and quantitative status of groundwater ("Official Gazette of RS", no. 74/2011) this water belongs to IV-V class.

Based on our results, the water of Channel "Surcin'' should not be recommended for irrigation crops without appropriate treatment. Channel "Surcin" is located about 200 m from the municipality center near markets, feed factory, livestock farm and many other facilities. It is assumed that all waste, generated from the mentioned facilities, arrive into the channal, as well as the local population often leave their waste into the Channel "Surcin". Also, there is an inflow of sewage water into the Channel "Surcin" under the bridge near downtown which indicates that the water is much polluted.

The water from Channel "Donje polje'', Channel between P.S ''Donje polje'' and P.S ''Petrac'', Channel ''Petrac'' and Pool ''I.S.C.'' belong to II and III class according to the above-mentioned Rulebook. These waters could be used for irrigation according to the Regulation on Water Classification ("Official Gazette of RS", No. 5/68). The smallest number of coliforms was

noticed in Channel ‘’Galovca’’ water 430 MPN/100 ml which means that this water belongs to I-II class and it is safe for irrigation crops (Table 3).
Also, the number of fecal coliforms as well as *E. coli* was the highest in Channel “Surcin’ water. The *E. coli* was also detected in waters of Channel “Donje polje’’ and Channel between P.S‘’Donje polje’’ and P.S‘’Petrac’’ but its number was much smaller. Other investigated waters were free for *E. coli*. Our results are in agreement with other authors which detected total coliforms in channel water ranged between 3.74 and 3.92 (logCFU/100ml) while the fecal coliforms results ranged from 3.39 and 3.82 (logCFU/100ml), respectively. The *E. coli* ranged from 3.17 to 3.54 (logCFU/100ml), while *Salmonella* sp. was not detected (Douti et al., 2021).
According to above-mentioned Rulebook (‟Official Gazette of RS‟, No. 74/2011) for presence of fecal coliforms in groundwaters, Channel ‘’Surcin” water belongs III-IV class. The large number of *E. coli* in this water indicates its huge contamination with fecal matter and it will be a big risk if this water should be used for irrigation, esspecially vegetables which are eaten in raw. The presence of *Salmonella sp.* and *Shigella sp.* was confirmed in waters of Channel ”Surcin’’ and Channel “Donje polje’’ (Table 3). The study of Mcheik et al.~~,~~ (2018) showed that fecal contamination was in the range from 92.4% to 17.5% out of 33 total well water samples and *S. aureus* was in the range from 78.7% to 14.5%.
The number of total coliform bacteria in vegetable samples (lettuce, hot pepper, cucumber) was insignificant, les then 30 MPN/gDM each sample. The pathogens, *E coli*, *Salmonella sp*. and *Shigella sp*. were also not detected and which indicates no fecal contamination and vegetables are safe for consumption. Unlike our results, Mcheik et al. (2018) noticed high level of faecal coliforms and *E.coli* at vegetables which were irrigated with contaminated water and the highest level of bacteria was at lettuce (6.0 and 5.0 $\log_{10}$CFU.g^{-1} fresh weight). Also, other authors found out high level of *E. coli* in vegetable samples irrigated with polluted water. The average number of *E. coli* for tomato samples were 3.27 logCFU/10g, for carrot samples 3.33 logCFU/10g and for spring onion and cabbage were 3.50 and 3.34 respectively (Douti et al., 2021).

Table 3. The number of coliforms (MPN/100 ml) and presence of pathogens in water samples

Water sample	Channel ”Surcin”	Channel “Donje polje”	Channel between P.S”Donje polje”and P.S”Petrac”	Channel ‘’Petrac’’	Channel ‘’Galovca’’	Pool ‘’I.S.C.’’
TC	>1.100.000	7.300	2.400	2.400	430	930
FC	70	< 30	< 30	< 30	< 30	< 30
E. coli	1100	200	36	0	0	0
Salmonella	+	+	-	-	-	-
Shigella	+	+	-	-	-	-

According to the German standard for irrigation waters (DIN 19650), the water of the Channel ”Surcin” should not be used for irrigation crops which are consumed in raw. Also, according to mentioned German standard, waters from Channel ”Donje polje’’ and Channel between P.S ”Donje polje’’ and P.S. ”Petrac’’ would not be used for irrigation, but our Regulation on water classification ("Official Gazette of RS", No. 5/68) allows using these water for irrigation (II-III class).

The presence of *Salmonella* sp. and *Shigella* sp. in waters of Channel "Surcin'' and Channel "Donje polje" indicate for fecal contamination and their presence in the groundwater is not specified by our law for waters which could be potentially used for irrigation. Considering worldwide epidemics caused by consumption of *Salmonella*-contaminated fresh products, it could not recommend these waters for irrigation. According to the Rulebook on general and special conditions of food hygiene at any stages of production, processing and trade ("Official Gazette of RS", No. 72/10) it is not allowed presence of Salmonlla *sp*. in food. *Salmonella sp.* and *Shigella sp.* were not detected in tested vegetable samples which indicate good microbiological quality of investigated vegetables.

Conclusion

Based on the microbiological analyzes of water, it could be concluded that investigated water have medium to good microbiological quality. The Surcin channel water has very poor microbiological quality and this water is a good environment for many human pathogens. It is not usable for irrigation, especially for irrigation vegetables which are eaten in raw. This water should undergo certain purification processes in order to get microbiologically safety water for irrigation.

The other tested waters could potentially be used for irrigation but appropriate water treatment should be recommended in order to improve microbiological quality of water and achieving health safety agricultural production.

The water from the well of the company "Iceberg Salat Center", which is otherwise used for irrigation, has satisfactory microbiological quality as well as vegetables which are healthy safe for consumption.

Abstract

The prognosis of *Cydia pomonella* L. appearance in apple plantations enables proper undertaking of protective measures without harmful effects on man and useful organisms. The indication pest extermination deadlines improve the efficacy of protection and diminishe the appearance of toxic substances in apple fruit. The aim of this work is to point out the significance of methods for the prognosis of pest appearance as the basis for pest suppression and the rational application of pesticides. The paper is accompanied by a flight of *Cydia pomonella* L. at two sites in Rasina district.The pest presence determination visually, by the usage of feromone traps, by calculation of efficient temperatures, enables the proper application of chemical protective measures, as well as the production of healthy organic food achieving the preservation of the environment. Among the areas with extremely suitable ecological conditions for intensive production of apples is the Rasina district. The modern growth of apples as a high intensive growing of fruit species iwass threatened by many economically important pests and pathogens. In order to suppress them effectively and economically, it is necessary to monitor the upgrowth of apple pests, to make the prognosis of their appearance and signalize the terms of treatment.

Keywords: *prognosis, indication, codling moth, apple.*

Introduction

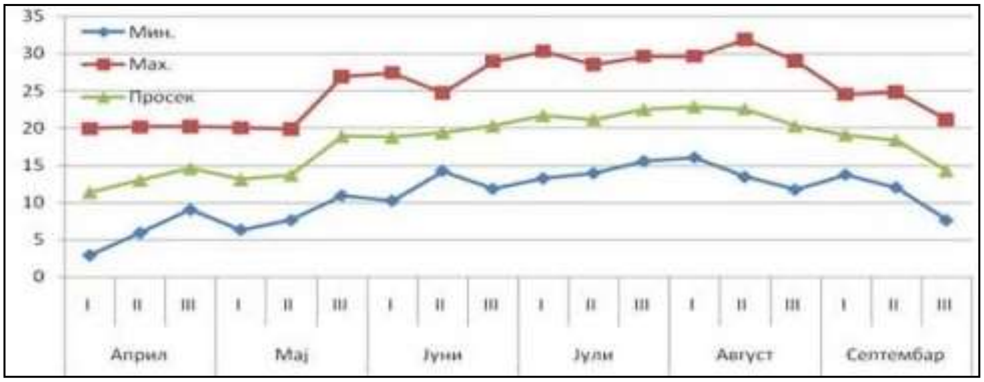
Fruit growing has a very significant place in the modern agricultural production. The special intention is paid to the spreading and organizing the fruit production in orchards. Among the areas with extremely suitable ecological conditions for intensive production of apples is Rasina district. The modern growing of apples as high intensive growing of fruit species is threatened by a large number of economically important pests and pathogens (Milenković and Stamenković, 2003). In order to suppress them effectively and economically, it is necessary to monitor the upgrowth of apple pests, to make the prognosis of their appearance and signalize the terms of treatment (Stamenković and Stamenković, 2000). Economically the most significant apple pest is codling moth – *Cydia pomonella* L., against which is necessary to make the measures of protection since it is regularly present each year in plantations in all the regions of apple production (Nikolić and Stamenković, 2003). The damage made by grubs of apple fryer can be direct (vermiculation, deformity and the earlier falling of fruit and indirect (rotting of fruit) and in some years the apple production and profitability can be threatened. The aim of the research is to point at the significance of the methods of prognosis of pest appearance as the base for their effective repression. Signalization of the terms of repression provides the rational use of pesticides and reduces the presence of toxic substances in apple fruit.

Material and methods

During the examination the appearance and prognosis of apple fryer in apple plantations were monitoring, at the territory of Rasina district (Serbia), in 2018. The main objects of research were the already existing apple plantations at two localities: Mala Drenova (between Kruševac and Trstenik) and Donji Stupanj (between Kruševac and Aleksandrovac). In Donji Stupanj flying of the butterfly of apple fryer was monitored at the apple area of 1,8 ha where the following species are: Golden delicious, Klon reinders, Idared, Granny smith and Red chief. The space between planting is 3,8 x 1,2 m. The cultivated shape is the modified pyramid and is in good health for now. In planting the chemical treatment was done against weed by Zoomer 390 SC (glyphosate 360 g/l + oxyfluorfen 30 g/l). Butterfly flying was monitoring from 20 April to 31 August 2018. In the area of Mala Drenova, the surface of planting was 1,5 ha, Idared, spindle shaped bushes. Planting space was 3,5 x 1m. Treatment against weed was done by Glyphosate 5 l/h, and mechanical inter row treatment. Butterfly flying was monitoring from 18 April to 30 September 2018. The gathering of data about meteorological conditions was done in the Weather station in Kruševac. Orientational prognosis was done at the basis of monitoring the sum of average daily temperatures. Appearance and butterfly flying were monitored by pheromonal batches which were set at the edge of orchard at the height of 1,5-2 m. Applying the everyday check the calculating and recording of caught butterflies were done. By visual method plant organs were examined and the first appearance of butterflies was determined, the beginning of oviposition, the beginning of grub drilling in the fruits and monitoring of their upgrowth. The sums of effective temperatures were calculated as the total of average daily temperatures which were diminished for 10^{o} C. The prognosis of flying of apple fryer can be done by monitoring the sum of daily temperatures. The sum of daily temperatures starts to be counted from so called biofix. Biofix stands for the first stable fly of butterfly and usually takes place around blooming, or after blooming. When biofix is determined from the day after the degree days (DD) are counted, that is, the sum of effective temperatures which is counted by subtracting 10^{o} C from the average value of temperature. On the basis of such monitoring, eggs are appearing at the sums of temperatures from 69 to 111, and cocoons from 200 to 345 .

Results and discussion

The climate in Kruševac and its surrounding is moderate continental with distinct seasons where autumn is slightly warmer than spring. When the data of perennial average value and average temperatures were analyzed in 2018 (Graph 1.), it can be seen that winter in 2017 was milder than perennial average value, while the other months were of approximate values.



Graph 1. Minimal, middle and maximal average temperature per decade in Kruševac in 2018.

During the research the presence of apple fryer was determined in all the localities from the period of vegetation to the end of the apple vintage. The activity of butterflies depends to a large amount on meteorological factors, while the greatest influences have the air temperature and rainfalls. The beginning of flying of butterflies in spring is one of the most important moments in the biology of pests since the period from laying eggs to grub drilling in fruits is the most convenient for the efficacy of chemical agents in the fight against apple fryer.

3.1. Locality Mala Drenova – The results of dynamics of the number of *C. pomonella* are shown in table 1. Looking at the results it can be seen that the first butterflies were noticed on 19 April 2018 and that they were presented during the whole vegetation period. The increase of number was particularly noticeable at the end of the first decade of May in the first generation and at the beginning of July in the second generation. The constant presence of adult butterflies during August indicates to the presence of the third generation of *C. pomonella*. In none of the generations the higher peaks are not expressive, but the mild increase in number in each generation of growth is clearly noticed. It is clear that climate changes, above all variable temperatures and increased number of rainy days in the year had the influence to not appearing of the regularity of the number of butterflies. The variability of upgrowth *of C. pomonella* depending on climate factors was pointed out by many researchers in their research (Rafoss and Sæthre, 2003). Climate factors (temperature, light, rainfalls, air flow, etc.) influence together and their influence is not the simple sum of separate factors . However, in the conditions of moderate climate the crucial role in the upgrowth of apple fryer has the temperature

.

31		1		0	1	
	0.54	1.90	2.57	1.90	2.23	0.37

3.2. Locality Donji Stupanj – At the locality Donji Stupanj the greater number of adult butterflies of *C. pomonella* was notified during the whole vegetation period in accordance to the locality Mala Drenova. The beginning of flying was notified on 21 April 2018 and the number was increasing up to 9 May, when the maximal flying of 28 imagoes was notified. The increasing of the number of butterflies and maximal flying are in accordance with temperatures at the beginning of May. The higher number of butterflies of *C. pomonella* in comparison to the locality in Mala Drenova is the surrounding of the monitored orchard by fewer apple trees nearby whose protection is deficient and movement of butterflies to the examined plantation. Apple fryer was earlier considered as "sedentary" species , but during the research it has been determined that particular individuals of this species can move even to few kilometers which significantly influences the spreading of this pest (Keil *et al.*, 2001) . This is particularly important since in that way the resistant types of *C. pomonella* are spreading. The significant role in that has also man. It is familiar that on the wooden boxes which are used for transporting apples grubs make their cocoons and in this way the pest spreads to further distances.

Table 2. Dynamics and number of *C. pomonella* in Donji Stupanj in 2018.

Theoretical model for the prognosis of appearance of *C. pomonella* butterflies is based on the sum of effective temperatures which is monitored from 1 March. On the base of the sum of effective temperatures the appearance of first butterflies should be expected in the interval from 22 to 30 April, and larvae from 22 May and later if it is considered that according to the sum needed for the upgrowth of a butterfly is from 69-111, and eggs 200-345. The average temperature above 10^{o} C was notified on 17 March and it was 11 days to the end of the month with temperatures above 10^{o} C. The sum of effective temperatures in March was 22,8; in April 93,4; in May 170; in June 296,1; in July 367,5; in August 369,5; in September 219.Wildbolz stresses that for the upgrowth of butterflies in spring the temperature should be 100 ^{o}C, grub for

eggs 90^{o} C, and only for one generation (from the phase of eggs to grown up butterflies) the needed sum of effective temperatures 610^{o} C.
According to that calculation the appearance of the second generation should be expected in the middle of July. According to our data the second generation appeared was a bit earlier, at the beginning of July. Literature is familiar with such a notion and it is connected to the effect of insecticide by whose use the resistance to certain chemical substances appears, on one hand, and the shortage of developing cycles, on the other hand.

Conclusions

On the base of shown results of appearance and dynamism of flying of *C. pomonella* it can be concluded the following: at both localities the appearance of three generations of *C. pomonella* was determined. The first generation appeared at the end of the first decade of May, the second at the beginning of July and third in the middle of August 2018. The first butterflies at both localities were noticed at the beginning of the last decade of April and is caused by variable meteorological conditions in that period.
The use of pheromone batches was a useful method for monitoring the flight of *C. pomonella* butterflies and the protection of plantation on the base of that.
Prognosticating the presence of apple fryer by calculating the sum of effective temperatures and monitoring meteorological factors provides the timely determination of treatment terms for its suppression. In that way the effective protection is reached, rational use of pesticides and protection of the environment.

Abstract

Erwinia amylovora, a bacterial blight of apple fruit, is one of the most important diseases of apples and pears. It is very difficult to suppress the disease and sometimes the infection is 100% and practically the fruits are not for use. Bacterial blight caused by E. amylovora belongs to the group of the economically most significant diseases of apple fruits. Since E. amylovora parasitizes all the organs of the plant (flower, fruit, skeletal branches, and trunk) and causes necrosis and tissue damaging on them, this bacterium is considered as one of the most destructive pathogens. With further significant spread of the infection in the Republic of Serbia, due to insufficient, superficial, or non implementation of measures to protect sensitive host plants, even more significant economic losses from the quarantine bacteria E. amylovora, should be expected in the near future. One of the measures that could ensure the normal yield of apples and pears in the coming period is the cultivation of autochthonous varieties. According to the data from the literature, autochthonous varieties are resistant to plant diseases. Apple ("Sarunka", "Sumatovka", "Kolacara", "Budimka") and pear varieties ("Vodenac", "Kaludjerka", "Lubenicarka", "Jecmenka", "Letnji kajzer" and "Karamanka") were used in the research. By using specific laboratory tests (ELISA test, IF test, Biologist test) as well as checking pathogenicity, inoculation of young apples and pears, the presence of Erwinia amylovora at autochthonous varieties will be proved. "Gloucester" apples and "William" pears were used as controls. The autochthonous varieties of apple and pear used in this study are resistant to Erwinia amylovora, although the occurrence of bacterial exudate by artificial inoculation was recorded.

Keywords: *Erwinia amylovora, apple, pear, autochthonous varieties.*

Introduction

Erwinia amylovora is the causative agent of bacterial blight of plants of the *Rosaceae* family. The most important hosts of this bacteria are pome fruit species (pear, apple, medlar and quince), *Sorbus spp*., *Cotoneaster spp*., *Crategus spp*. and *Pyracantha spp*. Hosts are also species of the genera *Chaenomeless* and *Photinia* (Panić and Arsenijević, 1996; Gavrilović and Arsenijević, 1998; Balaž *et al*., 2004; Gavrilović *et al*., 2008). Bacterial blight caused by *E. amylovora* belongs to the group of the economically most significant diseases of apple fruits. Since *E. amylovora* parasitizes all the organs of the plant (flower, fruit, skeletal branches, trunk) and causes necrosis and tissue damaging on them, these bacteria are considered as one of the most destructive pathogens. With further significant spread of the infection in the Republic of Serbia, due to insufficient, superficial, or non implementation of measures to protect sensitive host plants, even more significant economic losses from the quarantine bacteria *E. amylovora*, should be expected in the near future. One of the protection measures in the future could be the use of antibiotics, which are already used and give good results. It is also necessary to introduce bactericides into the market and use them, which we currently do not have on the Serbian market. However, not all apple varieties are equally sensitive to *E. amylovora*. Very sensitive are: Fuji, Gala and Jonathan, sensitive: Granny Smith, Golden Delicious and Jonagold, and resistant: Red Delicious, Prima and Priscilla (Fisher and Richter, 1998; Mohan *et al*., 2001; Boyd and Jacobi, 2005). Therefore, intensive work is being done to study this pathogen, the symptoms caused by it, its bacteriological characteristics (Meyer, 1973; Paulin, 1983) and to predict the occurrence of the disease. Adequate and effective measures to suppress pathogens include: cultivation of resistant plant genotypes, as well as the application of physical, biological, chemical and mechanical measures to suppress *E. amylovora* (Garrett, 1990; Beer, 1991), emphasizing that it must be carried out with mandatory disinfection of work equipment (Panić and Arsenijević, 1996). Intensive work is being done to find and create resistant genotypes to *E. amylovora* (van der Zwet and Beer, 1995). One of the measures that could ensure the normal yield of apples and pears in the coming period is the cultivation of autochthonous varieties. According to the data from the literature, autochthonous varieties are resistant to plant diseases (Gavrilović *et al*., 2014).

Material and methods

Artificial inoculation of immature fruits of autochthonous varieties of apple and pear was performed by applying drops of bacterial suspension, originating from the culture, by pricking a needle in three places of each fruit. Apple fruits of the varieties: "Sarunka", "Sumatovka", "Kolacara" and "Budimka" were inoculated, as well as pear fruits of the varieties: "Vodenac", "Kaludjerka", "Lubenicarka", "Jecmenka", "Letnji kajzer" and "Karamanka" (Figures 1-6). Inoculated fruits were stored in a humid chamber for 1-2 days, moistened by spraying, using hand sprayer, and then covered with moistened polyvinyl (Kudela, 1988; Arsenijević, 1988). Plant material was collected in the municipality of Nis, Serbia. 10 fruits were inoculated from each variety. Firstly they were sterilized with 70% ethyl alcohol on the surface, and then washed under a stream of distilled water, after which they were placed on filter paper for drying. The dried fruits were placed in Petri boxes, which were placed in plastic containers lined with moist filter paper, in order to create the optimal humidity necessary for the infection process and the formation of exudates. The control were the fruits of the "Gloucester" apple and the "William" pear.

Figure 1. Autochthonous variety "Lubenicarka"

Figure 2. Autochthonous variety "Vodenac"

Figure 3. Autochthonous variety "Kaludjerka"

Figure 4. Autochthonous variety "Karamanka"

Figure 5. Autochthonous variety "Jecmenka"

Figure 6. Autochthonous variety "Letnji kajzer"

Results and discussion

By inoculation of autochthonous pear varieties, the appearance of bacterial exudate was recorded on pear fruits, varieties: "Lubenicarka", "Letnji kajzer", "Kaludjerka", "Vodenac" and "Karamanka", while there was no change on variety "Jecmenka" (Table 1, Figure 7). The control strain of pear, the "William" variety, reacted positively and expressed its reaction with the appearance of bacterial exudate, which gives us confirmation of the correctness of the experiment.

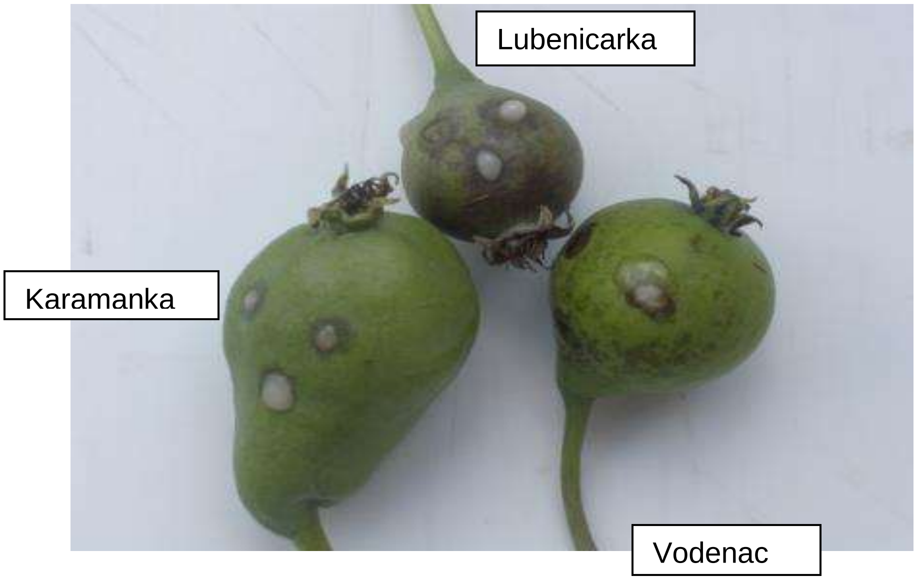

Figure 7. *E. amylovora*: Appearance of exudates on autochthonous pear varieties

By inoculation of autochthonous apple varieties, the appearance of bacterial exudate was not recorded on the fruits of the varieties: "Sarunka", "Sumatovka", "Kolacara" and "Budimka" (Table 1). The control strain of apple, the "Gloucester" variety, reacted positively and expressed its reaction with the appearance of bacterial exudate, which gives us confirmation of the correctness of the experiment.

Table 1: Appearance of exudates on autochthonous pear and apple varieties

Plant species	**Variety**	**Appearance of bacterial exudate**
Pear	Vodenac	+
Pear	Kaludjerka	+
Pear	Lubenicarka	+
Pear	Jecmenka	-
Pear	Letnji kajzer	+
Pear	Karamanka	+
Apple	Sarunka	-
Apple	Sumatovka	-
Apple	Kolacara	-
Apple	Budimka	-
Apple - control	Gloucester	+
Pear - control	William	+

The studied samples of fruits, leaves and branches, of apples and pears originating from autochthonous varieties taken from nature, show a negative reaction to the ELISA test, if test and express test (Table 2), which proves that autochthonous varieties of apples and pears in the natural environment do not suffer from bacterial blight of apple fruit.

Table 2. Specific tests for the identification of *E. amylovora* on autochthonous apple and pear varieties from samples taken from nature

Plant species	Isolate code	ELISA test	IF test	EXPRESS test
Pear	Vodenac	-	-	-
Pear	Kaludjerka	-	-	-
Pear	Lubenicarka	-	-	-
Pear	Jecmenka	-	-	-
Pear	Letnji kajzer	-	-	-
Pear	Karamanka	-	-	-
Apple	Sarunka	-	-	-
Apple	Sumatovka	-	-	-
Apple	Kolacara	-	-	-
Apple	Budimka	-	-	-
Apple - control	Gloucester	+	+	+
Pear - control	William	+	+	+

Control of *E. amylovora* is hampered by the lack of appropriate bactericides to prevent its spread. Copper-based pesticides show some efficacy, but may be phytotoxic in phenophases when the risk of infection is greatest (Arsenijević and Gavrilović, 2007). Antibiotics (streptomycin and oxytetracycline) are highly effective, but their long-term use leads to the development of resistance, which was recorded in the 1970s in the USA (Van der Zwet and Keil, 1979). In addition, antibiotics are not registered for use in plant protection in many European countries, but also in Serbia. Due to all this, intensive research has been conducted in many countries in recent decades with the aim of selecting resistant varieties of pear and apple to *Erwinia amylovora*. One of the possible solutions could be the cultivation of autochthonous varieties of apple and pear resistant to *Erwinia amylovora*.

Conclusion

Autochthonous varieties of apples and pears in nature do not suffer from bacterial blight of apple fruit caused by the bacteria *Erwinia amylovora*. This is confirmed by specific pathogen identification tests (ELISA test, IF test, Biologist test). By artificially infecting young apple fruits varieties: "Sarunka", "Sumatovka", "Kolacara" and "Budimka", and pear varieties: "Lubenicarka", "Letnji kajzer", "Kaludjerka", "Vodenac", "Karamanka" and "Jecmenka", the presence of bacterial exudate was determined on pears varieties: "Lubenicarka", "Letnji kajzer", "Kaluđerka", "Vodenac" and "Karamanka", while the variety "Jecmenka" did not show any changes. Artificially infected apple varieties did not show the appearance of bacterial exudate (Vojinović, 2010). The appearance of bacterial exudate proves the presence of *Erwinia amylovora*.With this research we wanted to draw attention to the fact that in this way the presence and spread of *Erwinia amylovora* can be controlled. This experiment was done on a small sample and errors are possible. The final confirmation of whether the autochthonous varieties of apple and pear are resistant or tolerant to *Erwinia amylovora* can be determined by analysis at a higher level using the latest technology. In addition to resistance to plant diseases, these varieties have other qualities that recommend them for cultivation.

Abstract

The paper presents the influence of the use of 1-methylcyclopropene (1-MCP) on the shelf-life quality of pear fruits of the cultivar 'Williams' with two different cultivation sites in the vicinity of Čačak (Serbia). The fruits were stored separately under the same cooling conditions in a controlled atmosphere (CA) at -0.5-0.5°C after treatment. The tests were performed before the treatment of fruits, and then 1 day, 30 days and 90 days after treatment and shelf life of 7 days of aging at room temperature (20°C). The application of 1-MCP affected the preservation of fruit weight and strength at different measurement intervals. The soluble solid content and pH increase, and total acids content decreases with storage length, with smaller variations in treated compared to untreated fruits. Based on the examined parameters, the optimal storage period of fruits treated with 1-MCP from both sites was 30 days and shelf life of 7 days. The storage period of 90 days affected the biochemical parameter of the fruits and their use immediately after taking them out of the cooler. The length of fruit storage depends on the results of the initial examined parameters during the harvest, the content of macronutrients and their relationship, climatic conditions, the length of the period between harvest and treatment with 1-MCP, etc.

Key words: *1-Methylcyclopropene, Shelf-Life Quality, Pear, 'Williams'.*

Introduction

Pear is one of the most widely grown fruit species across the world, but of all cultivars, the best and most appreciated is for sure 'Williams' or 'Bartlett' as better known in the West. Storage of 'Williams' pears is typically limited to 2–3 months in open air, even under ideal storage conditions at -1°C. In most cases, the end of storage life is due to the onset of physiological disorders, particularly superficial scald and core breakdown. Ethylene produced by the fruit can exacerbate these disorders, as well as cause premature yellowing and softening during storage (Ekman et al., 2004). Late harvested fruit are particularly susceptible to these disorders, which may begin to appear within a month of harvest (Ju et al., 2001).

Pears are climacteric fruits, in which the major negative changes are the results of maturation. During ripening, some changes are observed in firmness, color, acidity, sugar content and development of aroma (Alpalhao et al., 2006). After harvest, pears are conditioned with ethylene and marketed immediately or stored at low temperatures until ready to be marketed (Villalobos-Acun˜a and Mitcham, 2008). Controlled atmosphere related disorders in fruit can be minimized by delaying the exposure to CA storage after harvest or by pre-storage conditioning fruit under ambient air at higher temperatures than the final storage temperature (Flaherty et al., 2018). Besides storing fruits at lower temperatures, it is necessary to control fruit ripening using blockers at the site of ethylene binding. In recent years, increasing applications of 1-methycyclopropene (1-MCP) in the preservation of freshness for harvested fruits have been reported. As a result, treatment with 1-MCP reduces the production of ethylene and other

volatiles, respiration, peel color development from green to yellow and the rate of softening (Watkins, 2006; Chiriboga et al., 2013a, 2013b; Hendges et al., 2018). The ethylene perception inhibitor 1-methylcyclopropene (1-MCP) is known to delay softening and peel yellowing in pears following their transfer from low temperature and CA storage to shelf-life conditions (Villalobos-Acuna and Mitcham 2008; DeEll and Ehsani-Moghaddam 2011; Gago et al., 2015).
The aim of our research is to determine the influence of 1-MCP on the storage potential of 'Williams' pears in a controlled atmosphere (CA) from different production plantations and at different storage temperatures.

Materials and methods

Plant material
Pear fruits were collected from the plantations pear 'Williams' established in 2013, grafted on rootstock quince BA 29, with interstems 'Kaluđerka' in production plantations of an agricultural producer in the village Trnava and Viljuša, Cacak (Serbia), under conditions of temperate continental climate. The beginning of the harvest in the first plantation was 14.08-20.08.2020, and in the second orchard 16.08-22.8.2020. Fruits were harvested at optimal maturity stage and size for tested cultivar.

1-methylcyclopropene (1-MCP) treatment
Pear fruits of uniform shape and without visible mechanical damage were selected for the needs of the experiment, in order to include 30 fruits in three replications from each production plant, while an equal number of samples was left in the cold storage to serve as a control variant. After selection of samples for analysis, the fruits were placed in the cold storage with a control atmosphere (CA) for a period of 4-7 days (at a temperature of 1°C). The fruits selected for treatment were arranged in crates and placed in a chamber with a volume of 500 m^3 in the first cold storage with an occupancy capacity of 50% (CS 1) from the first production plant in Trnava and with a volume of 250 m^3 in the second cold storage with an occupancy capacity of 90% (CS 2) from another production plantation in Viljuša. Treating the fruits with the agent acting as an ethylene blocker was performed by dissolving tablets of 1-MCP (SmartFresh^{TM}) with activator tablets (blue activator tablets) in citric acid. After diluting 1-MCP (SmartFresh^{TM} protab), the chamber was sealed airtight for the next 24 hours, until the gas concentration of 750 ppb was achieved. Control fruits were stored in wooden crates and placed in an adjacent empty chamber, under the same cooling conditions, The temperature during treatment in the first cold storage was 1°C and in the second cold storage 0°C.

Fruit storage and sampling
All of the replications of the fruits selected for treatment, as well as the ones that were not subjected to the 1-MCP treatment, were placed in wooden crates and kept in vertical tiers. The fruits were kept in a cold atmosphere: 0-0.5°C in the first cold storage and -0.5 to 0°C in the second cold storage, 90 ± 5% relative humidity (20.9kPa 0_2+<0.5kPa CO_2), in the period of 90 days. Sampling of fruits for analyses was carried out before fruit treatment (Ø), and then in three phases: 1 day (1), 30 days (2) and 90 (3) days after treatment. After taking the samples from the cold storage, the fruits were left in conditions of normal atmosphere: 20 ± 1°C and 60 ± 5% RH, for 7 days (shelf life), followed by the displayed measurement and chemical analyses of fruits (1-control; 2-treatment). Fruit weight (FW) was determined on a Mettler 0.01 g precision scale (Switzerland). The fruit firmness (FF) measuring was performed using the penetrometer Fruit

Pressure Tester FT 327 (Winopal Forschungsbedarf GmbH, Germany) with an 8 mm probe. Two measurements were made in six fruits per each replication on both sides expressed in Newton (N/cm^2) = fruit firmness value (kg/cm^2) × 9.81.

Assessments

The soluble solid content (SSC) of the fruit was determined on a manual refractometer (3828, Carl Zeiss, Germany). Actual acidity (pH value) was measured by a pH Meter Iskra MA 5707, Slovenia. Titratable acidity (TA) was determined by neutralization of fruit extract with 0.1 N NaOH to pH 8.2, using phenolphthalein as indicator. Acidity was expressed as mg malic acid/100 g fresh weight.

Content of macro and microelements in the fruits of pear

The content of macro and microelements was determined before the experiment setup, by sampling 1 kg of average samples in three replications, for each cultivar. The content of macro (K, Ca, Mg, Na) and microelements (Cu, Zn, Mn, Fe, Co, Ni, Pb) was anlaysed using modified method (Moraisa et al. 2017). Readings were performed on AAS, Perkin-Elmer, PinAAcle 500 (USA 2018), and values were expressed in mg kg^{-1} of fresh weight of the sample, whereas K+Mg/Ca, K/Ca ratio was determined using calculation.

Statistical analysis

The data was subjected to analysis of variance (*ANOVA*) using statistical package MSTAT-C (Michigan State University, USA). The least significance difference (LSD) was used to compare treatment means and treatments declared different at $p = 0.05$ level of significance.

Results and discussion

Prolonging the period of fruit storage and delaying the ripening of fruits requires a better understanding of the physiological and biochemical role, especially the ratio of Ca, K, Mg, K+Mg/Ca, K/Ca, and the content of microelements is also important. In tab. 1, results of macroelement content in fruits of pear are shown. The content of K and Ca had higher values in samples number 2, and the lower content of Mg affected the lower ratio of K + Mg/Ca and K/Ca (17,57-17,10), which is a good predisposition for longer storage of fruit. In fruits of apple, if the K/Ca ratio is higher than 30, and in certain cultivars higher than 25, even 20, there comes to physiological diseases and lower potential of fruit keeping, accordingly.

Table 1. Content of macroelements and their relation in pear fruits

Samples	K	Ca	Mg	Na	K+Mg/Ca	K/Ca
	mg·kg^{-1}				computational ratio	
plantation 1	969,4±35,57a	45,20±9,62a	58,20±5,52a	22,00±2,36a	22,70±2,43a	21,50±2,89a
plantation 2	1096,2±76,85a	64,20±6,78a	32,00±3,23b	3,00±0,90b	17,57±2,08a	17,10±1,82a
ANOVA	ns	ns	*	*	ns	ns

The Mn content shows significantly higher values in sample 2 (0.66 mg·kg^{-1}), and the Fe content in sample 1 (4.95 mg·kg^{-1}). The other elements did not differ significantly in their content between the pear samples (tab. 2).

Table 2. Content of microelements in pear fruits

Samples	Cu	Zn	Mn	Fe	Co	Ni	Pb

Rapid deterioration of eating quality and high rates of disorders occurring in over-mature pears would diminish repeat consumer purchases (Gallardo et al., 2011). Postharvest 1-MCP application effectively suppressed ethylene receptors, maintained FF and green color retention, and reduced physiological disorder development in pears. 1-Methylcyclopropene (1-MCP) is an inhibitor of ethylene receptors, thus retarding ethylene-dependent responses such as ripening, senescence and physiological disorders (Watkins, 2006).

Taken as a whole, pear fruits in the first cold storage had greater weight, RSM and TA. With the length of storage, measurements show a decrease in fruit weight and firmness. SSC and TA increase up to 30 days of fruit storage then decrease, and the pH varied without special regularities. The application of 1-MCP significantly affected the preservation of fruit hardness, and the SSC and pH were increased in relation to untreated fruits. The initial hardness of 'Williams' fruits in the first cold storage was 54.39N, and in the second 68.02N, representing slightly lower values of hardness before treatment compared to the research of other authors (tab. 3). 'Bartlett' pear is harvested at 80 to 89N when the fruit is still green and firm but physiologically mature (Villalobos-Acun˜a et al., 2010). Recommended harvest maturity for 'Bartlett' pear is indicated by flesh firmness (FF) at 84 N; maturity is completed at 76 N, over the course of 14 days (Wang et al.,2016; Zhi and Dong, 2018). However, labor short working season and high temperatures in certain periods of vegetation, narrow the harvest period and as a result, a significant number of pears are picked at an over-mature stage. Over-mature pears are more prone to reduced FF, yellowing, physiological disorders (i.e. decay and scald) and rapid softening after long-term storage or long-distance shipping (Villalobos-Acu~na et al., 2011; Calvo et al., 2015; Zh and Dong, 2018).

The firmness and color of the fruit is characteristic of the cultivar, and the emission of ethylene is an indicator of the ripeness of the fruit. The content of SSC and TA during harvest had significantly lower values in sample number 2 (10.17 and 0.20, respectively) and a higher pH value, compared to the sample from the first cold store. Certain differences in initial parameters during fruit harvest in different orchards and storage in two different cold storages contributed to differences between measurement and treatment, but both treated and untreated fruits required market placement after 30 days of storage. Yingli L. et al., in 2021 were harvesting 'Williams' fruit for storage, the hardness of the pear was 84.6 N, the SSC was 11.5%, and the TA was 0.33%. Our research results show the variation of fruit hardness, SSC, pH and TA during fruit harvest in the year of the experiment.

In tab. 4, the correlation between the analyzed parameters is shown. Pear samples from different coolers had a medium degree of negative correlation to SSC content and a low degree to FW and TA, and a positive correlation was expressed to pH value. Measurement intervals show a high degree of negative correlation on pear FF (-0.840), a low degree on FW and a low positive correlation on SSC. Different treatments had a low positive effect on N, SSC and pH. Fruit hardness at SSC and TA and a positive effect on pH had a low degree of negative correlation. SSC has a low positive correlation with TA and a negative one at pH.

Table 4. Correlation of examined parameters

Parameters	CS	Meas.	Treatm.	FW	FF	SSC	pH	TA

Many studies have reported that 'Williams' pears generally ripen within 7 days at 20°C after purchase. Usually, this information is based on experiments that were performed in a controlled environment. In reality, at the point of sale, storage time and conditions are not known, neither commercial handling procedures implemented to extend the shelf life after storage (Huč et al., 2020). Measurements of these parameters in our studies were performed after 7 days of shelf life at room temperature, which further affected the results obtained.

Conclusion

Based on the results of the study of the influence of 1-MCP on the storage length of different fruits of pear `Williams', it was found that the initial parameters for longer storage of fruits were more favorable in pear samples from plantation 2, observing the ratio of K + Mg/Ca and K/Ca (17.57-17.10) and FF 68.02N. The pear fruits in the first cold storages had a higher FW, RSM and TA. With the length of storage, measurements show a decrease in fruit weight and firmness, and SSC and TA increase until the 30^{th} day of fruit storage, then decrease, while the pH varied without special regularities. The application of 1-MCP significantly affected the preservation of fruit hardness, and the SSC and pH were increased in relation to untreated fruits. Certain differences in initial parameters during fruit harvest in different orchards and storage in two different cold storages contributed to differences between measurement and treatment, but both treated and untreated fruits required market placement after 30 days of storage. The shelf life at room temperature of 7 days significantly affected the quality of the fruit and it is necessary to consider reducing the shelf life, especially in pears compared to apples, which are more resistant to longer storage.

Abstract

Oilseeds and crude oils may contain various contaminants that accumulate in the oil during vegetation, processing and storage of raw materials. All contaminants and their metabolites are harmful to human health. The refining process, in different stages, leads to the removal of these contaminants and they should not be found in refined oils. In addition to removing unwanted ingredients by refining, there are components of vegetable oils that need to be preserved due to their positive effect. As a result of the refining process, by-products appear to under go further processing. A special place among the contaminants is occupied by fungi (molds) that have the ability to produce mycotoxins, and the most important molds are *Aspergillus*, *Fusarium* spp., *Penicillium*, *Alternaria*. Some of the most common mycotoxins are aflatoxin, ochratoxin, fumonisins, trichothecenes, zearalenone, and patulin. The aim of this paper is to review the latest scientific knowledge, which relates to the influence of individual stages of the refining process on the content of mycotoxins in vegetable oils and fats, as well as the possibility of removing these contaminants from oils and fats during the refining process. In the production of vegetable oils and fats, the refining process is effective for reducing the content or removal of certain mycotoxins, in order to obtain quality, health-safe edible refined oil or fat. Since there are two basic refining processes, research has shown that chemical refining is, in that sense, more suitable than physical. The stages of refining during which most mycotoxins are removed are neutralization, bleaching and deodorization/dezoneutralization.

Keywords: *Edible oil, Contaminants, Mycotoxins, Removal.*

Introduction

Fungi (molds) contamination usually occurs during harvest or during storage of seeds and/or fruits. Inadequate storage conditions and other eco-physiological factors, especially those prevailing in tropical and subtropical conditions, such as high temperature and humidity, greatly contribute to the rapid growth of fungi. Fungis manage to produce mycotoxins even at low water activity (Bhat and Reddy, 2017). Food and feed fungi contamination is very widespread, and the most important fungi that contaminate food and feed are *Aspergillus*, *Penicilium* and *Fusarium*. They produce a group of various secondary metabolites - mycotoxins, showing a wide range of toxic effects on humans and animals (Gelderblom et al., 2014; Ji et al., 2015; Romanić et al., 2020). Several hundred different mycotoxins with high structural diversity have been discovered, differing in chemical and physicochemical characteristics. Most abundant mycotoxins occurrence are: aflatoxin and ochratoxin (produced by *Aspergillus* spp.), fumonisins, trichothecenes, zearelenone (produced by *Fusarium* spp.), patulin (*Penicillium* spp.). These compounds are strong toxins and have a wide range of effects on animals and humans because of their cytotoxic, neurotoxic, nephrotoxic, carcinogenic, mutagenic, immunosuppressive, teratogenic effect. In addition, most mycotoxins are causing dermatitis in humans and animals (Krska et al., 2009). Human exposure to mycotoxins mainly occurs through the food chain by consuming contaminated agricultural products, such as cereals, nuts, oilseeds and food products obtained from these sources (Lacoste, 2013; Gelderblom et al., 2014; Romanić et al., 2020; Abdolmaleki et al., 2021).

Good agricultural practice, plant disease management and adequate storage conditions of raw materials reduce the level of mycotoxins in the food chain, but mycotoxins are not completely removed from it in this way. Food processing can further reduce the content of mycotoxins by physical removal and chemical or enzymatic transformation of mycotoxins into less toxic products (Mariod and Idris, 2015; Karlovsky et al., 2016; Pinton et al., 2019). In edible vegetable oils and fats, the mentioned changes occur in the refining process. Refining, as a technological process, involves operations aimed at reducing the content or completely removing certain undesirable ingredients from crude oil, in order to obtain high quality edible oil. The refining process aims to remove all the ingredients from crude oil that reduce the sensory properties, quality and sustainability of refined oil. Undesirable ingredients in crude oil are of various origins and can be ingredients specific to a particular oil (protein residues, phospholipids, pigments, sulfur compounds, etc), degradation products formed during seed or during storage of seeds (free fatty acids, peroxides, aldehydes, ketones, non-hydrated phospholipids, etc) and converted into oil, residues of chemicals added during plant growth, degradation products and derivatives of these chemicals-pesticides, herbicides, desiccants, phosphoric acid-impurities from equipment or other oils (solvent, metals, soaps, etc) and pollution from soil, water, air or during seed drying (PAHs, dioxins, 3-MCP-diol, etc.) *(van Dujin, 2016; Chang et al., 2020; Zio et al., 2020; Abdolmaleki et al., 2021).

Two refining processes classical chemical (alkaline) refining and physical refining are represented (Ji et al., 2015; Gupta, 2017). Physical refining is suitable for oils with a high content of free fatty acids and a low content of non-hydrate phospholipids. Therefore, this refining process is suitable for crude palm and coconut oil. In case of the chemical refining of these oils, a large amount of soap would form, leading to a significant loss of neutral oil. Physical refining is also suitable for rapeseed oil with previously removed phospholipids, and in the case of sunflower and soybean oil it is possible only in the case of complete or enzymatic degumming in order to remove phospholipids and reduce phosphorus content to less than 10 ppm. Chemical refining is often used in the vegetable oils production, and mostly for oils of various oilseeds. In this process, the oil is pre-treated with an acid (e.g. phosphoric, etc) and then neutralized with a base solution (e.g. sodium hydroxide). In this phase, soaps are formed which are separated by centrifugation (separation), but also by water rinsing (Ji et al., 2015; Gupta, 2017; Flora et al., 2018; Abdolmaleki et al., 2021).

Influence of the refining process on mycotoxins as contaminants of vegetable oils and fats

Mycotoxins can be determined in vegetable oils and fats using chromatographic methods. Mycotoxins can be removed during different stages of refining process depending on their type, but they are all removed to the level of detection, ie below 1 μg/kg (Abdolmaleki et al., 2021). Table 1 shows the effect of physical and chemical refining on different contaminants in oils.

Table 1. Vegetable oils contaminants content and their removal in refining process stages (van Dujin, 2014; Pinton et al., 2019)

Contaminants	Mineral origin hydrocarbons (mg/kg)	PAH (polycyclic aromatic hydrocarbons) (μg/kg)	Pesticides (mg/kg)	Aflatoxin B1 (μg/kg)	Zearalenone (μg/kg)
Allowed amounts in oils	0.1-1	2		2	400
Degumming					
Neutralization			**	*	*
Bleaching	*	*	**	***	***
Deodorization	*	*	*		

* - chemical refining
** - chemical and physical refining
*** - physical refining

Aflatoxins are mostly removed during neutralization and bleaching. During bleaching, adsorption with bleaching earth is responsible for their removal. During deodorization, aflatoxins are removed in smaller quantities, because they can withstand high temperatures. For the removal of some mycotoxins, chemical refining of oil is better compared to the physical process, so zearalenone is removed more efficiently by chemical (80-98%) compared to physical treatment (70-80%) (van Dujin, 2014; Mariod and Idris, 2015). Short information about change in mycotoxin content during seed oil extraction and refining are available. In general, unrefined oils are excluded from the application of heat during the pressing process and are extracted mainly by mechanical process. This type of oil is washed, filtered or centrifuged without additional treatments such as alkali neutralization, bleaching or deodorization, while the reduction of mycotoxin content in refined oils can be attributed to the different stages of the refining process applied (Mariod and Idris, 2015; Bhat and Reddy, 2017; Abdolmaleki et al., 2021).

Degumming

The degumming process reduces the phospholipid content in the crude oil to a very low level. Phospholipids are structural components of plant cells and are extracted from seeds with oil. They have a great influence on the flavor, color, hydrolytic and oxidative stability of refined, bleached and deodorized oil, as well as on lower yields or higher losses of refined oil (Gupta, 2017). Degumming process is applied for removal of components precipitating from oil (during transport and storage), lecithin production (a very valuable by-product), removing ingredients that act as emulsifiers (phospholipids, carbohydrates) and physical refining, from the aspect of adequate oil "preparation".

Neutralization

Directly after harvest, lipolytic processes begin in the oilseeds, which can cause enzymatic or microbiological hydrolysis of oils and fats. The chemical and oxidative processes that occur cause the formation of free fatty acids. These fatty acids must be removed because they limit the use of oils and fats. Standard crude oils contain 1-3% free fatty acids (FFA). Up to 20% of FFA can be found in palm, olive and fish oil. Well-refined oils have about 0.1% FFA (Bockisch, 1993). Oil neutralization is the refining phase with the highest oil losses during refining. Two ways of neutralization, physical and chemical, are represented. Chemical neutralization by alkali is the most abundant.

Effect of the neutralization process on mycotoxins

The neutralization process includes heating the oil to 60°C, adding 13% sodium hydroxide, stirring for 10 minutes, centrifugation at 2000 rpm for 5 minutes. Thereafter, adding of water to the separated oil and rinsing with water until pH 7 is reached.

After alkaline treatment, the residual content of aflatoxin B1 is about 23%, aflatoxin B2 about 27%, and aflatoxin G1 and G2 below 0.1% in relation to the initial amounts, as seen in Figure 1 (Kamimura et al., 1986).

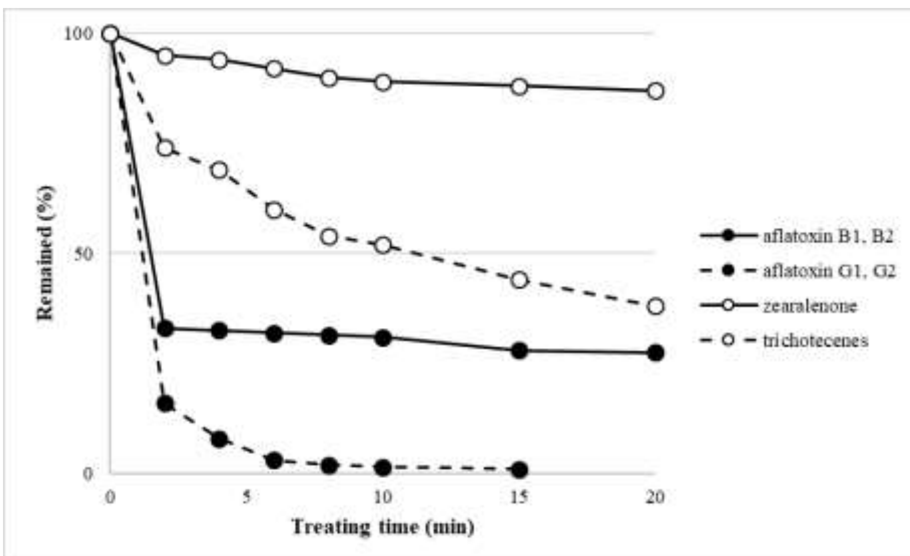

Figure 1. Stability of mycotoxins during neutralization (Kamimura et al., 1986)

Table 2 shows the mycotoxins content in oil and water used for oil washing after neutralization. After centrifugation, aflatoxin B1 and B2 were found in traces (0.01%), as well as deoxynivalenol and nivalenol. Aflatoxin G1 and G2 and zearalenone were not detected.

Table 2. Mycotoxin content in oil and water used for oil washing after neutralization (Kamimura et al., 1986)

Mycotoxins	Centrifugation (separation)		Washing	
	Oil (%)	Sludge (%)	Oil (%)	Water (%)

*nd - not detected

Bleaching

Bleaching is performed to remove color components from the oil. These components affect the appearance of the oil and also can negatively affect the taste and oxidative stability (Bockisch, 1993).

The pigments in the oil are in dissolved or colloidal form. In addition to the fact that bleaching is a physical process, ie. adsorption, so is the chemical process because there is an interaction between the pigments and the chemically active centers of the bleaching earth. In both cases the process takes place on the surface of the bleaching earth. Stained particles are bound adsorptively (hemisorption or physical adsorption) and are removed by filtration together with bleaching earth (Bockisch, 2004).

Effect of the bleaching process on mycotoxins

The bleaching process aims at adsorption and removal of pigments and trace components in the oil. Kamimura et al. (1986) investigated the influence of bleaching process on mycotoxind content. Active earth was used as an adsrobent, and the aim of the study was to determine whether mycotoxins are removed together with active soil or not. Bleaching earth was added in 2% to the oil and after 15 minutes it was separated from the oil, using a Bihner funnel. The part of the mycotoxin retained in the oil as shown in the Figure 2. After 15 minutes, zearalenone remained in the amount of 82%, and aflatoxins, deoxynivalenone and nivalenone were lagging behind in quantities below 0.5% (Kamimura et al., 1986).

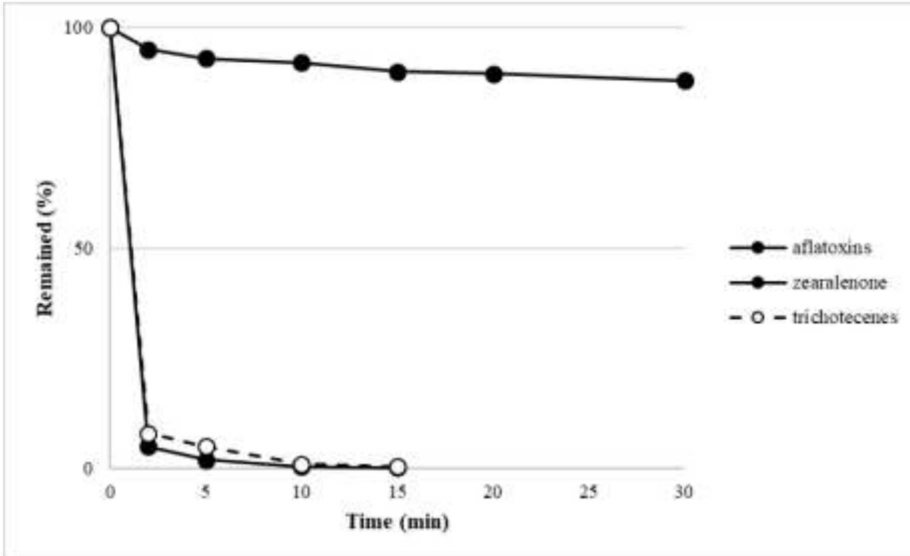

Figure 2. Effect of bleaching process on the mycotoxins content in oil (Kamimura et al., 1986)

Winterization

Winterization is a simplified form of fractionation, because it is not separated into two fractions, but a part of the oil components is removed. These components are triacylglycerols and high melting point waxes. If the oils are stored at low temperatures (in the refrigerator), the listed components will be separated. This adversely affects the appearance of the oil and consumers get the impression that the oil is spoiled. Also, under unfavorable conditions, the high content of waxes in the oil can affect the decomposition of oil emulsions, margarine, due to crystallization and separation of waxes. Thus, the goal of winterization is to reduce oil turbidity that occurs at temperatures from 0 to 8°C, by removing turbid substances (solid triacylglycerols, waxes, and oil polymerization products) (Bockisch, 2004).

Deodorization/dezoneutralization

Deodorization is the final step in the processing of vegetable oils and fats, by refining. This is followed by storage, packaging and distribution of the product, which means that the oil leaving the deodorizer must be ready for placing on the market (Gupta, 2017). Oils and fats contain undesirable components that give the oil an unpleasant taste and/or flavor and have to be removed during deodorization. Undesirable components include aldehydes, ketones, alcohols, hydrocarbons and other compounds formed during the oxidation and thermal degradation of peroxides, pigments and other natural constituents of oils, as well as free fatty acids. Deodorization is a physico-chemical process and represents the most complex operation in the refining process of vegetable oils and fats. This process represents the distillation of all undesirable volatile components at elevated temperatures in vacuum with the addition of direct superheated water steam.

Effect of the deodorization/dezoneutralization process on mycotoxins

Kamimura et al. (1986) investigated the thermal stability of mycotoxins at a temperature of 240°C and a pressure of 2-5 mmHg during the deodorization process. After 120 minutes of the process, aflatoxin B1 showed a tendency to decrease to 86% of the remaining aflatoxin B1, aflatoxin B2 to 80%, aflatoxin G1 to 72% and aflatoxin G2 to 70%, zearalenone and deoxyvalenol to 45%, while the level of nivalenol decreased to 7%, Figure 3 (Kamimura et al., 1986)

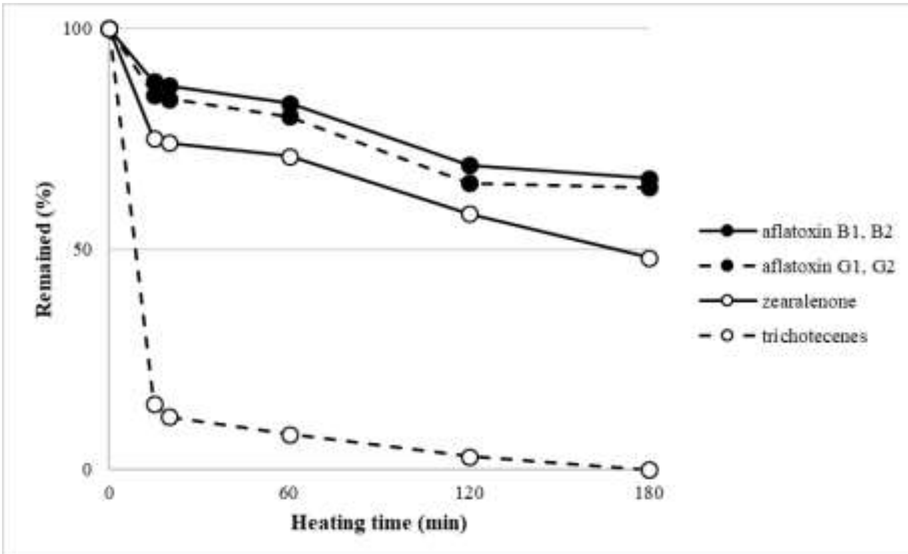

Figure 3. Stability of mycotoxins during heat treatment at reduced pressure (5 mmHg) (Kamimura et al., 1986)

Table 3 shows the content of mycotoxins in the oil before and after the refining process.

Table 3. Mycotoxins content in the oil before and after the refining process (Kamimura et al., 1986)

Mycotoxins	Aflatoxin				Zearale-none	Deoxyni-valenol	Nivale-nol
	B1	B2	G1	G2			
Initial oil (ppm)	1.0	0.8	1.0	0.8	10	8.0	8.0
Refined oil (ppm)	<0.02	<0.01	<0.02	<0.01	<1.0	<1.0	<1.0

Conclusions

Fats and oils, due to their high energy value and as important source of essential fatty acids and liposoluble vitamins, occupy an important place in human nutrition. On the other hand, raw materials for oil production are often contaminated caused by the production (cultivation) conditions and storage. These conditions can lead to the fungi growth and the formation of mycotoxins. Whether the oil is obtained by pressing or extraction, research has shown that

mycotoxins pass from the raw material into the oil. The maximum allowed amounts of mycotoxins in food around the world are regulated by appropriate regulations. Good agricultural practice, adequate plant disease management and adequate storage conditions limit the level of mycotoxins in the food chain, but do not completely eliminate their presence.
Various studies show that in the vegetable oils and fats production, the refining process is effective in reducing or removing certain mycotoxins, in order to obtain quality, health-safe edible refined oils or fats. Since there are two basic refining processes, research has shown that chemical refining is, in that sense, more suitable than physical. Within chemical refining, the best refining phases for mycotoxins removal are neutralization, bleaching and deodorization.

Abstract

Most vegetable oils obtained by cold pressing are yellow or yellowish-brown, with red or green tone. The color of the oil is a consequence of the presence of colored macromolecules (pigments). The most common natural pigments in the oils are carotenoids (yellow) and chlorophylls, green color pigments. The color is also affected by the content of various non-glyceride ingredients present in the oils, but also by various products formed during the inadequate management of the technological process. The aim of this study was to examine the content of the most abundant pigments (total carotenoids and total chlorophylls) in sunflower oil obtained by cold pressing of three confectionary (non-oily) sunflower hybrids (NS-H-6318, NS-H-6307 and NS-H-6308), as well as to determine their influence on instrumentally determined color parameters (CIE $L^*a^*b^*$ system and transparency). Negative a^* values noticed in examined samples indicate presence of green pigments in examined oils. Total chlorophyll content found in samples amounted from 0.41 to 0.70 mg/kg. Very strong negative correlation (R = -0.99) was determined between a^* color parameter and total chlorophyll content. On the other hand, strong correlation (R = 0.74) was noticed between yellow balance (b^*) and total carotenoids content. These compounds content amounted from 6.31 to 10.24 mg/kg. Also, very strong correlation (R = 0.90) was found between L^* color parameter indicating lightness and transparency obtained spectrophotometric..

Introduction

Carotenoids and chlorophylls are the most abundant pigments in sunflower oil. Carotenoids are tetraterpenoids, made up of eight isoprene molecules and containing 40 carbon atoms. They are classified into two groups: xanthophylls, which contain oxygen, and carotenes, which are pure oxygen-free hydrocarbons. Xanthophylls, together with dihydroxy carotenoids (mainly lutein), are the most abundant carotenoids in sunflower oil and make up 76 to 81% of total carotenoids (Rade et al., 2004). Carotenoids have a significant biological and protective role in the body, acting as provitamins and in protection against UV rays (De Leonardis et al., 2001; Tuberoso et al., 2007; Dimakou and Oreopoulou, 2012). In unrefined oils, carotenoids not only contribute to the color of the oil as an important parameter of sensory quality, but also have a strong antioxidant effect, such as tocopherols (Choe and Min, 2006; Dimakou and Oreopoulou, 2012).

The addition of β-carotene to sunflower oil increases oxidative stability at room temperature and under daylight due to the synergistic effect with tocopherols (Yanishlieva et al., 2001). Franke et al. (2010) found carotenoids in cold-pressed sunflower oil, but not in refined. The high proportion of carotenoids removed during refining is attributed to their thermolability (Ouyang et al., 1980). The content of total carotenoids in cold-pressed sunflower oil ranges from 2 to 4 mg/ml (Tuberoso et al., 2007), while Dimić et al. (2018) found a significantly higher content of total carotenoids (from 4.80 to 14.43 mg/kg). Other cold-pressed oils contain lower carotenoids content: walnut oil contains 0.93 ± 0.05 mg/kg (Martínez et al., 2013), grape seed oil 0.2 mg/kg (Lutterodt et al., 2011), blueberry oil 19 mg/kg (Parry et al., 2005).
Chlorophylls are green pigments, affect color, and are an important factor in sensory evaluation of oil (Matthäus and Brühl, 2004). Chlorophyll and chlorophyll derivatives are the most active promoters of photooxidation of oil in the presence of light and largely make oils susceptible to oxidative processes. Recent research also indicates the antioxidant properties of chlorophyll present in the oil (Tynek et al., 2012). Chlorophyll derivatives, pheophytin A, have shown a mild antioxidant effect in the dark, probably donating hydrogen to free radicals and thus interrupting the chain oxidation reaction (Dobarganes and Velasco, 2002). Crude sunflower oil has a low content of chlorophyll, which is removed during bleaching process. The chlorophyll content in cold-pressed sunflower oil ranges from 2.3 mg/kg (Tuberoso et al., 2007) to as much as 5.15 mg/kg in highoileic sunflower oil (Dimić et al., 2011). Dimić et al. (2018) examined the chlorophyll content in cold-pressed sunflower oils obtained from seeds with different proportions of organic impurities and hull and obtained a significantly lower content (from 0.00 to 1.21 ± 0.01 mg / kg). In refined oils, chlorophylls are found in amounts up to 0.6 mg/kg (Warner et al., 1989). In other cold-pressed oils, chlorophylls are found in higher concentrations, and in virgin olive oil the chlorophyll content can be higher than 31.97 mg/kg (Giuffrida et al., 2007), in cold-pressed rapeseed oil the content of total chlorophylls ranges from 22 to 118 mg/kg (Matthäus and Brühl, 2004), while cold-pressed flaxseed oil contains 0.8 to 5.76 mg/kg (Choo et al., 2007).

Material and Methods

Material
The latest confectionary (non-oily) sunflower hybrids (NS-H-6318, NS-H-6307, NS-H-6308) were used in the experimental research. Sunflower hybrids were grown in the experimental field of the Institute of Field and Vegetable Crops (45°15'6.01"N, 19°50'12.98"E), Novi Sad, Serbia from the 2017 growing season. Sunflower is grown under standard growing conditions without irrigation. All hybrids were sown in three blocks, randomly distributed. Up to 10 kg of seeds of an individual hybrid were collected, depending on the amount obtained in the experimental field. A representative amount of seeds was stored for 6 months at 20°C until the time of oil production (pressing). The seeds were pressed on a screw press. Before the beginning of the pressing process, the press was heated to the operating temperature (80 - 100°C) by a heater. The obtained cold-pressed oils were after precipitation for 48 h filtered through filter paper into 500 mL PET bottles, filled without empty space, closed and stored in a refrigerator at 6 ± 1°C until analysis.

Methods

Total carotenoids content, expressed as β-carotene, was determined by the standard spectrophotometric method (British standard, 1977) by measuring sunflower oil dissolved in cyclohexane (Lach-Ner, Czech Republic), at a wavelength of 452 nm, relative to pure cyclohexane as a blank, as described Dauqan et al. (2011).

Total chlorophyll content, expressed as pheophytin a, was determined by spectrophotometric method, by measuring the absorbance of pure oil, at a wavelength of 667 nm, relative to an empty cell as a blank, as described by Pokorny et al. (1985).

Oil color was determined by measuring instrumental color indicators in the CIE *L*a*b** system. The measurement was performed using a Minolta Chroma Meter CR-400 (Konica Minolta, Japan), using accessories for liquid materials, according to the manufacturer's instructions. To determine the color parameters, a colorimeter with an opening on the measuring head 8 mm and a standard measuring nozzle CR-A33b (Konica Minolta, Japan) was used. Measurements were performed in D-65 illumination with a standard shelter angle of 2°. Before each measurement series, the instrument was calibrated using a white calibration plate CR-A43 (Konica Minolta, Japan), according to the manufacturer's standard procedure. Oil samples were heated to room temperature (25°C) for 2 h before the color measurement.

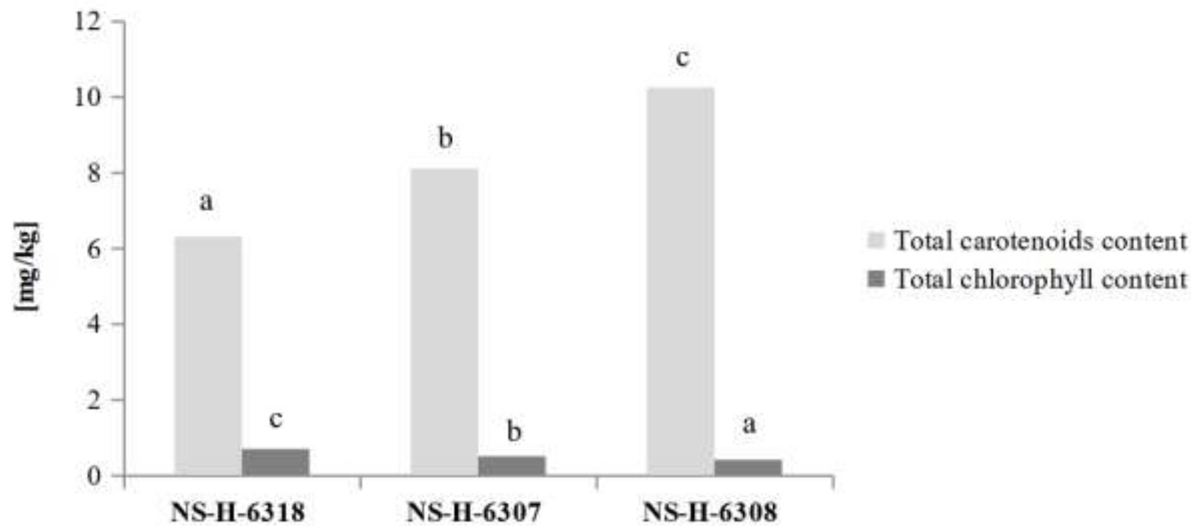
The oil color was also determined by spectrophotometric method, by measuring the transparency (% T) of pure oil, at 455 nm in relation to the empty cell as a blank (Dimić and Turkulov, 2000).

All spectrophotometric measurements were performed in a 1 cm - glass cells using a UV-VIS spectrophotometer, model T80 + (PG Instruments, UK).

Results are presented as mean ± standard deviation (n = 3). One-way analysis of variance (ANOVA) using the Tukey HSD test was used to determine significant differences between data at a significance level of $p < 0.05$. The degree of linear relationship between the two variables was measured using the Pearson correlation coefficient. For statistical data processing, the programs Statistica version 13.5.0.17 (StatSoft, Tulsa, Oklahoma, USA) and Microsoft Excel 2013 were used.

Results and Discussion

Carotenoids, yellow pigments, and chlorophylls, green pigments, in addition to affecting the sensory quality of unrefined oils and color formation (Parker et al., 2003; Matthäus and Brühl, 2004), also affect other aspects of quality, such as oil stability and shelf life (Pokorny et al., 1993; Karabagias et al., 2013). Carotenoids present in unrefined oils show an antioxidant activity, similar to tocopherols (Choe and Min, 2006; Rodriguez-Amaya, 2010; Dimakou and Oreopoulou, 2012). Some studies have also confirmed the antioxidant activity of chlorophyll (Lanfer-Marquez et al., 2005). The total carotenoids content (expressed as β-carotene) in the tested oil samples ranged from 6.31 ± 0.17 to 10.24 ± 0.15 mg/kg (Figure 1). The total chlorophyll content (expressed as pheophytin a) in the tested oil samples was determined in significantly lower quantities in relation to the total carotenoids content, up to 0.70 mg/kg (Figure 1), which is also characteristic for unrefined sunflower oils.



*different letter are significantly different based on Tukey HSD, at $p < 0.05$

Figure 1. Total carotenoids and total chlorophyll content of unrefined oil samples

Instrumental color parameters: *L** (lightness), *a** (+ red value / - green value), *b** (+ yellow value / - blue value) and transparency (% T) are summarized in Table 1. Oil color is a consequence of the presence of the pigments in cold-pressed sunflower oil. The lightness and the transparency are directly conditioned by the pigment content, with the increase of the pigment content the mentioned values decrease. The values of lightness ranged from 47.50 ± 0.02 to 48.93 ± 0.00, while the obtained values of transparency were in the range of 40.23 ± 0.05 to 55.93 ± 0.05%. However, a significant correlation of 0.90 ($p = 0.29$) was obtained between the values of lightness and transparency, shown in Table 2.

Table 1. Instrumental color parameters unrefined oil samples

Sample	Lightness *L**	+ red value / - green value *a**	+ yellow value / - blue value *b**	Transparency [% T]
NS-H-6318	47.96 ± 0.03^{b}	-4.76 ± 0.04^{a}	36.77 ± 0.04^{b}	51.67 ± 0.05^{b}
NS-H-6307	48.93 ± 0.00^{c}	-4.19 ± 0.01^{b}	35.31 ± 0.01^{a}	55.93 ± 0.05^{c}
NS-H-6308	47.50 ± 0.02^{a}	-3.87 ± 0.03^{c}	40.63 ± 0.05^{c}	40.23 ± 0.05^{a}

*different letter are significantly different based on Tukey HSD, at $p < 0.05$

The color values expressed through the *a** parameter ranged from -3.87 ± 0.03 to -4.76 ± 0.04. The obtained negative values indicate the presence of green pigments (chlorophyll) in the tested oils, but in small quantities (Figure 1). On the other hand, the color values expressed through the *b** parameter were in the range from 35.31 ± 0.01 to 40.63 ± 0.05, which indicates the presence of yellow pigments (carotenoids), in larger quantities compared to green pigments content (Figure 1). The obtained correlations between the *a** values and total chlorophyll content (R = -

0.99; p = 0.03) and between *b** values and total carotenoid content (R = 0.74; p = 0.47) confirm these statements (Table 2).

Table 2. Correlations between investigated parameters in unrefined oil samples

Correlation between	Pearson correlation coefficient R	Probability p
*L** and % T	0.90	0.29
*a** values and total chlorophyll content	-0.99	0.03
*b** values and total carotenoids content	0.74	0.47

Conclusions

Obtained negative *a** values indicate the presence of green pigments in the oils. Significantly higher *b** values indicate a significantly higher total carotenoids content in relation to total chlorophyll, which was confirmed in this paper.
The sunflower oil sample obtained by cold pressing of seeds of the NS-H-6307 hybrid had the highest lightness (48.93 ± 0.00) and transparency (55.93 ± 0.05) values. The lowest total pigments (carotenoids and chlorophyll) content was not found in the mentioned sample, which indicates that the oils color is affected by various non-glyceride components present in oils, as well as various products formed during the production process.
In this paper, the lightness and transparency of unrefined oils obtained by cold pressing of confectionary sunflower hybrids were also examined. Confectionary hybrids achieve a higher temperature during pressing, which can lead to the creation of products affecting the mentioned color parameters. Therefore, the obtained lightness and transparency results can also serve as a parameter of production process control. Also, the seeds of confectionary sunflower hybrids have a large hull content that can be of different colors, which affects the examined color parameters of unrefined oils obtained by cold pressing.

Abstract

Cherry is a deficient fruit species in the world and in Serbia, where it has become the most economically viable fruit species. There has been a growing interest among agricultural producers in raising orchards and growing cherries, in recent years. During flowering, in spring, climatic conditions are convinient for the development of the pathogen *Monilinia laxa*, which causes drying of flowers, twigs, branches and fruits. In order to produce healthy food and protect the environment, it is necessary to choose the right fungicides, as well as their timely and proper application, which is not cared about a lot in the area of southeastern Serbia. The research was conducted during 2020 and 2021 on the registered agricultural farm of the municipality of Lebane in Serbia, KM (cadastral municipality) Bošnjace. The experiments were performed according to a block system with three variants. The fungicide boscalid+pyraclostrobin (Signum) was applied in the first variant and in the second - cyprodinil (Ciprodex). The third variant was control, without the application of chemical protection measures. Evaluation of the effectiveness of the tested fungicides was performed by counting infected (dried) and healthy flowers on the tested trees. A thousand flowers were counted in a variant, and samples were taken from four different sides of the tree. The effectiveness of the tested fungicides was calculated according to the Abbott formula. The efficiency of chemical measures was high in both years of research and ranged from 94.56% for the fungicide Ciprodex in 2020, to 97.69% for the fungicide Signum in 2021.

Key words: *Cherry Burlat, Monilinia laxa, efficiency, fungicides.*

Introduction

Cherry is a deficient fruit species in the world and in Serbia, where it has become the most economically viable fruit species. There has been a growing interest among agricultural producers in raising orchards and growing cherries, in recent years. The pathogen *Monilinia laxa* can be a limiting factor in cherry cultivation due to its harmfulness. It is the most destructive stone fruit pathogen in USA, Europe, Australia and New Zeland (Archer, 1988). Byrde and Willets (1997) state that *M. laxa* causes large losses on stone fruit species with amount of about 50%. In California, *M. laxa* often causes damage to all types of stone fruit, and the greatest damage is caused on cherries in the area of large lakes, because there are ideal climatic conditions for the rapid development of this pathogen - humid weather and temperatures from 24 to 25^{o}C (Christensen 2003). It causes significant damage in years when the thermo-hygrometric factor is very favorable for the pathogen, i.e. when the flowering period and fruit ripening are accompanied by rainy weather and when the flowering period is extended (Ivanović, 1992; Perić, *et al*., 1996). If flowering is prolonged and time promotes the development of infection, may be necessary to perform interfacial treatment from the popcorn stage (Gubler et al., 2006). Perennial diseases of stone fruits lead to their exhaustion, general weakening and drying (Gudžić and Stojanović, 2011). There are many authors which pointed out this pathogen destructiveness on almost all stone fruit species (Kišpatić, 1985; Radman, 1979; Marić, 1991; Ivanović, 1992). The pathogen overwinters in the form of mycelium in cancer wounds in the bark of infected branches and twigs and in mummified fruits. Monilinia species form conidia on mummified fruits and diseased branches already at a temperature of 5^{o}C under favorable humidity conditions (Ogawa et al., 1995). The perfect, teleomorphic stage of the fungus (formation of apothecia) is a rare occurrence in Europe, so ascospores are not of significant importance in the epidemiology of this fungus (Balaž, 2000). Vojvodić (1979) states that the number of treatments against moiniliosis depends on the distribution of precipitation and that the number of treatments increases if it often rains or the humidity increases during flowering. In order to produce healthy food and protect the environment, it is necessary to choose the right fungicides, as well as their timely and proper application, which is not cared about a lot in the area of Lebane municipality in Serbia.

Material and Methods

The research was conducted during 2020 and 2021 in orchard on the registered agricultural farm of the municipality of Lebane in Serbia, on cadastral parcel 1243/3, KM (cadastral municipality) Bošnjace (Fig. 1). The fruit variety in orchard is Cherry Burlat, six years old. The cultivation system is a canopy in the shape of a vase, the planting density is 6 x 4 m and the exposure is southeast. The experiments were performed according to a block system with three variants, each variant in four repetitions and each repetition with five trees, so the study covered a total of 60 trees. The treatments were performed in the white balloon phase and in full bloom in both trial years. The fungicide boscalid+pyraclostrobin (Signum) was applied in the first variant and in the second - cyprodinil (Ciprodex), which are registered in Serbia for this purpose. The third variant was the control one, without the application of chemical protection measures. Evaluation of the effectiveness of the tested fungicides was performed by counting infected (dried) and healthy flowers on the tested trees. A thousand flowers were counted in a variant and samples were taken from four different sides of the tree. The effectiveness of the tested fungicides was calculated according to the Abbott formula.

Figure 1. Experimental field in the locality Bošnjace - Lebane

According to our observations, the cultivar Burlat is of medium early flowering. Cherry blossoms in the area of the municipality of Lebane took place in the third decade of March in both years of testing (Table 1). The onset, length and end of flowering are directly correlated with temperature as well as infection with the pathogen *M. laxa*.

Table 1. Dynamics of cherry blossoms and flowering length in the municipality of Lebane

Year	Phenophase of flower development			
	The start of Flowering (BBCH 61)	Full flowering (BBCH 65)	Overblown (BBCH 67)	Flowering length
2020	21.03.	27.03.	4.04.	14
2021	22.03.	29.03.	4.04.	13

The year 2020 was very rainy, with special reference to March, which was on average the warmest and rainiest, in the most part of southeastern Serbia. There were medium air temperatures, but also quite dry weather during April. Weather conditions with increased humidity favored the spread of the pathogen *M. laxa.* during the flowering period in 2021. It was rainy in this part of Serbia in terms of the amount of precipitation during the spring. The number of treatments directly dependent on the weather conditions and the length of cherry flowering (Perić i Perić, 2000; Todorović i Perić, 1996).

Results and Discussion

M. laxa, the causative agent of drying flowers, twigs and brown fruit rot is one of the most economically significant pathogens of stone fruits. The thermohygrometric factor was favorable to the pathogen *M. laxa* during the two-year study in 2020 and 2021 in the area of the municipality of Lebane. The rainy season in the flowering phase in both years affected the realization of the cherry blossom infection. Drying of flower bouquets was observed on control trees in both years. They turned brown, dried and mostly fell off, or remained stuck on the branch. It was noticed in further observation, that the pathogen from the diseased flower parts moved into the branches and caused their drying, and as a consequence of their drying, the leaves on them also became extinct (Fig. 2).

Figure 2. *Monilinia laxa* – drying of cherry flowers and twigs

Two treatments were performed during the two-year trial. The effectiveness of the tested fungicides was calculated according to the Abbott formula. The efficiency of applied fungicides during 2020 was high, for Signum 96.69%, and Ciprodex 94.56%. In 2021, higher efficiency was achieved in both variants, the preparation Signum, 97.69%, and Ciprodex 95.38%. The percentage of infected flowers in the control was different and ranged from 51.5% in 2020, and 47.7% in 2021 (Tables 2 and 3).

Table 2. Efficacy of chemical measures in the control of *M. laxa* on cherries in 2020 in the municipality of Lebane

Number of variants	Plant protection product	Concentration (%)	Average infection (%)	Efficiency (%)
V_1	Signum	0.075	1.7	96.69
V_2	Ciprodex	0.05	2.8	94.56
V_3	Control	-	51.5	-

Table 3. Efficiency of chemical measures in the control of *M. laxa* on cherries in 2021 in the municipality of Lebane

Number of variants	Plant protection product	Concentration (%)	Average infection (%)	Efficiency (%)
V_1	Signum	0.075	1.1	97.69
V_2	Ciprodex	0.05	2.2	95.38
V_3	Control	-	47.7	-

Differences in the efficiency of the tested preparation and the number of infected flowers are reflected in the different distribution of precipitation during flowering. During the flowering in 2020, all the conditions for the realization of the infection were fulfilled, the flowering lasted longer, so that a stronger infection was recorded, and a slightly lower efficiency of the applied preparations in relation to 2021.

Conclusions

There has been a growing interest among agricultural producers in raising orchards and modern cherries growing, in recent years. The pathogen *M. laxa* occurs almost every season, so it is necessary to prevent economic losses with as few treatments as possible. Persistence is important for the suppression of this pathogen, because depending on the year, the application of fungicides can be reduced to 1-4 treatments. Thermohygrometric factor in the years of research favored the development of the pathogen *M. laxa* on cherry. Treatment tests were performed at the beginning of flowering (20-30% of open flowers) and in full bloom (70-80% of open flowers) in both years. The second treatment should be done even in the absence of precipitation in order to reduce the infectious potential and avoid the possibility of infection, which would later cause fruit rot. The fungicide boscalid+pyraclostrobin (Signum) was applied in the first variant and in the second - cyprodinil (Ciprodex). Our two-year (2020-2021) studies show that the effectiveness of chemical measures was high in both years, ranging from 94.56%, for the fungicide Ciprodex in 2020, to 97.69%, for the fungicide Signum in 2021, as well as the fact that with two timely treatments, excellent results are achieved in the control of the very dangerous cherry pathogen *M. laxa*. The research is important, not only from the aspect of increasing productivity, i.e. economy, but also because of obtaining ecologically correct food and preserving the natural ecosystem.

Abstract

In an *in vitro* experiment, the morphological characteristics of three *Eutypa lata* isolates (EL129, EL153 and EL199), previously determined at the molecular level, and two reference isolates BX1.10 and 8F obtained from the Institute National de la Recherche Agronomique, INRA, France were observed. The following morphological features of the studied isolates were studied on the nutrient medium of potato dextrose agar (PDA): macroscopic (appearance, color and zoning of the front and back of the culture) and microscopic (vegetative organs of mycelium, reproductive organs of anamorphs - conidia, pycnidia, conidiophores and reproductive organs of teleomorphs - perithecium, ascus with ascospore). On potato dextrose medium (PDA) 24 h after placing, the studied *E. lata* isolates formed at the beginning a white mycelium. After 10 days, the mycelium had a cottony appearance, white color with a weak air growth. The entire colony developed evenly and had a fine diffuse edge. After 30 days, the face of the colony was white with a thick cotton aerial mycelium and a pale yellow conidial mass, which was excreted from the pycnidia. The studied *E. lata* isolates formed pycnidia, which were formed in culture. The pycnidia of the studied *E. lata* isolates were spherical or irregular in shape, from dark brown to black in color. The dimensions of the pycnidia were from 0.5 to 1 mm. Conidial mass was a cream to pale orange color on a PDA base. All studied isolates formed conidia in culture. None of the studied *E. lata* isolates, originating from the stem and branches of the grapevine from Serbia, as well as the control isolates, formed perithecia in culture.

Key words: *Isolates, breeding traits, substrates, Eutypa lata.*

Introduction

The grapevine dieback occurs in almost all countries of the world where vines are grown commercially. This is understandable given the wide range of host plants that *E. lata* fungus attacks. In addition to the wide distribution, grapevine dieback as an economically important grapevine disease is more significant in areas where annual rainfall is above 600 mm. On the other hand, it rarely occurs in areas where the average annual rainfall is less than 250 mm (Carter, 1994). In Serbia, this disease was first detected by Živković *et al*. (2012a, b).
E. lata is a pathogen of a large number of plants, from different genera of stone fruits, apples, berries and other fruits and causes great damage. The fungus is also isolated from a large number of ornamental, wild or woody plants. According to Carter *et al.* (1985) the grapevine (*Vitis* sp.) is the universal host for the distribution of *E. lata* to other species growing nearby.
Trouillas and Gubler (2010) studied the host circle of *E. lata* in the vineyard regions of California. The authors monitored the presence of *E. lata* perithecia on vine stems, in orchards

on apricot, almond, cherry, sweet cherry, apple and pear trees, as well as on natural hosts of large-leaved maple, willow and oleander. By phylogenetic analysis of the DNA sequences of the ITS region and the β-tubulin gene, the DNA-dependent RNA polymer gene (RPB2) was confirmed and identified by *E. lata* isolated from different plant hosts. The interspecific phylogenetic diversity according to Trouillas and Gubler (2010) does not match the geographical origin of the isolates, and the interspecific groups after different DNA phylogenies do not match. Significant phenotypic variations of *E. lata* isolates were detected on the vine, in terms of the length of ascospores and conidia as well as the levels of aggressiveness of isolates. The aim of this study was to describe the morphological (macroscopic and microscopic) properties of three isolates of *Eutypa lata* (EL129, EL153 and EL199) on a nutrient medium PDA.

Material and methods

The tested isolates were obtained from grapevine plants with grapevine dieback symptoms collected in the period 2015-2019. Sampling was performed in the main vine production areas on the territory of the Republic of Serbia from 14 sites: Dobričevo, Drenovac (Pomoravlje district), Praskovče, Lipovac (Nišavski district), Kobilje, Bela Voda, Krvavica, Suvaja, Trnavci, Tulež (Rasina district), Gudurica (South Banat district), Karbulovo (Bor district), Strezovac (Pčinja district), Sremski Karlovci (South Banat district). A total of 50 samples were taken and analyzed. After being brought to the laboratory, the samples were first washed with running water, and then fungal isolation was performed using standard phytopathological methods. Pathogen isolation was performed from grapevine stems and cordons. In order to remove surface impurities, parts of the stem and cordon were washed with running water for 2 h, and then cut into fragments 1 cm long. Fragments of the stem and cordon were cut at the junction of necrotic and healthy tissue, surface disinfected for 5 minutes in 5% sodium hypochlorite solution (NaOCl) (14% NaOCl, Superlab, Belgrade) and washed 3 times for 5 minutes in sterile distilled water. The fragments were transferred to sterile filter paper to remove excess fluid and then placed on a nutrient medium. Potato dextrose agar (PDA) with the addition of 300 μl / l gentamicin sulfate was used to isolate the pathogen. This medium was prepared from 200 g of potatoes, 20 g of dextrose (Torlak, Institute of Immunology and Virology, Belgrade), 20 g of agar (Torlak, Institute of Immunology and Virology, Belgrade) and 1 l of distilled water (Dhingra and Sinclair, 1995). Petri plate with fragments were incubated in a thermostat at a temperature of 24 ± 2˚C, in the dark until the development of fungal colonies around the fragments, and incubated at 24 ° C in the 24 h UV light for 30 days. Individual conidia were selected and transferred directly to the PDA plate according to the procedures described by (Dhingra and Sinclair, 1995), and stored on PDA in tubes at 4 ° C. In this study, the macroscopic and microscopic morphological characteristics of 3 isolates (EL129, EL153, EL199) isolated from Serbia and 2 reference isolates BX1.10 and 8F obtained by the Institute National de la Recherche Agronomique, INRA, France, were studied. Of the macroscopic characteristics, the traits of colonies are described, such as the appearance, color and zoning of the face and back of the culture on the tenth day after transferring (Muntanola-Cvetković, 1987). Identification was done by pathogenicity test (Peros and Berger, 1994), morphology (Glave and Rogers, 1982; Glave *et al.,* 1982) and PCR methods (Lecomte *et al*., 2000).
Considering the microscopic morphological characteristics, the appearance of mycelium, the presence of asexual (conidia, pycnidia, conidiophores) and sexual reproduction (perithecia, asci, ascospores) were studied.

Macroscopic and microscopic morphological characteristics of 3 *Eutypa lata* isolates and 2 *E. lata* reference isolates were studied on a PDA medium, according to the method of Glawe *et al.* (1982). The appearance, color and zoning of the face and back of the culture were observed, followed by the appearance, structure, color and growth of the mycelium. Inoculation of the studied isolates on medium was performed by aseptic application of round fragments of colonies of pure cultures of the studied isolates with a diameter of 10 mm, in the center of Petri plate, which were then grown at 25 ° C, and under 24 h UV light for 30 days. In all 3 isolates of *E. lata* and 2 reference isolates of *E. lata*, the shape and dimensions of conidia were studied. The study of conidia was performed by observing 100 randomly selected conidia of the studied isolate, using a microscope at a magnification of 400 times (Olympus BX51 / BX52, Japan) and a digital camera (Olympus DP71, Japan). The average dimensions of the conidia were determined by measuring the length and width of 100 randomly selected conidia of the studied fungal isolates, grown on a PDA medium using a light microscope and a digital camera.
To monitor the formation of the teleomorphic stage, 3 studied *E. lata* isolates and 2 reference *E. lata* isolates were grown on PDA medium, cultures were grown in a thicker layer (40 ml of medium per Petri dish with a diameter of 100 mm), at a temperature of 25 ° C. Readings of the presence of teleomorphic formations were performed after 30 days, 6 and 12 months. Monitoring of the appearance of teleomorphs was also performed in nature. After removing the bark from the dead wood of naturally infected grapevine plants, fragments of dead wood were cut and the presence of a stroma with perithecia was observed under binocular microscope (Olympus SYX7, DFPLAPO 1 x 4).
Statistical analysis performed in order to determine the relationship between *E. lata* isolate and two reference isolates 8F and BX1.10. Data were analyzed by variance analysis (ANOVA) using the computerized software (PROC GLM, SAS, System, version 8.1; SAS Institute, Cary, NC). To satisfy the assumptions of the ANOVA, the arcsine transformation of the proportion was used ($Y=2x \text{ arcsine } \sqrt{p}$). Homogeneity of groups was assessed using Duncan's test with $p = 0.05$.

Results and discussion

Examination of vineyards in several sites of grapevine cultivation in our country in the period from 2015 to 2019, revealed symptoms of grapevine dieback. Symptoms on the leaves of diseased vines are manifested in the form of small, chlorotic spots, distributed along the edge of the leaves, while the central part of the leaf blade had a wrinkled appearance. The edges of the leaves were worn and bent downwards, and in severe infections the surface of the leaves is mostly covered with necrotic spots. The shoots are light green in color, have a shortened appearance and the so-called zigzag rise of internodes.
On potato dextrose medium (PDA) 24 h after transferring, the studied *E. lata* isolates form the beginning of white mycelium. After 10 days, the mycelium was a cottony appearance, white color with a weak air growth. The entire colony develops evenly and were a fine diffuse edge. The back of the colony is cream in color, without fruiting structures (Figure 1). After 15 days, a dark pigment forms in the substrate. After 30 days, the face of the colony is white with a thick cotton aerial mycelium and a pale yellow conidial mass, which was excreted from the pycnidia. Macroscopic examination of colonies of *E. lata* isolates showed no differences in the morphological characteristics of the mycelium. Glawe *et al.* (1982) and McKemy *et al.* (1993) described cotton-white colonies of *E. lata* isolates on a PDA medium whose color changes to cream over time, which is in agreement with our results.

The studied *E. lata* isolates form pycnidia, which are formed in culture (Figure 1). The pycnidia of the studied *E. lata* isolates are spherical or irregular in shape, from dark brown to black in color. Conidial mass is a cream to pale orange color on a PDA base. The dimensions of the pycnidia were from 0.5 to 1 mm. Namely, under the influence of a change of 12 h of light - 12 h of darkness and at alternating temperatures of 19 ° C and 15 ° C, sporulation occurs after 30 days, which agrees with the statements of Carter (1994) and Munkvold (2001). The same authors state that in some cultures a gray pigment is formed after 15 days and the back of the colony turns black. Three to four weeks after placing, small black pycnidia appear in the culture under the influence of constant UV light. Conidia were excreted from the pycnidia in the form of a cream to an orange gelatinous mass (Rolshusen *et al.*, 2006; Trouillas and Gubler, 2010).

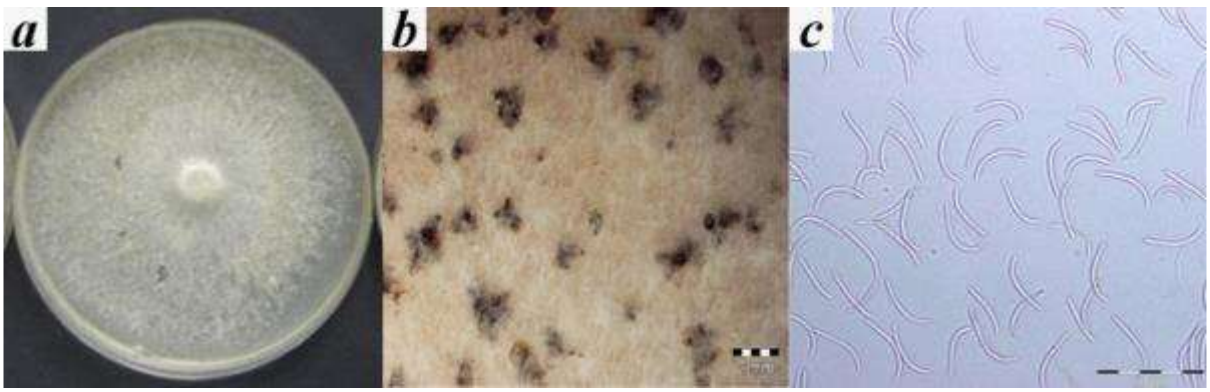

Figure 1. *Eutypa lata* EL129 isolate on PDA medium: a) Colony of isolates on PDA medium after 10 days of development; b) Stromatic formations of isolates in cultures 30 days old; c) Conidia EL153 in 30-day-old cultures.

In the studied *E. lata* isolates there are no morphological differences related to the appearance of conidia. All conidia were unicellular, unseptated, hyaline, elongated, and moderately curved with a flattened base (Figure 1). Conidia length and width were parameters that were individually statistically analyzed in order to determine suitability as a criterion for distinguishing between the tested *E. lata* isolates (Table 1). Based on data from the literature, the morphological characteristics of the anamorphic stage of the genus *Eutypa* were not sufficiently reliable traits for the identification of isolates up to the species level, although they were of great importance in the classification of the *Diatrypaceae* family (Trouillas *et al.*, 2010; Rolshausen *et al.*, 2014).
The genus *Eutypa* exhibits a very high similarity in the appearance of conidia, the ontogenesis of conidia, the characteristics of cultures, as well as the similarity of the teleomorphic stage with other genera within the fam. *Diatrypaceae*, such as the genus *Eutypella*, *Diatrype*, and *Diatrypella*. This makes it difficult to separate and identify the genus *Eutypa* (Glawe and Rogers, 1982; Rolshausen *et al*., 2006; 2014). On the contrary, the morphological characteristics of the teleomorphic stage of these fungi, due to their high uniformity, are very important for the determination of pathogens up to the genus level. However, during the tour of the terrain in the vineyards, no teleomorph was found in any locality where the symptoms of the dieback of the grapevine were observed. Therefore, the characteristics of teleomorphs were not used in the determination of this pathogen. Investigations of the morphological characteristics of anamorphs of the fungus served to identify the cause of the grapevine dieback to the level of genus. The

morphological and biometric values of the anamorphs were in agreement and fully corresponded to the reference values from the literature considering the pathogen *E. lata*. Considering the morphological characteristics of anamorphs, unicellular, conical, hyaline and slightly bent conidia with a flattened base, 19.50- (24.69) -33.34 μm long and 1.20- (1.69) -2.74 μm wide, were observed on PDA medium (Table 1), which is characteristic of *E. lata* species. These results were in agreement with the results presented by other authors. Glawe *et al.* (1982) describe the conidia of *E. lata* as unicellular, conical, slightly bent and hyaline, measuring 25-74 μm × 1–2 μm. Carter (1994) stated that conidia are 18-45 μm × 0.8–1.5 μm in size. Munkvold (2001) described the conidia of *E. lata* isolates as conical, straight or curved, very numerous, measuring 20-45 μm × 0.8–1.5 μm. Rolshausen *et al.* (2006, 2014) state that the dimensions of conidia of *E. lata* isolates from different hosts were 23.6-35.00 μm × 1.8-4.7 μm. In all tested isolates, conidia were formed in pycnidia, which is in agreement with the literature (Glawe and Rogers, 1982; Munkvold, 2001).

Table 1. Biometric values of conidia dimensions of the studied *Eutypa lata* isolates on PDA substrate

Isolate	Conidia length (μm)			Conidia width (μm)		
	Max	Min	Average*	Max	Min	Average*
EL 129	33.34	23.24	26.75	2.74	1.28	1.81
EL 153	23.10	19.50	20.94	1.81	1.20	1.54
EL 199	33.25	23.06	27.80	1.50	1.39	1.45
8F	26.25	22.54	24.33	2.19	1.58	1.94
BX1.10	24.99	20.04	23.62	2.16	1.28	1.71

*Average value of 100 repetitions

None of the studied *E. lata* isolates, originating from the stem and branches of the vine from Serbia, as well as the control isolates of *E. lata*, formed perithecia in culture, which agrees with the statements of Munkvold *et al.* (1993) and Munkvold (2001). Despite the very long storage of cultures until their complete exhaustion and observation on several occasions, after 30 days, 6 and 12 months, there was no formation of the teleomorphic stage. Also, the teleomorphic stage did not appear on grapevine plants inoculated with *E. lata* isolates, even after 27 months. Despite many years of monitoring this disease in vineyards, no teleomorphic stage has been found in nature. Glawe and Rogers (1982) and Carter (1994) stated that it is prevalent in vineyards older than 10 years in areas with frequent rainfall, and in vineyards where irrigation systems exist Munkvold *et al.,* (1993).

Conclusion

Macroscopic examination of cultures on a PDA medium showed that the studied *E. lata* isolates developed uniform colonies. In all studied isolates, conidia are formed in pycnidia from which a mucous mass (matrix) is secreted, which is a cream to a pale orange color. Isolates identified as *E. lata* had unicellular, smooth, hyaline, slightly bent, at the end narrowed, stringy conidia, 19.50- (24.69) -33.34 μm in length and width of 1.20- (1.69) -2.74 μm.

Abstract

In recent decades, the American highbush blueberry (*Vaccinium corymbosum* L.) has gained an increasingly important place in the fruit production of several countries around the world, especially in the highly developed ones. Also, there is a growing interest of berry fruit producers from Serbia in growing highbush blueberry plantations. Currently, in Serbia, highbush blueberries are grown on an area of about 2,500 ha with a tendency to increase production. Blueberries are attacked by numerous diseases that can cause greater economic damage, and in exceptional cases lead to the decline of entire orchards. There have been no systematic studies of blueberry mycopopulation in Serbia so far. In this study, we present the results of preliminary research on the mycopopulation of blueberries originating from Serbia. Samples were collected in the period June-August 2020. A total of 18 samples from five sites were analyzed (Ivanjica 3, Čačak 3, Sopot 3, Bačka Topola 6 and Zlatibor 3). The developed mycelium was placed on a new PDA medium and, after the initial growth, the top part of the mycelium was placed again on PDA. Microscopic examination was performed using an Olympus CX31 microscope. Morphological identification of fungi by genus was performed using standard keys. A total of 350 plant parts were examined from which 8 genera of fungi were isolated: *Fusarium, Phomopsis* (*Diaporthe*), *Alternaria, Epicoccum, Penicillium, Ulocladium, Trichoderma* and *Pestalotiopsis*. Macroscopic symptoms of infection were clearly visible on the plants from which the fungi were isolated. Given the growing importance of blueberries as a berry fruit species, the aim of this study is to determine fungi, potential pathogens of blueberries, in order to better understand the problems (plant dieback, yield reduction, etc.) that arise as a result of fungal presence on blueberries.

Keywords: *blueberry, fungal diseases, isolation, Serbia.*

Introduction

In recent decades, highbush blueberries have gained an increasingly important place in the fruit production of many, especially in highly developed, countries. The economic importance of blueberries, identical to other types of berries, is determined by: a) the use value of the fruit, b) profitability and b) high marketability of production (Leposavić and Jevremović, 2020). Greater interest in growing highbush blueberry plantations in Serbia arose in the 1990's, as a result of reduced interest in raspberries and the increase in demand for blueberries on the world market. During that period, plantations were established at several sites: Lučani, Viča, Osečina, Pecka and others (Leposavić, 2006). Highbush blueberry is the host of numerous pathogens and pests that can cause minor or major economic damage, and sometimes even lead to crop failure. Economically, the most important mycotic (fungal) causes of blueberry disease are *Botrytis*

cinerea (gray rot), *Colletotrichum gleosporioides* and *C. acutatum* (anthracnose) (Wharton and Schilde, 2003), *Monillinia vaccinii-corymbosi* (monilinia), *Phomopsis vaccinii* (blight), *Microsphaera vaccinii* (powdery mildew), *Fusarium acuminatum* (Fusarium branch blight) (Wright *et al*., 2014), *Septorioa albopunctata* (leaf and shoot spot), *Thekospora minima* (blueberry rust), *Valdenisinia heterodoxa* (leaf spot), *Godronia cassandrae* (blueberry shoot cancer), *Botryosphaeria dothidea* (blueberry trunk cancer) (Cardinaals *et al.*, 2018; Phillips *et al*., 2006), *Alternaria tenuissima* (alternaria blueberry leaf spot) and *Phytophthora cinnamomi* (blueberry root rot) (Wright et al., 1998; Michalecka *et al.,* 2017; Tennakoon *et al.,* 2018; Petrović *et al.,* 2020). While the most economically significant bacterioses on blueberries are *Pseudomonas syringae* pv. *syringae* (bacterial blueberry blight) and *Agrobacterium tumefaciens* (blueberry root cancer) (Leposavić and Jevremović, 2020). The American highbush blueberry is a host to numerous viruses and virus-like organisms. The presence of two viruses has been confirmed in Serbia: the blueberry red ringspot virus (BRRV) and the blueberry mosaic associated ophiovirus (BIMaV). Also, eight blueberry viruses have been detected, worldwide, that cause significant economic losses: blueberry scorch virus (BIScV), blueberry shock virus (BIScV), blueberry leaf virus (BISSV), Blueberry leaf mottle virus (BLMoV), Peach rosette mosaic virus (PRMV), tomato ringspot virus (ToRSV), tobacco ringspot virus (TRSV) and one phytoplasma blueberry stunt phytoplasma (Jevremović *et al.,* 2015; Jevremović *et al*., 2016a, b; Jevremović *et al*., 2019).
The aim of this research was to identify fungi on blueberries in Serbia, as possible causes of disease, in order to better understand the problems (plant dieback, reduced yields, etc.) that arise as a result of the presence of fungi on blueberries.

Material and methods

For the study of mycopopulation, samples of different varieties ('Duke', 'Draper', 'Cantichleer', 'Patriot', 'Berkly') of highbush blueberry (*Vaccinium corymbosum* L.) originating from Serbia were collected. Samples were collected in the period June-August 2020. A total of 18 samples from five sites were analyzed (Ivanjica 3, Čačak 3, Sopot 3, Bačka Topla 6 and Zlatibor 3). The plant parts of the branches and roots were carefully washed under running water. After rinsing, parts of the branches and roots were cut into pieces measuring 0.5-1 cm. Samples prepared in this way were disinfected with 96% ethanol for 10 seconds, 1% sodium hypochlorite (NaOCl) for 1 min. and washed three times in sterile distilled water. They were then dried on sterile filter paper and placed on potato dextrose agar (PDA) with streptomycin. Five plant parts were placed in each Petri plate in five repetitions. They were kept in a thermostat at 24 °C. The examination was performed every 3 days, and on most samples the mycelium developed by the 14th day. The developed mycelium was then transferred again on a new PDA medium and, after the initial growth, the top part of the mycelium was placed again on PDA.
Microscopic examination was performed using an Olympus BX61 microscope. Morphological identification of fungi by genus was performed using standard keys. The frequency of isolation in % was calculated using the formula (Vrandečić *et al*., 2011):

$$\textit{Frequency of isolation} = \frac{\textit{Number of parts colonised with fungi}}{\textit{Total number of analysed plant parts}} \times 100$$

Results and discussion

In these studies of the mycopopulation of blueberry plants, a total of 350 plant parts were examined (Table 1). Symptoms on the stem, in the form of necrotic spots and lesions, were clearly expressed on all plants from which the fungi were isolated. Fungi from the genera *Phomopsis* (*Diaporthe*), *Alternaria* and *Pestalotiopsis* were isolated from these plants. Also, in a large number of plants, light to dark brown changes (necrosis) were observed on the cross section of the roots, and fungi from the genera *Fusarium* and *Epicoccum* were isolated from these plants. In a large number of plants, black fruiting bodies (pycnidia) were observed on the leaves and stem. It was determined that they belong to the genera *Phomopsis* (*Diaporthe*) and *Pestalotiopsis*. A difference in the frequency of fungi isolation was noticed between the sites Ivanjica, Čačak, Sopot, Bačka Topola and Zlatibor. Namely, fungi from the genus *Pestalothiopsis* were isolated from samples from all studied sites (Ivanjica) in different percentages and the frequency of isolation ranged from 20% (Ivanjica 2) to 80% (Čačak 2) (Table 1). It was determined that the frequency of isolation includes fungi of the genus *Alternaria*, which were isolated in most samples in a large percentage of 30 to 80%. Regarding fungi of the genus *Phomopsis*, a difference in the frequency of isolation by sites was observed. In the samples originating from the sites Zlatibor 1, 2, 3 and Sopot 1, 2, 3, there were no isolates of fungi from this genus. In all other samples, the frequency of isolation of fungi from the genus *Phomopsis* ranged from 10 to 40%. Also, it was observed that fungi of the genus *Fusarium* were isolated from samples from all studied localities and the frequency of isolation ranged from 30 to 80%. The obtained results indicate that highbush blueberry is susceptible to attack by a large number of fungi, which can significantly affect and reduce its yield and quality.

Table 1. Frequency of fungal isolation on highbush blueberries in Serbia.

Region	***Number of samples***		***Fungi genus-branch***	***freq. of isol. (%)***	***Fungi genus-root***	***freq. of isol. (%)***

Clearly visible disease symptoms were present on all plants from which the isolations were made. A difference in the frequencies of isolation of individual genera of phytoparthogenic fungi was observed in samples from different localities in these studies. It was determined that in samples originating from Bačka Topola, Čačak and Ivanjica, isolated fungi from the genus *Pestalotiopsis* were more frequent. Also, the genus *Phomopsis* is more often isolated in samples originating from Čačak. Regarding the remaining six genera of isolated phytopathogenic fungi, they were present in all studied sites.

Phomopsis (*Diaporthe*) species are known to cause several blueberry diseases, including powdery mildew, branch cancer, and fruit rot (Lombard *et al.*, 2014). The same authors describe three species from the genera *Diaporth*, *D. asheicola*, *D. baccae*, and *D. sterilis*, based on phylogenetic analyzes, morphological, and molecular traits. *Diaporthe baccae* and *D. sterilis* originate from Europe and *D. asheicola* originates from Chile. *Diaperher baccae* and *D. sterilis* have been found to be sterile and therefore described on the basis of molecular characteristics. *Diaporthe vaccinii* causes cancer of twigs and rot of blueberry fruits and is currently listed as a quarantine disease in the European Union. In the Netherlands, two species from the same genus *Diaporthe*, *D. eres* and *D. rudis*, were detected, which were isolated from infected blueberry twigs (Cardinaals *et al.*, 2018). The same authors state that based on the results of the experiment in the greenhouse, the species *D. vaccini* is more aggressive than the species *D. eres.* In the field, it was shown experimentally that the development of lesions caused by *D. eres* did not differ significantly from those caused by *D. rudis*. Cardinaals *et al.* (2018) stated that fungi isolated in Europe, *D. eres* and *D rudis*, do not cause significant damage to blueberries. Although several *Diaporthe* species have been observed on blueberries, in various countries of the world, *D. vaccinii* remains a major problem in Europe. Wright *et al.* (2014) reported the existence of a new parasite on the blueberry in Argentina - fungus *F. acuminatum*. In their research, they came to the conclusion that fungi from the genus *Fusarium* can cause damage to blueberry plants, especially in plants that are weakened by frost and cold weather. Symptoms of the fungus *F. acuminatum* were observed during cold springs. The species *A. tenuissima* and *A. alternata* are considered to be the cause of leaf spot and rot of blueberry fruits around the world. However, most *Alternaria* species show significant morphological similarities including *A. tenuissima* and *A. alternata* species (Zhu and Xiao, 2015). According to research by Zhu and Xiao (2015) in California, only 5% of isolates of *A. tenuissima*, 61.5% of *A. alternata* and 32.9% of *A. arborescens* caused damage to blueberries. In their research, the same authors, in addition to the species *A. tenuissima, A. alternata, A. arborescens*, also detected the species *A. infectoria* and *A. rosae*. *A. tenuissima* has been identified as a cause of leaf spot and fruit rot on blueberries in Argentina, China, the United States and New Zealand (Fernández *et al*., 2015). *Pestalotiopsis guepinii* has been found to cause damage to blueberries in China, Turkey, Argentina (Wright *et al*., 1998) and Chile (Zhang *et al*., 2003; Fernández *et al*., 2015). In Chile, in addition to *Pestalotiopsis guepinii*, the species *Pestalotiopsis clavispora* (syn. *Pestalotia clavispora* GF Atk.), *P. neglecta* (syn. *Pestalotia ignocta* Thüm.) and *Truncatella angustata* (syn. *Pestalotia angustata* (Pers.) Arx) (Espinoza *et al*., 2008) have been also detected as causes of branch cancer and the dieback of blueberry plants.

Conclusions

This paper presents the preliminary results of mycopopulation of 18 samples of highbush blueberry from five sites. So far, there has been no significant research in this direction in Serbia, so future research related to highbush blueberries will go in the direction of studying fungal pathogens as well as finding ways of controlling them.

Abstract

Modern wheat production increasingly relies on its additional nutrition through leaves, and numerous biostimulators and water-soluble fertilizers are used for foliar feeding. This kind of nutrition regime makes plants more resistant to pathogens. During its growth wheat is attacked by many pathogenic fungi. Septoria leaf blotch (*Mycosphaerella graminicola*) and powdery mildew (*Blumeria graminis*) are the diseases occurring every year. This investigation was carried out with three wheat cultivars (Sosthene, Simonida and Evropa), during growing season 2018/2019, in the area of Gračanica municipality (K&M), on vertisol soil type. The trial was set in RCBD with four replications. The treatments were the following: 1) Control; 2) $N_{50}P_{90}K_{90}$; 3) $N_{100}P_{90}K_{90}$; 4) $N_{150}P_{90}K_{90}$; 5) $N_{100}P_{90}K_{90}$+ Agrostemin; 6) $N_{100}P_{90}K_{90}$ + Murtonik; 7) $N_{100}P_{90}K_{90}$ + Agrostemin + Murtonik. Occurrence and development of both diseases were observed, and attack intensity was graded during the first weeks of June, according to the standard scales for septoria leaf blotch and powdery mildew. Fertilization regime significantly affected occurrence and intensity of septoria leaf blotch. In cultivar Sosthene foliarly applied Agrostemin and Murtonik reduced the disease development. The treatments with those two supplements applied ($N_{100}P_{90}K_{90}$ + Agrostemin and $N_{100}P_{90}K_{90}$ + Murtonik) had the lowest infection intensity (5.0%). Powdery mildew was registered in all three studied cultivars, but not in all the treatments. Unlike septoria leaf blotch, powdery mildew occurred sporadically, and with low intensity.

Keywords: *Wheat, Septoria leaf blotch, Powdery mildew, Fertilization.*

Introduction

Wheat is one of the field crops making a group of strategic products within the total agricultural industry. Along with soybean, wheat is a "top-selling merchandise", because its price on global stock market strongly affects international trade relations (Cvijanović *et al.*, 2017). Yield and quality of wheat grain is largely influenced by balanced mineral nutrition, weather conditions (Đekić *et al.*, 2017), use of non-certified seed (Protić *et al.*, 2005) and occurrence of diseases, such as septoria leaf blotch (causal agent *Mycosphaerella graminicola*) and powdery mildew (causal agent *Blumeria graminis*).
Demand for nutritive elements is dependent on the amount of planned grain yield. Blanchet *et al.* (2016) points out the application of fertilizers as a necessary measure to keep sustainable productivity of agricultural ecosystems. Among the major elements of mineral nutrition, nitrogen plays the main role in grain yield increase (Đekić *et al.*, 2014; Jelić *et al.*, 2015). Inadequate nutrition can weaken plant vitality so they lose resistance to pathogens. Modern wheat production increasingly relies on its additional nutrition through leaves, and numerous biostimulators and water-soluble fertilizers, containing both macro and micro elements, are used

for foliar fertilization. Absorption of nutritive elements from these formulations is several times greater than the absorption through the root pathway (Bolcu and Andrei, 2003). This kind of nutrition regime, besides grain yield and quality improvement, makes plants healthy and more resistant to pathogens.

Septoria leaf blotch is the disease present in the all regions where wheat is grown and, according to Stammler *et al.* (2008), it is one of the most important wheat diseases in northern Europe. During humid years the disease can massively attack susceptible genotypes, and in Serbia it occurs on a regular basis with a high percent of infection (Jevtić *et al.,* 2008). Powdery mildew is a common disease in the all wheat production areas, including the territory of Serbia. It occurs every year with greater or lower intensity. The causal agent is considered as a high-risk pathogen because of its significant adaptability potential and change of virulence in populations of the pathogen (Lalošević *et al.*, 2016).

Small grain diseases cannot be completely eradicated from our production fields. The basic goal is to make them less damaging, which can be achieved by applying various measures (creating and growing resistant cultivars and applying proper agrotechnique practice). If plants are developed under the optimal nutrition regime, they will be able to express their natural resistance to pathogens. This investigation aimed to establish the effect of increasing nitrogen doses, as well as application of water-soluble fertilizers and biostimulators, on occurrence and intensity of septoria leaf blotch and powdery mildew of wheat, in the conditions of natural infection.

Material and Methods

The investigation, dealing with the effect of increasing nitrogen doses and application of water-soluble fertilizers and biostimulators on occurrence and intensity of septoria leaf blotch and powdery mildew of wheat, has been carried out with three wheat cultivars (Sosthene, Simonida and Evropa), during the growing season 2018/2019, in the area of Gračanica municipality (K&M), on vertisol soil type. Local coordinates of the location were the following: latitude 42º 36', longitude 21° 11', altitude 588 m. The trial was set in a randomized complete block design with four replications. Elementary plot area was 6 m^2 (3x2). The experimental treatments were the following:

1. Control (unfertilized)
2. $N_{50}P_{90}K_{90}$
3. $N_{100}P_{90}K_{90}$
4. $N_{150}P_{90}K_{90}$
5. $N_{100}P_{90}K_{90}$ + Agrostemin
6. $N_{100}P_{90}K_{90}$ + Murtonik
7. $N_{100}P_{90}K_{90}$ + Agrostemin + Murtonik.

Nitrogen was applied in three doses, namely 50, 100 and 150 kg ha^{-1}, while the dose of phosphorus and potassium was 90 kg ha^{-1} for each element. The whole amount of phosphorus and potassium was applied pre-sowing, along with a part of nitrogen. The rest of nitrogen, following predetermined combinations, was administered in dates during plant growth, by the fertilizer LAN (limestone ammonium nitrate, 27% of N). Foliar application of biostimulator Agrostemin was at the dose of 25 g ha^{-1}, while water-soluble fertilizer Murtonik (19:9:27 + microelements) was administered at the dose of 3 kg h^{-1}. During the period of maximal development of septoria leaf blotch and powdery mildew (the first ten days of June), occurrence and development of both diseases were observed. Intensity of attack by septoria leaf blotch was estimated according to the scale of Gešele (1978), grading severity of infection from 0 to 100%. For powdery mildew, reaction mode of the investigated cultivars was graded by determining infection type from 0-4 and severity of infection from 0-100% (Peterson *et al.*, 1948). On the basis of determined infection type and severity of infection we calculated coefficient of infection.

Results and Discussion

Septoria leaf blotch was registered in the all three investigated wheat cultivars and in all the treatments (table 1).

Table 1. Attack intensity of *Mycosphaerela graminicola* during growing season 2018/19

Treatments	Cultivars		
	Sosthene	Simonida	Evropa
	I (%)	I (%)	I (%)
Ø (unfertilized control)	18	20	20
$N_{50}P_{90}$ K_{90}	7	11	12
$N_{100}P_{90}$ K_{90}	7	5	10
$N_{150}P_{90}K_{90}$	7	7	10
$N_{100}P_{90}K_{90}$ + Agrostemin	5	10	18
$N_{100}P_{90}K_{90}$ + Murtonik	5	9	18
$N_{100}P_{90}K_{90}$ + Agrostemin + Murtonik	8	10	18
Average	8.14	10.28	15.14

Comparing the studied wheat cultivars, the highest average intensity of the disease caused by *M. graminicola* was observed in the cultivar Evropa (15.14%), then in the cultivar Simonida (10.28%), and the lowest one was observed in the cultivar Sosthene (8.14%). Such result indicate that in this study the cultivar Sosthene showed the greatest resistance to the causal agent of septoria leaf blotch. An elaborate comparison can clearly reveal that the difference in the average attack intensity between the cultivars Evropa and Simonida was 4.86%, while between Evropa and Sosthene it was 7%. Similar reaction of the cultivar Evropa to the causal agent of septoria leaf blotch in the conditions of natural infection at Kosovo and Metohia province, during 2015 (10%) and 2016 (20%), has been reported previously by Gudžić *et al.* (2018). Various nutrition regimes affected significantly occurrence of the disease and severity of infection. The disease occured in the all three cultivars with the highest attack intensity at unfertilized plots of the trial (control). At this variant, the cultivar Sosthene was attacked with intensity of 18%, while in the cultivars Simonida and Evropa attack intensity was slightly higher and amounted 20% in each. There was a clearly visible trend in the cultivar Evropa that attack intensity of the variants with foliar fertilization applied ($N_{100}P_{90}K_{90}$ + Agrostemin, $N_{100}P_{90}K_{90}$ + Murtonik and $N_{100}P_{90}K_{90}$ + Agrostemin + Murtonik) was slightly lower than in unfertilized control. Attack intensity of those variants was 18%. In this cultivar the lowest disease intensity was observed in the variants $N_{100}P_{90}$ K_{90} and $N_{150}P_{90}K_{90}$, and in the variant $N_{50}P_{90}K_{90}$ was insignificantly higher and amounted 12%. The effect of fertilization on increasing resistance of wheat to the causal agent of

septoria leaf blotch was visible better in the cultivar Simonida, and especially in the cultivar Sosthene. Sosthene expressed a positive influence of foliarly applied Agrostemin and Murtonik on the disease occurrence. In the variants where one of these two preparations was applied ($N_{100}P_{90}K_{90}$ + Agrostemin and $N_{100}P_{90}K_{90}$ + Murtonik) the lowest attack intensity was observed (5%), which was not the case in the variant where they were applied together ($N_{100}P_{90}K_{90}$ + Agrostemin + Murtonik). *M. graminicola* is a pathogen causing problems for wheat production. Growing susceptible cultivars, suitable weather and sufficient amount of inoculum present at the crop are necessary conditions for this disease to occur (Kalentić *et al.*, 2006).
Along with septoria leaf blotch, occurrence of powdery mildew was also observed in the investigated wheat cultivars (table 2).

Table 2. Attack intensity of *Blumeria graminis* during vegetation 2018/19

Variants	Cultivars								
	Sosthene			Simonida			Evropa		
	t	I	IC	t	I	IC	t	I	IC
Ø (unfertilized control)									
$N_{50}P_{90}K_{90}$				2	10	4			
$N_{100}P_{90}K_{90}$	1	10	2						
$N_{150}P_{90}K_{90}$							3	20	16
$N_{100}P_{90}K_{90}$ + Agrostemin									
$N_{100}P_{90}K_{90}$ + Murtonik									
$N_{100}P_{90}K_{90}$ + Agrostemin + Murtonik	2	10	4						
Average		2.86			1.43			2.86	

t – Infection type; I – Severity of infection (%); IC – Infection coefficient

The obtained results showed that powdery mildew occurred sporadically, and in a low intensity when it did. In the cultivar Sosthene severity of infection of 10% was observed in the variants $N_{100}P_{90}K_{90}$ and $N_{100}P_{90}K_{90}$ + Agrostemin + Murtonik. In the other two cultivars powdery mildew was observed in only one variant each. So in the cultivar Simonida severity of infection of 10% was found in the variant $N_{50}P_{90}K_{90}$, while in the cultivar Evropa the disease was observed only in the variant where the highest amount of nitrogen was applied ($N_{150}P_{90}K_{90}$), and severity of infection was 20%. Previous reports by Stojanović *et al.* (2004) and Gudžić *et al.* (2008) pointed out to specific reaction of various wheat cultivars to the causal agent of powdery mildew in the conditions of natural infection. Lower severity of wheat infection by the causal agent of powdery mildew was the result of a prolonged latent period and less successful infection (Jerković and Jevtić, 2000).

Conclusions

Septoria leaf blotch was registered in the all three investigated wheat cultivars and in all nutrition treatments. Occurrence of the disease was found highest for the all three cultivars in the absence of any mineral fertilization of wheat. The highest average attack intensity was observed in the cultivar Evropa (15.14%), and the lowest one in cultivar Sosthene (8.14%). Application of the biostimulator and foliar fertilizer, used both alone and combined, showed the best effect on septoria leaf blotch in the cultivar Sosthene. Powdery mildew occurred sporadically, and in fertilization combinations where it did, severity of infection was low.

Abstract

Sweet corn is a well-established product in the market, and popular food all around the world. It is a source of phytochemicals which, due to their antioxidant activities, demonstrate significant beneficial contribution in reducing the risk of many diseases, and therefore sweet corn could be considered as a functional food. The aim of this study was to examine phytochemicals content in four sweet corn hybrids. Carotenoids, tocopherols and phenolic acid content was determined by HPLC-DAD/FLD and functional oligosaccharide by HPAEC-PAD. The highest content of lutein + zeaxanthin was found in hybrid ZP515su (37,53 μg/g), while hybrid ZP553su had the highest content of β-carotene (1,01 μg/g). Sweet corn grains are a considerable source of phenolic acids such as ferulic, caffeic and p-coumaric acids which have a wide scope of effects against human diseases including cancer, cardiovascular and neurodegenerative diseases. The highest content of total phenolic acids was found in hybrid ZP553su (73,94 μg/g) and ferulic acid in hybrid ZP515su (26,67 μg/g). Functional oligosaccharides could bring benefit to human health and are consider as dietary fiber and prebiotics. Hybrid ZP504su had the highest content of trehalose and turanose, hybrid ZP355su maltose and panose, as well as hybrid ZP515su raffinose, isomaltose and maltotriose. As an important component of a healthy diet, sweet corn provides high nutrition value in addition to the enjoyment in taste. Therefore, developing of sweet corn genotypes with high phytochemicals content is challenge for breeders.

Key words: *sweet corn, functional sugar, phytochemicals, health benefits.*

Introduction

Sweet corn is used around the world in the human diet in the milk (technological) phase of maturity when the grain is tender, sweet, and juicy and is therefore considered a vegetable. In Europe, the largest producers, according to the sown areas, are Hungary (39,000 ha) and France (26,000 ha). In the world, however, the largest producer and exporter of sweet corn is the United States. According to statistics, in the last decade, the total world export volume of frozen and canned products based on sweet corn has increased by about 49% and 33% respectively (FAOSTAT, 2016). This data indicates an increased demand and consumption of sweet corn in the world and at the same time indicates a greater need for its production. Functional foods contain substances that promote human health. Many studies have been published and a positive correlation has been shown between consuming functional foods and reducing various diseases. Carotenoids, tocopherols, and phenolic compounds that exhibit antioxidant properties are receiving increasing attention. Carotenoid consumption is associated with a number of human health benefits, such as prevention of heart and vascular diseases (Agarwal *et al.*, 2012), prevention of cataracts and macular degeneration of the eye, (Basu *et al.,* 2001), cancer chemoprotection (Tanaka *et al*., 2012), as well as neurodegenerative diseases (Obulesu *et al*., 2011). Vitamin E is known as a powerful antioxidant and has anticancer (Saini and Keum, 2016), antihypertensive (Kizhakekuttu and Widlansky, 2010), and neuroprotective activity (Rashid *et al.*, 2015). One of the most studied phenolics metabolites is ferulic acid, which is an outstanding antioxidant agent very common in vegetables. Chaudhary *et al*. (2019) reported that ferulic acids have a wide scope of effects against human diseases including cancer, diabetes, and cardiovascular and neurodegenerative diseases. Also, recent research shows that functional oligosaccharides exhibit antioxidant activity and provide positive effects on human health. The beneficial roles of functional oligosaccharides are primarily prebiotic, but they also increase mineral absorption; improve HDL/LDL cholesterol ratio; reduce serum lipids as well as blood cholesterol; they eliminate toxins from the body and have a low glycemic index (Cheng *et al*., 2017). Sweet corn kernel in addition to sugar contains 2.1 - 4.5% protein, 3 - 20% starch, 1.1 - 2.7% fat, 0.9 - 1.9% cellulose, 9-12 mg of vitamin C, small amounts of vitamins A, B1, B2 and mineral components. Also, sweet corn has a wide range of phytochemicals exhibiting health benefits of lowering risk of chronic diseases. The health benefits of sweet corn are mainly attributed to the high contents of carotenoids and phenols. Health benefiting properties of carotenoids and phenolic compounds are related to high anti-oxidant and radical scavenging activities and also to anti-inflammatory, anticancer and neuroprotective properties (Balasubashini *et al*, 2003; Tokuji *et al*, 2009). The aim of this study was to examine phytochemicals content (carotenoids, tocopherols, phenolic acid and functional oligosaccharide) in four sweet corn hybrids.

Material and methods

In this research phytochemicals profile (carotenoids, tocopherols, phenolic acids and sugars) was determined in kernel of four sweet corn hybrids ZP504*su*, ZP355*su*, ZP553*su* and ZP515*su*, planted 2019 in Maize Research Institute trail field. Carotenoids and tocopherols extraction and quantification by HPLC-DAD/FLD (Dionex UltiMate 3000 Thermo Scientific, Germany) was the same as it was proposed by Mesarović *et al*., 2019. The detection of tocopherols and carotenoids was conducted by fluorescence (λ_{ex} 290 nm; λ_{em} 325 nm) and photodiode array (at 450 nm and 470 nm) detector, respectively. The extraction of free phenolic acids was achieved by using (2 × 5 mL) 80% methanol (Mesarović *et al*., 2017). After homogenization in the ultrasound bath (30 min at 25 ºC) for all analyses, the extracts were centrifuged, filtered (0.45 µm nylon syringe filter) and directly injected into the HPLC system (Dionex UltiMate 3000 Thermo Scientific, Germany). The free phenolic acids were detected on 278, 260, 290 and 320 nm. The sugars extraction from approximately 5g of fresh kernel was accomplished by using ultraviolet ultrapure water (50ml), (Schmitzer *et al*., 2011), and sugar quantification was accomplished by high performance anion-exchange chromatography – HPAEC (Thermo Scientific) with pulsed amperometric detection-PAD. Concentrations of the analyzed phytochemicals are expressed as µg per g of dry matter (DM), except for sugars which were expressed as mg/g DM and reported as the mean value of three independent injections.

Results and discussion

Sweet corn contains phytochemicals such as carotenoids, tocopherols and phenolic acids (Ibrahim and Juvik, 2009; Das and Singh, 2016). The content of those phytochemicals is highly influenced by the genotype and also by applied agrotechnical practice (Suri and Tanumihardjo, 2016, Mesarović *et al.*, 2019). Since, humans cannot synthesize carotenoids they have to obtain them from the diet to meet minimal nutritional requirements and maintain optimal health (Jerome-Morais, *et al*, 2011; Sen and Chakraborty, 2011). Sweet corn contains significant amount of lutein, zeaxanthin and other carotenoids (Junpatiw *et al*., 2013) and has been widely consumed as a healthy food. The genetic variation for carotenoids among maize hybrids showed zeaxanthin and lutein were the most predominant. Lutein and zeaxanthin are the primary pigment compounds found in the retina where they protect eye tissue from phototoxic damage by absorbing 90% of harmful high-energy blue light (Roberts and Dennison, 2015).

Content of lutein + zeaxanthin ranged from 17,88–37,53 μg/g, and *β*-carotene content vary from 0,52–1,01 μg/g, Table 1. The higest content of L+Z had hybrid ZP515*su* (37,53 μg/g), and the highest β-carotene content had hybrid ZP553*su* (1,01 μg/g). Regarding total carotenoid content of all four hybrids, ZP515*su* hybrid achieves the highest value, namely 38,04 μg/g, followed by hybrid ZP553*su*, which recorded values of 25,66 μg/g. The content of lutein+zeaxanthin and *β*-carotene in kernel of four sweet corn hybrids was in accordance with results of Kurilich *et al* (1999) and Ibrahim *et al* (2009). In our previously research (Drinic *et al*., 2019) carotenoids were determined in the set of maize inbred lines with different kernel type (dent, flint, sweet corn, popcorn) and kernel color (yellow and orange). The highest average lutein+zeaxanhtin and β – carotene contents had lines with orange kernels, folowed by yelow inbreds, sweet corn and popcorn.

Table 1. The content of carotenoids and tocopherols in sweet corn hybrids (μg/g)

	ZP504*su*	ZP355*su*	ZP553*su*	ZP515*su*
Lutein+zeaxantin	24,25±0,75	17,88±0,17	24,75±0,97	37,53±0,63
β-carotene	0,92±0,04	0,53±0,01	1,01±0,04	0,52±0,06
Σ carotenoids	24,78±0,78	18,40±0,18	25,66±0,98	38,04±0,69
δ- tocopherol	0,15±0,04	0,75±0,03	0,83±0,02	0,81±0,02
β+*γ*- tocopherol	8,23±0,07	20,06±0,09	10,00±0,05	12,66±0,07
α-tocopherol	2,06±0,09	9,48±0,07	3,89±0,01	2,48±0,04

The highest value of *β*+*γ* -tocopherols has hybrid ZP355*su* (20,06 μg/g) as well as *α*-tocopherols (9,48 μg/g), Table 1. The hybrid ZP553su has the highest value of *δ* –tocopherol (0,83 μg/g). Tocopherols content detected in grain of four sweet corn hybrids was in accordinance with results of Kurilich *et al.* (1999), Ibrahim *et al.* (2009), Xie *et a.l* (2017), and Baseggio *et al.* (2018).

Our previous study of tocopherols content in set of different inbred lines showed that sweet corn inbreds had higher β+γ tocopherols content than inbred lines with standard kernel type but α tocopherol content was lower than in inbreds with standard kernel type (Drinic *et al.* 2017, 2019).

Table 2.The content of phenolic acids in sweet corn hybrids (μg/g)

	ZP504*su*	ZP355*su*	ZP553*su*	ZP515*su*
sinapic acid	8,07±0,08	9,90±0,03	22,71±0,00	12,31±0,01
cinnamic acid	2,18±0,05	2,31±0,06	1,87±0,04	3,72±0,02
protocatechuic acid	20,42±0,50	22,30±0,61	29,73±0,71	17,82±0,54
caffeic acid	1,11±0,03	1,46±0,04	1,05±0,02	1,08±0,03

p-coumaric acids	4,92±0,02	7,59±0,03	8,26±0,03	9,21±0,06
ferulic acid	11,80±0,01	11,89±0,05	10,31±0,01	26,67±0,38
Σ phenolic acids	48,50±0,69	55,45±0,83	73,94±0,90	70,81±1,05

The highest total content of phenolic acids was recorded in hybrid ZP553*su* (73,94 μg/g), Table 2. The highest content of ferulic acid was shown by the hybrid ZP515*su* (26,67 μg/g) which also has high content of total phenolic acid (70,81μg/g), and the highest content of *p*-coumaric acids and cinnamic acid (9,21μg/g and 3,72 μg/g), respectively. The hybrid ZP553*su* has the highest value of protocatechuic acid and sinapic acid but the lowest value of ferulic acid. The hybrids ZP355*su* has the highest caffeic acid content (1,46 μg/g). However, the content of phenolic acids obtained in our study was lower in comparison with the results obtained by Das and Singh (2016). Zhang *et al.* (2017) showed significant genotypic differences for phenolic acids exist in the tested sweet corn varieties. Mesarović *et al.* (2018) reported a significant effect of growing season on total phenols in the grain of three sweet corn hybrids. Total phenol content was lower in drier growing season for all hybrids.

Due to diverse health benefits of ferulic acid, including antioxidant, anti-inflammatory, and anticancer activities, it is regarded as one of the most important phenolic acids and receiving increasingly more attention (Kroon and Williamson, 1999). Also p-coumaric acid is of great interest due to the antioxidant and cardiovascular protective properties (Jyoti and Stanely, 2013).

Recently, functional oligosaccharides (isomaltose, panose, trehalose, maltotriose, raffinose, etc.) are receiving increasing attention according their functional proprieties. They are indigestible and provide positive effects on human health, and therefore considered dietary fiber and prebiotics (Cheng *et al*., 2017). Primarily the beneficial roles are prebiotic that enhance beneficial bacteria in the colon, but they also increase mineral absorption, improve HDL/LDL cholesterol ratio, reduce blood cholesterol, eliminate toxins from the body and have a low glycemic index (Ibrahim *et al*., 2018).

Table 3. Content of functional oligosaccharides in sweet corn hybrids (mg/g)

	ZP504*su*	ZP355*su*	ZP553*su*	ZP515*su*
trehalose	2,00±0,02	1,98±0,08	0,56±0,03	1,26±0,02
turanose	11,56±0,09	8,56±0,07	4,10±0,02	4,42±0,00
maltose	11,10±0,09	27,61±0,04	14,17±0,01	10,53±0,02
panose	1,09±0,09	2,84±0,04	0,40±0,02	0,25±0,04
raffinose	18,33±0,15	18,41±0,25	14,93±0,09	72,50±0,93
isomaltose	4,09±0,03	3,90±0,03	6,35±0,05	18,40±0,30
maltotriose	0,89±0,07	1,30±0,02	0,44±0,03	3,33±0,06

In the case of hybrids ZP504*su*, the highest content of trehalose (2,00 mg/g), and turanose (11,56 mg/g) were recorded, Table 3. The ZP355*su* hybrid had the highest content of maltose (27,61 mg/g) and panose (2,84 mg/g). The highest contents of isomaltose (18,40mg /g) and maltotriose (3,33 mg/g) were found in grain of hybrid ZP515*su*.

Conclusion

The hybrid ZP515*su* had a high level of lutein+zeaxanthin, total carotenoids, cinnamic acid, *p*-coumaric acids, ferulic acid, raffinose as well as moderate content of tocopherols. Hybrid

ZP355*su* had the favorable content of tocopherols and maltose, panose and caffeic acid while hybrid ZP553*su* has the highest contents of total phenolic acids, protocatechuic acid, sinapic acid, β-carotene, and δ-tocopherol. The hybrid ZP504*su* has the highest contents of trehalose and turanose, and the lowest one of *p*-coumaric acids, sinapic acid and tocopherols. The genetic background undoubtedly influences chemical quality and hybrids with high content of particular phytochemicals could be considered as functional food. Consumption of sweet corn would afford health benefits to consumers so it useful for functional food industry.

Abstract

This experiment evaluated the effect of soil management systems (bare soil and black foil mulch) on the generative potential (number of clusters per inflorescence, number of flowers per inflorescence, number of berries per cluster, berry set percentage, cluster weight, berry weight, yield per bush, yield per unit area) and fruit quality (soluble solids content, total sugars, total acids, pH value and protein content) in black chokeberry [*Aronia melanocarpa* (Michx.) Elliott] of cultivar 'Nero'. Significant differences in generative potential were detected among soil management systems. The experimental results showed that black foil mulch, due to its ability to increase temperature and moisture in the soil directly led to an increase in the number of clusters per inflorescence, number of flowers per inflorescence and number of berries per cluster. In contrast, bare soil, with lower soil water content and temperature stimulated an increase in the cluster weight and berry weight, as well as yields per bush and per unit area. Also, soil management systems had a significant effect on the chemical composition of the fruit. Black foil mulch promoted the synthesis of soluble solids, sugars and protein, while bare soil favoured the accumulation of acids in chokeberries. Generally, the results suggested that black chokeberry grow well under varied soil management systems, and indicated that soil management systems had a significant effect on the generative potential and fruit quality.

Keywords: *Aronia melanocarpa, bare soil, black foil mulch, generative potential, chemical fruit traits*

Introduction

Black chokeberry [*Aronia melanocarpa* (Michx.) Elliott] is a deciduous shrub native to North America, botanically classified as belonging to the family *Rosaceae*. Shrub of chokeberry grows 1.2 to 2.4 m producing beautiful white flowers and navy-blue berries of tart-sweet taste and aromatic flavour (Jeppsson, 2000; Brand, 2010). Chokeberry plantation can be established in any climate condition. It is a cold-hardy plant tolerant of very low temperatures even below –35°C and it is not sensitive to the spring frosts (Bussières *et al*., 2008). Chokeberries are noted for their modest requirements and adaptability to different soil types (sandy, acid and humid soils) and soil management systems. They grow well under bare soil or continuous tillage as the most common system tested, but mulching with foil has increasingly been used in recent years. Numerous studies have highlighted the importance of mulch as an effective method for weed control and for maintaining a favourable soil structure and regulating the water and temperature regimes of the soil. According to Kawecki and Tomaszewska (2006), mulching the soil with foil promotes the vegetative and generative potential of black chokeberry.

In recent years, chokeberry has become more popular among small berries for their nutritional quality and potential health benefits. Berries have high levels of primary metabolites, especially

sugars, acids, tannins, pectins and pigments (Wu *et al*., 2004; Oszmianski and Wojdylo, 2005). Many epidemiological studies have showed that consumption of berries on regular basis offers potential health benefits to a number of diseases, including cardiovascular diseases, cancer, aging, neurological diseases, inflammation, diabetes and gastritis (Kokotkiewicz *et al*., 2010; Denev *et al*., 2014; Jurikova *et al*., 2017). The primary metabolites of berries may be affected by various factors, such as genotype, harvesting time, growth conditions and cultivation method (Jeppsson and Johansson, 2000).
Considering that there are not many scientific studies on the soil management systems in black chokeberry growing, the objective of this research was a comparative analysis of the effect of soil management systems in a black chokeberry orchard on the generative potential and fruit quality.

Material and method

The research was conducted at the Fruit Research Institute, Čačak (Serbia), during 2015-2017. The experiment was including chokeberry grown on the bare soil and black foil mulch in cultivar 'Nero'. The black chokeberry orchard was established in the spring of 2013. It was grown at a spacing of 3 m between rows and 1.5 m in the row. The experiment was set up at a randomized block design with three replications, giving a total of 60 black chokeberry bushes. During the trial, standard cultural, training and pruning practices were used, including drip irrigation.
Generative potential parameters (number of cluster per inflorescence, number of flowers per inflorescence, number of berries per cluster) were observed by counting. Cluster weight and berry weight were determined on a Mettler precision scale with an accuracy of 0.01 g. Yield per bush was determined by weighing harvested fruit on an ACS system electronic scale, whereas yield per unit area was the result of multiplying yield per bush by number of bushes per hectare.
Chemical analysis of the fruit included following: 1. Soluble solids content was determined by a digital refractometer (Kruss); 2. Total sugars were determined using the Loof-Schoorl method (Egan *et al*., 1981); 3. Total acids were measured using a burette containing 0.1 N NaOH; 4. pH value was measured by potentiometer (pH Meter MA 5707, Iskra, Slovenia); 5. Protein content was determined by Kjeldahl's method (Helrich, 1990).
During the experimental period, the average air temperature from May (fruit set) to August (fruit maturation) was 21.9°C in 2015, 21.3°C in 2016 and 20.7°C in 2017. Rainfall totals from May to August were 192.6 mm in 2015, 299.4 mm in 2016, and 383.5 mm in 2017, respectively.
The experimental data obtained during the three-year research period were subjected to statistical analysis using Fisher's two-factor analysis of variance - ANOVA. The significance of differences between the mean values of the tested factors and and their interactions was determined by LSD test at $P \leq 0.01$ and $P \leq 0.05$ significance levels.

Results and discussion

The analysis of the data showed significant differences in generative potential among soil management systems (Tables 1a and 1b). Mulching with foil directly led to an increase in the number of clusters per inflorescence (4.01), number of flowers per inflorescence (28.21) and number of berries per cluster (22.71). It can be assumed that black foil due to its ability to absorb much sunlight, directly increases soil temperature throughout the growing season and conserves more soil moisture, which had a positive effect on the some tested parameters of generative potential compared to bare soil. On the other hand, bare soil increased the cluster weight (13.93 g) and berry weight (0.83 g), as well as yields per bush (1.94 kg) and per unit area (4.265,1 kg/ha). Bare soil and foil mulch treatments did not differ in the berry set percentage. The results of the present study are comparable with those of Kawecki and Tomaszewska (2006), who found higher number of blossoms per cluster (15.2-18.3) and number of berries per cluster (9.4-17.0), and lower berry weight (0.78-0.85 g) in bushes mulched with black plastic compared with the other mulch treatments. In contrast, Paunović *et al*. (2016a) reported that bare soil was effective in increasing generative potential in black currants, while the lowest values were obtained under foil mulch. Namely, Kasirajan and Ngouajio (2012) recorded that plastic mulch prevents soil moisture loss and weed occurrence, which is good to balance vegetative and reproductive growth, and does not reduce the flower bud formation in chokeberry.

Table 1a. Generative potential of chokeberry cultivar Nero

Treatment/Year		Number of cluster per inflorescence	Number of flowers per inflorescence	Number of berries per cluster	Berry set (%)
Treatment (A)	bare soil	3.64±0.12 b	24.75±0.89 b	20.87±1.46 b	83.67±3.30
	foil mulch	4.01±0.15 a	28.21±1.27 a	22.71±1.34 a	81.16±4.41
Year (B)	2015	3.56±0.14 c	24.22±1.17 c	20.17±1.06 b	83.23±1.76 b
	2016	4.08±0.15 a	28.80±1.12 a	26.83±0.81 a	93.38±1.81 a
	2017	3.83±0.19 b	26.43±1.68 b	18.37±0.42 b	70.62±3.91 c
ANOVA					
Treatment (A)		**	**	ns	ns
Year (B)		**	**	**	**
A x B		ns	ns	ns	ns

Means followed by different letters within the treatment and year columns are significantly different at P≤0.01 and P≤0.05 according to LSD test and ANOVA (F-test) results.

In general, Kurtović *et al*. (2016) recorded similar number of clusters per inflorescence (3.03-4.08), number of flowers per inflorescence (14.02-25.74), number of berries per cluster (13.53-25.54) and berry weight (0.52-0.71 g), while Skender *et al*. (2017) reported a lower number of berries per cluster (13.0-14.6), but higher berry weight (1.02-1.20 g). Also, berry weight is in agreement with the results of Jeppsson (2000), who reported that berry weight varies from 0.61 to 0.85 g, which may be considered large fruits. In contrast, the present results are significantly lower than in the study of Strik *et al*. (2003), who obtained values for berry weight from 1.03 to 2.80 g.

Table 1b. Generative potential of chokeberry cultivar Nero

Treatment/Year		Cluster weight (g)	Berry weight (g)	Yield per bush (kg)	Yield per unit area (kg/ha)

Means followed by different letters within the treatment and year columns are significantly different at P≤0.01 and P≤0.05 according to LSD test and ANOVA (F-test) results.

As regards yield, the results of the present study are comparable with the findings of Kawecki and Tomaszewska (2006), who reported that the five-year yield in chokeberry was highest in bushes mulched with conifer bark, and lowest in bushes mulched with black plastic. Namely, McKay (2001) reported that plants of chokeberry responded with high yield when mulched properly. The author found that chokeberry in the first years gives small yield, because plants have weak branches that fall over onto the ground, while in the fourth year can be expected yield about 7-8 tons per hectare. Additionally, Kivijarvi *et al*. (2005) found that mulching orchard soil with foil contributes to increased yields compared to unmulched soil. In contrast, according to Bakshi *et al*. (2014) and Pandey *et al*. (2015), strawberry mulched with black polyethylene produced higher yield by 24.20% and 17.80% compared to control. Generally, Kurtović *et al*. (2016) observed that yield per plant ranged from 0.64 to 0.79 kg and from 1.926,3 to 2.370,6 kg per unit area, in the first years after planting. Radanović *et al*. (2012) found yield per plant of 340 g already in the second year and 4200 g of fruits per plant in the third year, while Jeppsson (2000) harvested an average from 440 to 1.050 g per plant for 3- to 5-year-old plantings. However, all of these reported yields were low compared with the findings of Strik *et al*. (2003) in Oregon, which obtained 4.4 to 24.1 kg per plant for 3- to 5-year-old plantings of various selected cultivars of black chokeberry.
Soil management systems during the experiment had an effect on synthesis and accumulation of the chemical ompounds in berries (Table 2). Black foil mulch had a significant positive effect on the synthesis of soluble solids (23.57%), total sugars (10.75%) and protein (1.18%), while bare soil had the effect on the higher accumulation of acids (2.31%) and pH value (3.45). The present results of primary metabolites are within the range determined by Skender *et al*. (2017). Also, Jeppsson and Johansson (2000) and Ochmian *et al*. (2012) reported that aronia berries are high in sugar (12 to 20% soluble solids), and have a pH of 3.3 to 3.7, and 0.7 to 1.2% titratable acidity.

Table 2. Fruit quality in black chokeberry cultivar Nero

Treatment/Year		Soluble solids content (%)	Total sugars (%)	Total acids (%)	pH	Protein (%)
Treatment (A)	bare soil	20.74±0.46 b	10.36±0.21 b	2.31±0.26 a	3.45±0.11 a	1.09±0.07 b
	foil mulch	23.57±0.34 a	10.75±0.25 a	2.23±0.24 b	3.38±0.09 b	1.18±0.09 a

	2017	23.27±0.56 a	11.43±0.15 a	2.56±0.03 b	3.19±0.01 b	0.83±0.01 c
ANOVA						
Treatment(A)		**	**	**	**	**
Year (B)		*	**	**	**	**
A x B		ns	ns	ns	ns	ns

Means followed by different letters within the treatment and year columns are significantly different at $P \leq 0.01$ and $P \leq 0.05$ according to LSD test and ANOVA (F-test) results.

In terms of soil management systems, the present results are comparable to those obtained by Bakshi *et al*. (2014), who reported that black polyethylene mulch affected the increase of soluble solids and sugars, and a decrease of acids in strawberry. Also, Melgarejo *et al*. (2012) observed the higher contents of soluble solids and sugars, and lower acids content in plum fruits from trees grown under plastic mulching compared to control. The highest values of primary metabolites, as observed under black polythene mulch, indicate a greater role of elevated soil temperature as a catalyst for root activities, which is ultimately reflected in higher yield and better quality of the fruit (Pandey *et al*., 2016). According to Albert *et al*. (2010), plastic mulch in blueberries resulted in the lowest content of soluble solids, while Vool *et al*. (2007) recorded that the highest soluble solids content was obtained under plastic mulch compared to non-mulch in blackberries and raspberries. Actually, Paunović *et al*. (2016b) reported that bare soil had a significant positive effect on the synthesis of total sugars, while foil mulch had the effect on the accumulation of total acids.

During berry formation and ripening, air temperature was higher and rainfall amount was lower in 2015 than in 2016 and 2017, which had a stimulating effect on the synthesis of acids and protein. Conversely, moderate air temperatures and precipitation amounts in 2016 promoted the number of clusters per inflorescence, number of flowers per inflorescence, number of berries per cluster and berry set in comparison to 2015 and 2017. Heavier precipitation and lower air temperature in 2017 increased cluster weight and berry weight, as well as yields per bush and per unit area, and had a positive effect on the synthesis and accumulation of soluble solids and sugars compared to the other two experimental years. Kawecki and Tomaszewska (2006) reported that the number of blossoms per cluster, the number of berries per cluster, and berry weight of chokeberry varied considerably from year to year. Also, Asănică *et al*. (2017) reported that the average number of flowers inside the inflorescences did not vary too much between years, while Jeppsson (2000) recorded lower mean berry weight and a remarkable loss in yield in higher temperature and precipitation. In terms of chemical composition of fruits, Paunović *et al*. (2016c) recorded that higher air temperature and lower rainfall had a positive effect on the synthesis of soluble solids, sugars and proteins, and negative on the synthesis of total acids and fruit pH value. Rubinskiene *et al*. (2006) observed a positive correlation between air temperature and the content of soluble solids and sugars, and a negative correlation between rainfall and these parameters. Similarly, as determined by Kaldmae *et al*. (2013), temperature is positively correlated with the contents of soluble solids and sugars, as opposed to precipitation. The difference in chemical compounds contents can be explained by strong variations in their synthesis and accumulation under different climates.

Conclusion

Soil management systems have a significant effect on the generative potential, and promote the synthesis and accumulation of chemical compounds in berries, which should be considered when establishing commercial black chokeberry orchards. Also, climatic factors (air temperature and precipitation) have an important effect on the generative potential and the biosynthesis of primary metabolites in the fruit, thus affecting the quality and commercial value of the fruit. In general, chokeberry is an exceptionally rich source of primary metabolites, suggesting that berries can be used as natural agents in the pharmaceutical and food industries.

Abstract

Anthocyanins are the more important plant pigments visible to the human eye. They make a significant contribution to the colour, and hence acceptability, of many fruits, some vegetables and associated products, including beverages and preserves. The study of natural colourants is extensive and active area of investigation due to the growing interest of substituting synthetic colourants with toxic effects in humans with anthocyanins which possess an array of health-promoting benefits. Considering the beneficial effect for the health of these molecules, their incorporation in food and beverages industries represents an important value. Similar to other anthocyanins, cyanidin can take on various structural forms in aqueous environments, which depend on pH. To determine their stability in detail, we stored (4320 min) cyanidin in aqueous solution at pH 6.0 at room temperature (25.0 °C) and tracked the colour stability by UV–Vis spectrometry. The aim of this study was to investigate colour stability of the cyanidin in slightly acidic solutions during storage at room temperature in order to obtain more precise information to evaluate the possibility of its use as a food colour. Cyanidin colour stability in the first three hours after dissolution was high. However, after three days of storage, colour stability was decreased to half and the colour of the solution changed. The use of anthocyanins like cyanidin as food colourants in slightly acidic products should therefore be considered at least in products with limited storage.

Keywords: *cyanidin, anthocyanins, colour stability, UV–Vis spectrometry.*

Introduction

Anthocyanins (in Greek *anthos* means flower, and *kyanos* means blue) are the more important plant pigments visible to the human eye. They belong to the widespread class of phenolic compounds collectively named flavonoids. They are glycosides of polyhydroxy and polymethoxy derivatives of 2-phenylbenzopyrylium or flavylium salts (Kong, 2003). These pigments are responsible of the shiny orange, pink, red, violet and blue colours in the flowers and fruits of some plants (Castañeda-Ovando et al., 2009). Up to now there are reports of more than 500 different anthocyanins and 23 anthocyanidins of which only six are the most common in vascular plants, pelargonidin, peonidin, cyanidin, malvidin, petunidin and delphinidin (Castañeda-Ovando et al., 2009). The glycoside derivatives of the three non-methylated anthocyanidins (cyanidin, delphinidin and pelargonidin) are the most common in nature, being

found in 80% of pigmented leaves, 69% in fruits and 50% in flowers (Castañeda-Ovando et al., 2009; Kong, 2003).
The isolated anthocyanins are highly instable and very susceptible to degradation. Their stability is affected by several factors such as pH, storage temperature, chemical structure, concentration, light, oxygen, solvents, the presence of enzymes, flavonoids, proteins and metallic ions (Castañeda-Ovando et al., 2009). Anthocyanins are unique among flavonoids as their structures reversibly undergo pH-dependent transformation in aqueous solution (He & Giusti, 2010). Anthocyanins can be found in different chemical forms which depend on the pH of the solution (Figure 1) (Rakić et al., 2019). At pH 1, the flavylium cation (red colour) is the predominant species and contributes to purple and red colours. At pH values between 2 and 4, the quinoidal blue species are predominant. At pH values between 4 and 6, four structural forms of the anthocyanins coexist: flavylium cation, anhydrous quinoidal base, colourless carbinol base and the pale yellow chalcone. At pH values higher than 7, the anthocyanins are degraded depending on their substituent groups (Castañeda-Ovando et al., 2009). In general, anthocyanins show their highest colour intensity in the flavylium ion form (Harborne & Williams, 2001; Rakić et al., 2015; Rakić & Poklar Ulrih, 2021).

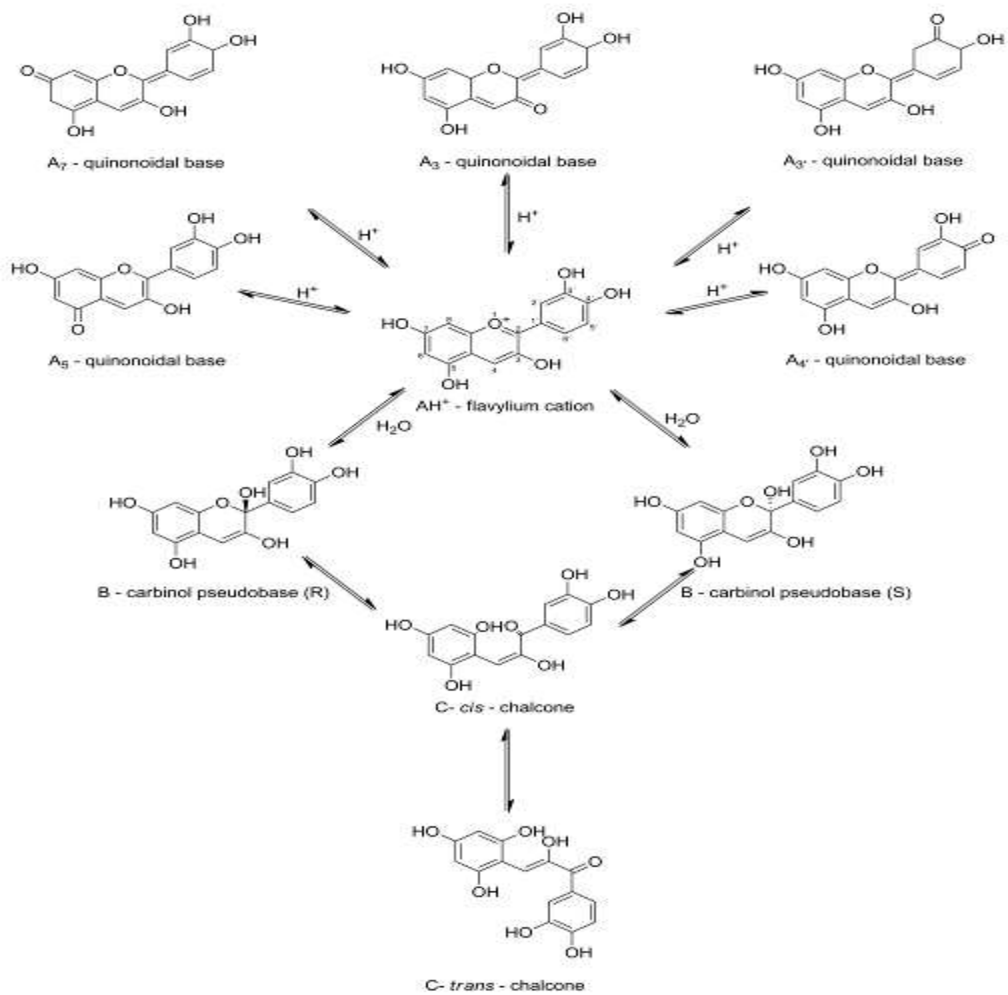

Figure 1. Transformations of cyanidin in aqueous solutions at different pHs (Rakić et al., 2019).

The anthocyanin content of fruit and vegetables, and their corresponding antioxidant activity, contribute to protective effects against degenerative and chronic diseases, thus also giving them further nephroprotective and anti-inflammatory effects, among others (Castañeda-Ovando et al., 2009; Popović, Kocić, Katić, Jović, et al., 2019; Popović, Kocić, Katić, Zarubica, et al., 2019; Veljković et al., 2017).
Anthocyanins make a significant contribution to the colour, and hence acceptability, of many fruits, some vegetables and associated products, including beverages and preserves. It was recognized that anthocyanin-rich extracts might have potential as food additives (Clifford, 2000). Anthocyanins are used as food colourants primarily in the beverage industry. As public concern about synthetic food dyes has increased recently, consumers and food manufacturers desire colourants from natural sources. Synthetic dyes commonly used in the food industry have been suspected to cause adverse behavioral and neurological effects. Consumers are willing to pay more for products that are perceived more natural, healthier, and with potential disease prevention benefits in addition to their nutritional value. This, in turn, is stimulating the food industry toward the incorporation of more natural ingredients into foods, including the use of anthocyanin-based colourants as an alternative to the use of synthetic dyes. Use of anthocyanin based colourants presents a number of challenges, including stability for processing and storage. Application of anthocyanin-based colourants in fruit yogurt and many types of fruit-flavored dry mixes is becoming more popular. Indeed, synthetic dyes are not allowed in the rapidly growing natural foods market, where anthocyanins are becoming increasingly important (He & Giusti, 2010). Considering the beneficial effect for the health of these molecules, their incorporation in food and beverages industries represent an important value (Castañeda-Ovando et al., 2009). To determine their stability in detail, we storage the cyanidin in aqueous solution at pH 6.0 at room temperature (25.0 °C) and tracked the colour stability by UV–Vis spectrometry. The aim of this study was to investigate colour stability of the cyanidin in slightly acidic solutions (pH 6.0) during storage at room temperature (25.0 °C) in order to obtain more precise information to evaluate the possibility of its use as a food colour.

Materials and methods

Chemicals and reagents

The chloride salt of cyanidin was from Polyphenols Laboratories AS (Sandnes, Norway). Sodium hydroxide was from Merck (Darmstadt, Germany). The aqueous solution was prepared from Milli-Q water (resistivity >18 MΩ cm; Millipore, Bedford, MA, USA).

Measurements of stability

The colour stability of the cyanidin in aqueous solution was determined at 25.0 °C. The chloride salt of cyanidin was dissolved in Milli-Q water to 0.2 mmol/L. The pH of cyanidin solution was adjusted to pH 6.0 using NaOH (concentration 9.8×10^{-3} mol/L). The sample tube was sealed with parafilm, in a water bath at 25.0 °C (room temperature) and the cyanidin was stored under air atmosphere. The pHs was measured using a pH meter (Seven Easy; Mettler Toledo, Schwerzenbach, Switzerlend) equipped with a micro electrode (InLab; Mettler Toledo, Schwerzenbach, Switzerlend). UV–Vis measurements were made immediately after dissolution and then after specified time intervals, during 4320 min (3 days). The absorption spectra (190–900 nm) were recorded at 25.0 ± 0.1 °C, using a UV– Vis spectrophotometer (Cary 100 Bio; Varian, Mulgrave, Victoria, Australia) in a thermostated 10-mm-pathlength quartz cell, with

Milli-Q water as the reference, and a resolution of 1 nm. Colour stability was expressed as the percentage of absorbance remaining after a certain time interval, measured at visible absorption maxima ($\lambda_{vis-max}$) at pH 6.0.

Results and discussion

The colour stability in the 0.2 mmol/L cyanidin aqueous solution was studied at pH 6.0 during 4320 min (3 days) of storage at room temperature (25.0 °C). According to Cabrita et al. (Cabrita et al., 2000) and Fossen et al. (Fossen et al., 1998) colour stability was expressed as the percentage of the absorbance remaining after a certain time interval, measured at absorption maxima.

The shape of the absorption band in the visible spectra of cyanidin at pH 6.0, immediately after dissolution, was broad with visible absorption maximum at 580 nm (Figure 2). Broad visible absorption band suggest presence of mixture of various equilibrium forms (Castañeda-Ovando et al., 2009; Fossen et al., 1998). The shape of the absorption band did not change during first 150 minutes. Accordingly, the position of absorption maximum did not change during this period. This indicates high and almost constant colour stability of cyanidin in first 150 minutes of storage. The colour stability of cyanidin was above 98.0% in the first 150 min (Figure 3).

The absorption band changed its shape and decreased in intensity after 4320 min. Also, the position of the absorption maximum was changed. Consequently, the colour of the solution has changed. This was probably a consequence of the change in ratio of various equilibrium forms and cyanidin degradation. After 4320 min (3 days) of storage colour stability decreased to 51.1%.

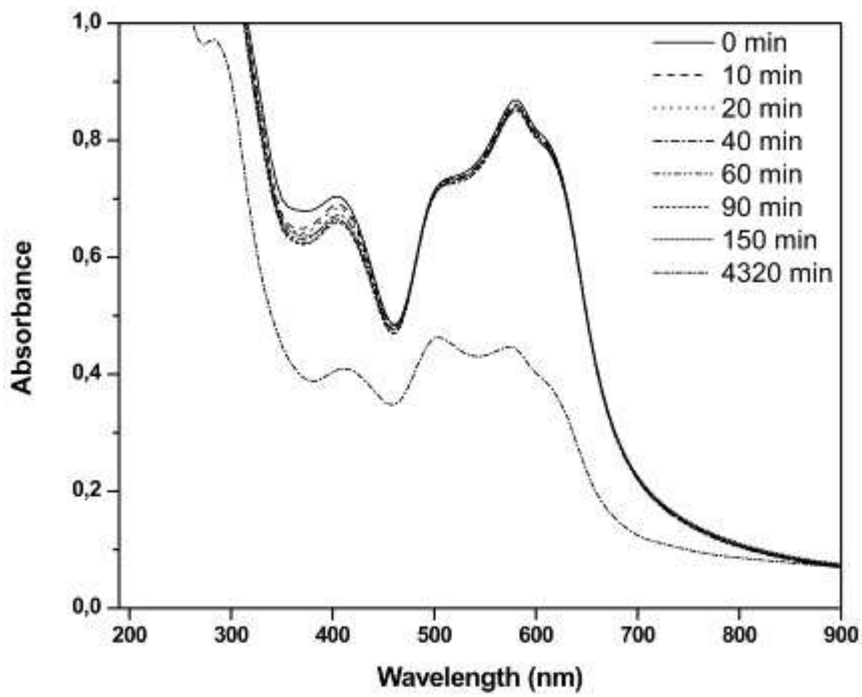

Figure 2. Changes in the UV–Vis spectra of 0.2 mmol/L cyanidin solution during storage (up to 4320 min) at pH 6.0, and 25.0 °C.

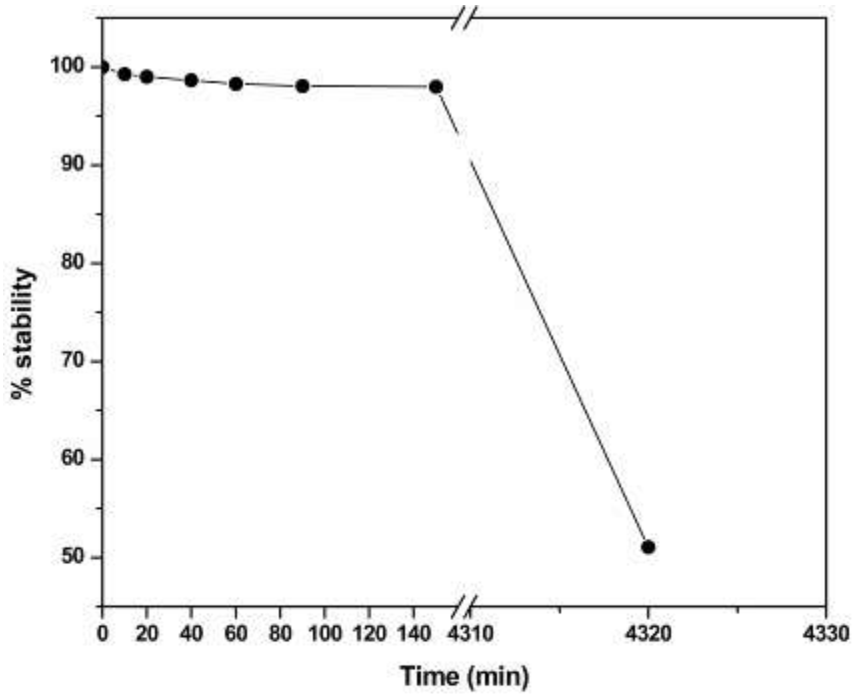

Figure 3. Colour stability of 0.2 mmol/L cyanidin solution during storage (up to 4320 min) at pH 6.0, and 25.0 °C.

Conclusions

Cyanidin colour stability in the first three hours after the dissolution was high. However, after three days of storage, colour stability was decreased to half and colour of the solution has changed. The use of anthocyanins like cyanidin as food colourants in slightly acidic products should therefore be considered at least in products with limited time of storage.

INFLUENCE OF DIFFERENT DENSITIES DURING SOWING ON BUCKWHEAT (*FAGOPIRUM ESCULENTUM* L.) YIELD AS A SUBSEQUENT IN AGRICULTURE

Vladimir SABADOŠ*, Danijela ŽUNIĆ, Zoran BOCA

Agricultural Extension Service "Sombor", Serbia

Abstract

Buckwheat is a very old culture native to Asia. It does not show great demand for the soil, it can be grown on slightly acidic soil (up to pH 5.5), but it requires a more humid climate (with more precipitation) because it is quite sensitive to drought and high temperatures, especially during flowering and pouring grain. Sowing is done when the soil is heated to about 15 °C. Sowing can start from 01.05. to 15.05. when there is no danger of frost. The density of the assembly is about 200-250 germinating seeds per m^2. An experiment with 12 different buckwheat populations was set up on the PSS "Sombor" experimental field. Three experiments were set up with the same row spacing of 25 cm, while the row spacing on the first variant was 5.0 cm, on the second 3.75 cm and on the third variant 2.5 cm. During the experiment, the condition of the crops was monitored, as well as the yields after the harvest, which clearly showed that when using buckwheat as a side crop, we had to go for a denser sowing (2.5 cm). Due to relatively low yields (about 2 t/ha), the production of buckwheat as the main crop in Vojvodina is less profitable. Buckwheat is a very competitive plant with weeds due to its rapid germination and strong initial growth, so it quickly over shadows the surface, and thusthus sprouted weeds. That is why it is good to sow it as a functional food, and if necessary for green manure.

Keywords: *agriculture, subsequent, research, experiment, population.*

Introduction

Buckwheat is a culture native to Asia and has been grown in Europe since the 16th century (Bystricka et al, 2014). Significant species of the genus Fagopyrum are also *F.giganteum* Krotov, which was formed by crossing the tetraploid form *F. tataricum* and F.cymosum (Stoletova, 1940; Krotov, 1963.). Buckwheat is grown for its grain, which is well digested and also serves as a dietary food. Due to the similarity in the chemical composition of the grain as well as the manner of use, it is classified as a cereal, although according to its botanical affiliation it belongs to the family Polygonacea. Hulled grain contains about 80% starch, 10-15% protein, 1-2% crude fiber, 2-3% fat and 1-2% minerals, iron, phosphorus, iodine and increased content of vitamins B1 and B2. Buckwheat seeds are equated in nutritional value with straw of spring cereals, but cattle should not be given in larger quantities because they contain the alkaloid phagopyrin. Buckwheat is pollinated by bees because it blooms for a long time and has a flower that bees easily come to, but only in the morning. Under favorable conditions, 80-100 kilograms of honey can be obtained from one hectare. From 100 kilograms of buckwheat grains, 60-70 kilograms of dark flour can be obtained. Green leaves and buckwheat flowers can be used as a source of rutin, a glycoside used in medicine as a remedy for diseases such as hypertension (high blood pressure), rheumatism and diabetes, while buckwheat tea helps in recovery from radiation and chemotherapy. It has a well-developed spindle root of good absorbing strength. It penetrates the soil up to 120 centimeters. The stem is branched, hollow, about 150 centimeters high, and when ripe it acquires a reddish color. The leaves are heart-shaped and the grain is triangular in shape. The leaves are reddish in color and 5 to 10 cm long (Clayton, 1997). The weight of 1000 grains is 20-30 grams, and the hectoliter weight is 50-65 kilograms. White flowers are gathered on flower twigs that grow from the bud in the axils of the leaves. Flowering lasts a long time, about 30 days.

Photo 1. Buckwheat in bloom (photo by Vladmir Sabadoš)

Buckwheat is a crop that has low heat needs but is sensitive to both high and low temperatures (Björkman, 2000). The minimum soil temperature required for sowing and sprouting buckwheat is 4-9 °C (Varga, 1966). The optimal temperature for the growth and development of buckwheat is between 18 and 23 °C, and the optimal temperature for flowering is 17-19 °C. Inhibition of flowering occurs below 15 °C (delayed flower germination and reduction in the number of flowers). If the temperature drops below minus 1 °C, then the plants die, also below 10 °C assimilation (drying of flowers) stops, and above 25 °C fertilization stops (Guan and Adachi, 1992). The sum of the temperature required for buckwheat vegetation is from 1000 to 1200 °C. During flowering, temperature influences yield formation directly through influencing flower development and fertility, (Björkman, 2000). Buckwheat stalk is erect, hollow and branched into 5 to 10 branches, but can be without side branches, 3 to 15 mm in diameter, (Gondola and Papp, 2010). There are no big demands on the land. Due to relatively low yields (about 2 t / ha), the production of buckwheat as the main crop in the area of Vojvodina is less profitable, so in our country it is grown almost exclusively as a side crop after removing barley and winter fodder plants.

Material and Methods

For the area of Vojvodina Autonomous Province in Serbia, post-sowing of buckwheat is recommended, where solid yields are achieved. An experiment with 12 different buckwheat populations was set up on the Agriculture Extension Service "Sombor" experimental field. Three experiments were set up with the same row spacing of 25 cm, while the row spacing on the first variant was 5.0 cm, on the second 3.75 cm and on the third variant 2.5 cm. About 80 kg / ha of seeds are needed for sowing buckwheat in the earlier sowing period, while 80-100 kg / ha of seeds are needed for late sowing. They are sown with planters in narrow (spacing between rows about 10 cm) or wide rows (spacing between rows 45 - 50 cm) to a depth of 4 - 5 cm. After sowing, the soil is rolled.

If a crust forms after sowing, and before germination, it should be destroyed occasionally by harrowing. The spacing within a row depends on the density of the assembly. Buckwheat is a very competitive plant with weeds due to its rapid germination and strong initial growth, so it quickly overshadows the surface, and thus sprouted weeds. The experiment was sown with a single-row Wintersteiger seed drill, which is used for sowing smaller experiments. In order to have good germination when measuring the seeds, we added 20% more seeds.
During the experiment, the condition of the crops was monitored, as well as the yields after the harvest, which clearly showed that when using buckwheat as a side crop, we had to go for a denser sowing (2.5 cm). Due to relatively low yields (about 2 t/ha), the production of buckwheat as the main crop in Vojvodina is less profitable.

Results and Discussion

The results of the research are presented in Table 1. The tables list all the varieties that were tested and also the row spacing with sowing densities. Since the sowing was on May 11, the harvest went successively when most of the plantations began to ripen, when two thirds of the grain took on a dark brown color, with the use of grain harvesters, with a sieve that rotates a little slower, so as not to happen yield loss. It is very important to start just then, in order to avoid seed shedding.

Table 1. Results of varieties of buckwheat in post-sowing on PSS Sombor plots

	Variety	sowing 25 x 5 cm		sowing 25 x 3.75 cm		sowing 25 x 2.5 cm	
		yield t/ha	mass 1000 grains (gr)	yield t/ha	mass 1000 grains (gr)	yield t/ha	mass 1000 grains (gr)
1	Oberon	1.30	30	1.58	30	1.90	30
2	B. Petrovac	2.58	26	2.80	26	2.45	25
3	Darja	3.25	26	2.80	26	1.92	26
4	Populacija B.T.	2.37	27	2.87	28	2.15	28
5	Novosadska plus	2.52	25	3.20	26	3.10	26
6	Češka	2.65	28	2.57	28	2.77	29
7	Bamby	1.75	26	1.55	26	1.70	25
8	Novosadska	1.32	27	1.95	25	2.10	24
9	B.Petrovac exp.2	1.95	26	1.60	25	2.20	24
10	B.Petrovac exp.3	1.65	28	1.40	27	1.87	25
11	K - 11	1.65	24	1.35	24	1.15	26
12	Bily	1.75	28	1.80	26	1.92	25
	Average	2.06	27	2.12	26	2.10	26

Statistically significant were two varieties where we can see that the variety Darija gave the highest yield of 3.25 t/ha in the variant 25 x 5 cm, while the variety Novosadska plus gave the highest yield in the variant 25 x 3.75, as well as in variants 25 x 2.5 cm at 3.10 t/ha.
Based on these data, we can conclude that different populations have different sowing densities. Some varieties, if they have more room for growth, develop a higher plant height and the number of internodes, while in other varieties the opposite is true, some varieties with increasing density

give opposite results. As for the mass of 1000 grains, we could clearly see that the sowing density in the variety Oberon has no effect on the mass of 1000 grains, while in other varieties it is different. In some varieties we have an increase in the weight of 1000 grains with increasing density, while in others we have a decrease in the amount of grain weight with decreasing density. If we generally look at the results on average, we can see that the best variant was sowing at a row spacing of 25 cm and a density of 3.75 cm. With this agrotechnics we got an average yield of 2.12 t / ha.

Conclusions

Buckwheat (*Fagopyrum esculentum*) it is a very useful plant that is used inhuman nutrition, for animal feed, as bee pasture, and its honey is of exceptional quality. Buckwheat grain yields in post-sowing are from 1.5 to 2 t/ha. Based on the results, we can conclude that buckwheat, depending on the variety, gives different yields depending on the method and spacing of sowing in a row. Some varieties prefer denser sowing, while some rarer. Sustainability of agricultural production and biodiversity of agroecosystems are significantly increasing by introducing stubble crops into the crop rotation which should be its indispensable component. The use of arable crops leads to the improvement of agricultural production due to numerous benefits they bring to plant production systems. It is very much in the system of side farming it self important proper selection of plant species that will be used as such for various purposes. As a satisfactory solution when choosing side crops is buckwheat because of its characteristics that effectively lead to numerous benefits for the agroecosystem as a siding crop. Buckwheat quickly and efficiently covers the ground thus fulfilling the first and basic function of each post-cover crop, which is soil cover. This protects the soil from the negative effects of water and wind, direct solar insolation and excessive water loss which is otherwise pronounced due to evaporation on "bare" ground. Because it has a rapid initial growth, a large amount of biomass has a positive effect on reducing weeds through direct competition with weeds plants. It enriches the soil with nutrients and is very important as grazing by bees due to the long period flowering. It also attracts numerous entomofauna and increases biodiversity.

THE BLACK PARLATORIA SCALE *PARLATORIA ZIZIPHI* (LUCAS, 1853) (HEMIPTERA: COCCOMPORHA: DIASPIDIDAE): BIOLOGY, CONTROL OPTIONS AND PEST MANAGEMENT APPROACH

Hanen JENDOUBI[1*], Pompeo SUMA[2]

Abstract

The Black Parlatoria Scale (BPS) *Parlatoria ziziphi* (Lucas, 1853) (Hemiptera: Coccomporha: Diaspididae) is an invasive notorious scale insect species that affects citrus crops, notably in the southern Mediterranean basin. No approach to an Integrated Pest Management (IPM) strategy has currently been adopted for BPS control in the newly invaded citrus regions (Algeria, Egypt, and Tunisia). Our research aims to elucidate the pest management rules of the BPS in citrus orchards through a comprehensive study on the pest, exploring the bio-ecological environment and the life cycle stages in relation to the available control tools. The distinct life history dynamic of the BPS and the control measures, as reported in several citrus-growing countries, were critically reviewed. Eventually, interactions between the application of agro-chemicals and the life cycle stages were also revealed. Control timing is highly crucial for the BPS, since treatment methods vary significantly for each stage (feeding, moulting, dormant, reproducing, protected, producing wax) and its biological discreteness (generation overlapping, protected forms, high survival). Appropriate treatment must be timed to coincide with BPS population peaks, targeting the first crawler generation at their settlements and precisely before migration to fruits. A life cycle stage-based control model for the BPS is established to outline the future research directions of an integrated control program in the newly invaded citrus regions. Complementary studies on ecological and biological aspects of the insect population are required in the invaded citrus areas.

Key words: *P. ziziphi*, citrus, overview, chemical control, management approach.

Introduction

The Black Parlatoria Scale (BPS) *Parlatoria ziziphi* (Lucas, 1853) (Hemiptera: Coccomporha: Diaspididae) is one of the most successful invader diaspids of citrus areas and a scale insect which is difficult to control (EPPO, 2015; Garcia Morales *et al*., 2016). The species has a very limited host range, restricted to the Rutaceae species from Citrus, Murraya, Poncirus, and Severinia. *Citrus* spp. are the predominant host plants to the BPS with a preference to lemon, orange and mandarin trees, and to a lesser extent on other species often used in the ornamental trade (Balachowsky, 1953; CABI, 1964, 2007; Pellizzari and Germain, 2010). The BPS is probably native to Asia in Southern China, and has been spread around the world where citrus is grown, in more than 90 countries across four continents (Longo *et al*., 1995; Miller and Davidson, 2005; Foldi and Germain, 2018; Jendoubi and Suma, 2021). The BPS has on many occasions been the major threat to citrus crops (Citrus spp.: Rutaceae) in different citrus growing areas with an important economic impact on fruit production (Talhouk, 1975; Kosztarab, 1990;

Miller and Davidson, 2005). Nowadays, severe outbreaks of the pest are reported in the southern Mediterranean countries (e.g. Algeria, Egypt, Tunisia), reaching severe pest status and recording complicated control situations (Jendoubi and Suma, 2021).
Despite the worldwide pest position of the BPS, a few detailed and advanced studies have been published. Old and recent experiments are focused on the bio-ecological behavior of this diaspid and have provided almost inconclusive results. Until recently, the BPS population has remained misidentified and has been confused with particles on citrus fruits and *Parlatoria* species during inspections and monitoring of citrus trees (Jendoubi *et al*., 2021; Jendoubi, 2018). No Integrated Pest Management (IPM) concept has been adopted for the management of the BPS in citrus orchards. The control of the BPS population has previously been almost entirely based on insecticides applications which, in many cases, were not very efficient. Different chemical actives have been evaluated by researchers, but very few alternatives to chemicals have been studied (Ipraloran, 1971; Grafton *et al.,* 1996; Morse *et al.,* 1996; Harrathi, 2008; Mangoud, 2008).
Recently, a detailed field description of all the life cycle stages for both male and female lineage of BPS was carried out recently, as one of the primary crucial steps of an IPM program that should be completed for this invasive pest (Jendoubi *et al*., 2021). Then, the actual pest status and the spread history of the scale insect were reviewed. The spread and establishment of BPS populations in new geographical zones appears to be rapid, mainly in the Mediterranean basin. This study was considered as a starting point of references for pest management decision-makers (Jendoubi and Suma, 2021). Therefore, it was necessary to better know the fundamental biological features of the BPS, examine the relations between chemical control and developmental stages, finally establishing the impact of all parameters on the management of the BPS in the different invaded citrus areas.
In the present research, a chemical control model, including life cycle stages, is proposed for controlling populations of this diaspid within an IPM program. Basic information regarding the BPS biology/life cycle and control methods, being followed presently in the different citrus growing countries from the Mediterranean basin and South Asia were reviewed. This information was used as support to discuss the rules of a chemical control scheme adapted to the BPS.

Extreme variability in generation number between regions

In Mediterranean countries, the BPS completes several overlapping generations each year, numbering from two to five. Conversely, in the Asiatic area, the generation number is relatively higher and the overlapping generations are less accentuated (table 1). Variations in cycle duration were observed too in different countries, even if they share similar climates. In Egypt, on mandarin trees, the first spring generation starts from early March recording peaks in mid-April early May (43.17 individuals), and ends in early June or mid-July, lasting 3.5-4 months. The second autumn generation starts in early July, peaks in mid-October (104.83 individuals) and continues until December (El-Bolok *et al*., 1985; Salama *et al*., 1985; Tawfeek and Abu-Shall, 2010; ElSayed-Darwish, 2016). In southern Italy (i.e. Sicily), the complete life cycle is much shorter than in Egypt, taking 1-1.5 months under favorable conditions (Monastero, 1962). In Tunisia, which has comparable climate conditions to Sicily, Bénassy and Soria (1964) noted that a generation requires more time than in Sicily to be accomplished, specifically 75-80 days during warm periods and up to 160 days during cool periods. A generation in Taiwan requires approximately 42 days to develop from June to August and around 93 days during cooler weather (Huang *et al*., 1988; Miller and Davidson, 2005). These differences may be related to the difficulty to 3 factors 1. The segregate generations during sampling due to the permanent presence of all instars along the year, 2. The mean temperature differences and 3. The host plant susceptibilities.

All BPS stages are affected in their vertical distribution by the different microclimates resulting from the tree architecture. Sessile populations tend to form three separable groups along the heights of trees, showing an important accumulation in the central core. The highest populations densities (50.54% of first instar, 48.15% of first molt stage, 46.69% of female stages and 43.7% of male nymphs) colonize the middle stratum (Sigwalt, 1971; El-Bolok *et al*., 1985; Tawfeek, 2012; ElSayed-Darwish, 2016; HJ personal communication, 2016).

Actually, the distribution pattern of the BPS in citrus orchards was correlated with environmental conditions such as sun inclination, wind direction, and hot temperatures in the same citrus orchard. The species chooses in fact shady zones more than the sunny exposed zones of trees, looking for the most suitable sites for its protection upon settlement, development and oviposition. In fall and spring, populations were accumulated on leaves in the western parts of trees, while summer populations settled in the southern parts (Salama *et al*., 1985; Harrathi, 2008; Medjoub, 2014).

Control options limited to agro-chemicals

Currently, no approach to IPM strategy has been adopted for the BPS. The main control options available are limited to some preventive practices, and mainly to agro-chemicals (Ipraloran, 1971; Grafton *et al*., 1996; Mangoud, 2008; Jendoubi, 2018). Chemical group of organophosphates (chlorpyrifos, malathion, parathion, quinalphos, methidathion, omethoate) and pyrethroids (lambda-cyhalothrine, fenvalerate, cypermethrine) are the main insecticides applied to manage BPS infestations. In China, it is efficiently controlled with total eradication, using different agro-chemical actives as parathion, quinalphos, methidathion, omethoate or lambda-cyhalothrine and fenvalerate (Dekle, 1976; Huang *et al*., 1988). In Tunisia, the regular application of chlorpyrifos and its dimethyl homologue, chlorpyrifos-methyl, and methidathion actives, has led to an important decrease in the populations of the BPS in some citrus orchards. The methidathion efficacy could reach 91% (Jendoubi *et al*., 2008; Harrathi, 2008).

In California and different Mediterranean countries (such as Algeria, Egypt and Tunisia), many experiments have been conducted with mineral oils (Citrole, Misrona, Volk-Ete, Triona) to

reduce crawler populations during the growth season. Dekle (1976) recommended combining oils and insecticides, precisely Malathion 0.05% plus oil 0.01% in citrus orchards from Florida. In Tunisia, Harrathi (2008) demonstrated that the mineral oil Citrole was as effective as methidathion in the control of the BPS on citrus in the northeastern area. Coll and Abd-Rabou (1998) have reported Triona oil was more effective than Shecrona oil and reduced BPS populations by up to 99%. The two spray oils used did not significantly affect the activity of the parasitoid *Encarsia citrina* (Craw), the primary parasitoid of the BPS. Mangoud (2008) demonstrated that Misrona oil and the insect growth regulator buprofezin had a long-term insecticidal effect on the BPS population occurring on citrus in Egypt. Therefore, the application of paraffin oils (Triona 81%, Misrona 95%) applied with buprofezin treatments should be employed as an alternative to other synthetic insecticides used for controlling the BPS populations in citrus orchards (Mangoud, 2008). Oils must be used as a contact insecticide, which requires thorough complete coverage and repetitive applications. In Algeria, three essential oil concentrations (0.4ml, 0.2ml, 0.1ml) extracted from grapefruits leaves showed a high significant insecticide effect against the BPS crawlers on citrus trees (89-90.2% larvae mortality at 0.2ml, 0.1ml; 94.4% mortality at 0.4ml) (Belguendouz *et al*., 2014).
Accordingly, pesticides play a key role in pest management programs for the BPS and may be the only control method available in cases of large invasion or chronic infestation. The use of oil spray could be one of the most common and effective scale control options used in out-season to control BPS crawlers. Nowadays, the market has increased the legislative restrictions on the presence of insecticidal residues on fruits, making the management of this pest increasingly more complicated, especially because alternatives to chemical control are limited and natural enemies associated with the BPS are not well investigated.

Potential role of natural enemies

A number of parasites have been recorded in literature as effective in controlling the BPS (table 2) (Miller and Davidson, 2005). In Tunisia, the aphelinid wasp *E. citrina* have reduced the BPS population at different periods of the year, causing two important declines at the beginning of July and at the end of August and attacking 20-40% of individuals (Sigwalt, 1971; Jerraya, 2003). Moustafa (2012) have demonstrated a strong correlation between both parasitoids *E. citrina* and *Aphytis lingnanensis* Compere and BPS pest population in citrus trees in Egypt (r = 0.39, 0.85 in 2011; 0.45, 0.81 in 2010, respectively). Augmentative release of the aphelinid wasp *A. melinus* was used for BPS control in Egypt in five citrus growing locations where the parasitism level (91%) resulted in a significant decrease of BPS populations. This parasitoid *A. melinus* could constitute a promising biocontrol program of BPS in citrus orchards as the case of the California red scale, *Aonidiella aurantii* (Maskell) (Coccoidea: Diaspididae) in different Mediterranean countries (Abd-Rabou, 2009). As predators (table 2), Stathas et al. (2008) demonstrated that the predation of the coccidophage *C. bipustulatus* reached 34% under laboratory conditions in Greece. As acari, studies carried out on the predatory activity of the phytoseiid mite *Euseius scutalis* (Athias-Henriot) under laboratory conditions, showed a 100% survival rate and a consistent average number of consumed prey eggs by adults, 16.11 and 10.30 eggs per individual (El-Sharabasy *et al*., 2017).
Additionally, the fungus *Aschersonia placenta* (Berkeley, 1873) is recognized as an important biological control agent able to causing epizootic disease in whiteflies and scale insects in the tropics and subtropics (table 2) (Zhu *et al*., 2008). Recently, Homrahud et al. (2016) demonstrated that the pest cumulative mortality of BPS population is higher when increasing the

conidial concentration of the fungus *A. placenta*. Conidial suspension at 1 × 109 conidia/ml caused 23.73% and 27.42% mortality of BPS population 14 and 21 days post inoculation, respectively. In Cuba, El-Choubassi et al. (2001) observed up to 49% infection of the BPS by two fungi belonging to the same genus, namely *A. aleyrodis* (Webber, 1897) and *A. goldiana* (Sacc. & Ellis, 1899). Entomopathogenic fungi belonging to *Aschersonia* genus can play an important role in the mortality of the BPS and eventually be successful biocontrol agents. The natural enemies' potential for the biological control of BPS appeared to be promising in the field.

Control rules in relation to BPS biological features

Actually, the BPS has developed more adaptation capacities over time to survive different conditions, from tropical to temperate regions, becoming lately a key pest of citrus in the southern Mediterranean countries (Jendoubi and Suma, 2021). In these regions, the BPS marks three important periods of activity during the growth seasons of citrus trees in autumn, spring and occasionally in summer. The lowest population levels on foliage have been recorded usually during the coldest or/and hottest months, when the BPS infests mainly leaves and moves to fruits (Miller and Davidson, 2005; Tawfeek, 2012; Bouazza and Guenaoui, 2015; Taibi *et al*., 2016; Jendoubi, 2018). Then, the BPS time control must be maintained in mid-April (Algeria, Egypt, and Tunisia) and in mid-October (Egypt, Tunisia) or in November (Algeria).

Crawlers are the most difficult instars to be detected and identified in the field due to their small size and high mobility. The crawler emergence varies depending mainly on seasonal weather conditions and location. The crawling time is usually short, lasting only a few days. Chemical treatment must be applied when the first crawlers start emerging and approximately 10 days later to control those still emerging during all the period of laying eggs. It should be applied with sufficient volume and pressure to thoroughly cover all the woody portions of the tree, because the BPS individuals are usually concealed inside the canopies of trees, which makes them

invisible to farmers and allows them to escape the chemical treatments (Salama *et al*., 1985; Tawfeek, 2012; Medjoub, 2014; EPPO, 2015; HJ personal communication, 2016).
A regular plant inspection (visual inspection, sampling) is highly recommended for BPS life cycle monitoring and control. Catching males using chromatic traps should be introduced in monitoring programs of BPS populations in the field (Jendoubi *et al*., 2016). This tool gave consistent information on male abundance and flight patterns, allowing for pest injury detection before the symptoms appeared.
BPS populations must usually be kept in check by the natural limiting factors (e.g. temperature, cultural practices, and soil fertilizers) that should be considered in control program and used in combination with insecticides. Population growth, abundance and survival of BPS are limited in fact by the extensive summer heat, drought and cold. The natural mortality can even exceed 74-80% of the population for the BPS citrus orchards from Tunisia. During the tropical summer, the global mortality of this species presents 3 peaks around the year with the summer rate being the highest one [November (62%), February (66%) and August (75%)]. In some countries with extremes climatic conditions (e.g. Egypt), an important proportion of the spring population is overwintering as dormant stages during August (Bénassy, 1975; Salama *et al*., 1985; Harrathi, 2008; Tawfeek and Abu-Shall 2010). BPS control is so needless in summer and should be delayed to the autumn or spring seasons.

Chemical control approach for the BPS: life cycle stages in making control decision

A good IPM strategy for the BPS has three components: identifying the pest, monitoring infestation and selecting the best management tactics depending on the situation.
Identification of the pest life cycle stages is critical for the BPS, since appropriate management methods may vary dramatically for each stage. Recently, Jendoubi *et al*. (2021) have provided a field guide of the life cycle male and female, so as to achieve the correct and rapid recognition of the pest at immature and adult stages. Accordingly, two sorts of life cycle stages were indeed distinguished for the BPS, depending on their susceptibility to insecticides. The feeding stages group is the most vulnerable to agro-chemicals, while the second group contains protected instars which are the dormant, moulting and reproducing stages (Jendoubi *et al*., 2021).
The newly emerged first-instar nymph is highly mobile and the main dispersal agent either passively or actively for the species. **The BPS crawler stage** is the only instar to be controlled efficiently. These instars are vulnerable to agro-chemicals due to the absence of protective scales. Systemic agro-chemicals are unnecessary to be used at this stage. Chemical spray with contact insecticides should be applied at a specific time when the crawlers are the most dominant instar of the population, appearing as white circular masses on plant surfaces. Treatment, at this stage, should be applied exactly at the white cap stage with the settlement of crawlers on the host plant and before the beginning of the moulting process. Later, once crawlers start to cement wax and the dorsum becomes heavily sclerotized, systemic insecticides are recommended and insecticides of contact are only slightly efficient. The systemic ones can provide excellent options for the BPS control, due to their chemical properties which could fight the overlapping aspect and the protective scales of the diaspid.
When young males and females are developed, the use of systemic insecticides as a foliar spray to control this stage during the growing season is obligatory. Treatment, at this stage, should also be applied with care while scales are feeding (secretion of new wax around previous armor) not moulting (blackness of armor) at the appearance of black scale armors on leaves and fruits of citrus trees.

The adult stage should be used in the monitoring system as indicators of crawler emergences. Adult female is armored and does not feed and it is mated and producing eggs. The treatment of this stage is ineffective with any agro-chemicals. The photo illustrations provided by Jendoubi *et al*. (2021) can allow growers to recognize the developmental phases of each BPS stage and should be used as decision tool for its management. As in example, is looking at the exuviae rejected on plant surfaces by males. The presence of the third exuvium indicates that the emergence of males will occur in a short time as well as the mating process. Also the presence of the yellowish-brown wax fringe at the posterior end of the female body indicates as the production and lying of eggs is starting. When, the fringe becomes dark brown the emergence of crawlers start (Jendoubi *et al*., 2021). So, with these indications, it will be easy to limit the egg hatching duration and predict the emergence time of crawlers and then to fix the proper timing of crawler sprays, considering obviously the climate conditions differences between seasons and regions.

The dormant stages should be never treated. The diapause and the moulting are two dormant stages which do not need to be treated or sprayed by insecticides, as the insects are protected and not feeding**.** Hence, during the blackness of the female scales (moult stage), until the appearing of the orange ring moult, the treatment is a misapplication and a waste. Accurately,
oil sprays are used to control dormant stages in winter, while oil penetration may not be completed as the stages are protected by their armor. A descriptive model for the control treatment rules of the BPS is set out in figure 1.

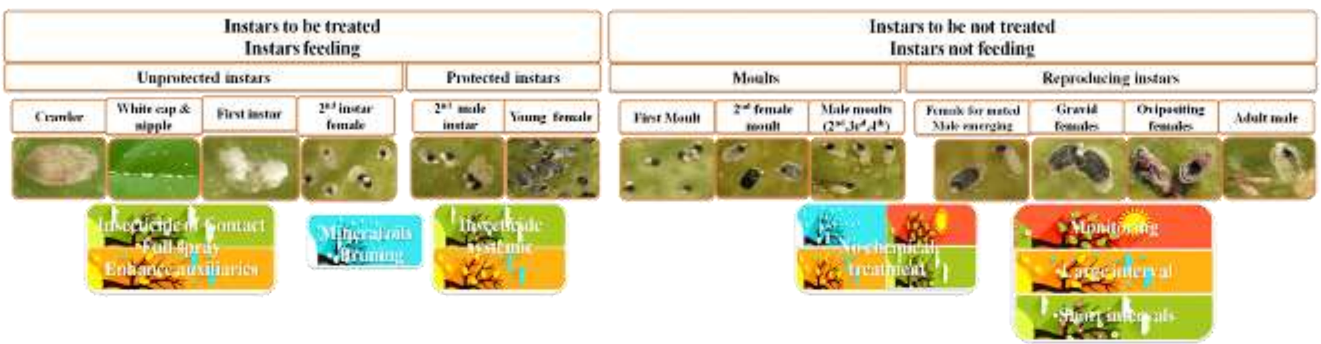

Figure 1. Control scheme of the BPS in citrus orchards

Conclusion

The BPS is a highly specialized plant-parasitic insect, to which the citrus is the main and quasi only host plant. Nonetheless, the BPS is a historic pest of citrus with a legacy of persistence to control methods and high adaptation potential to different climates. Inconsistent knowledge about this pest still exist in literature and no comprehensive approaches have yet been developed to allow for efficient monitoring and management of the BPS in many citrus-growing countries, mainly in the newly invaded areas from the southern Mediterranean basin. This paper attempts to provide valuable background information on the BPS, while paying particular attention to the potential use of all parameters together as baselines in view of a sustainable management solution for the expanding challenge that the BPS poses to the Mediterranean citrus production.

A compilation of an information management vision for the BPS is actually achieved as a primary step of an effective management program for the pest. A chemical control concept based on life cycle stages, in conjunction with other IPM components and early regular monitoring, is given for the sustainable control of the BPS in Mediterranean and African countries. Insecticides play a key role in pest management programs for the BPS. The feeding stages are the most vulnerable to pesticides, while the dormant, moult and protected stages shall not be treated as they do not feed and are armored. The reproducing females should be better used during monitoring as indicators of crawler emergence and to subsequently control timing. Some biological control agents (*A. melinus, A. placenta, E. citrina, E. scutalis* and *C. bipustulatus*) are promising in controlling BPS populations in regions where they are abundant, despite their efficacy is unclear under field conditions.

Perspectives

Currently, future research areas should be investigated, using the currently-existing management information option, to prevent further expansion of the pest in citrus-growing countries. Studies about pest interactions with citrus trees, the environmental factors affecting population growth and the selection of performing auxiliaries to enhance biological control, should be deeply investigated. For BPS bio-control, the challenge lies in finding successful combinations of entomopathogens, predators and parasitoids along with other interventions to maintain populations of the BPS below the economic threshold level.
We expect in the future to develop advanced approaches, such as bioinformatics solutions for the BPS to forecast the sessile population dynamics on citrus trees based on weather data and pest biological behavior.

Abstract

The Black Parlatoria Scale (BPS) *Parlatoria ziziphi* (Lucas, 1853) (Hemiptera: Coccomporha: Diaspididae) is a serious citrus pest, and has the potential for establishment and spread, and for economic consequences in the citrus growing areas. Pest status dynamic and spread history of the scale insect are reviewed. The incidence of *P. ziziphi* is usually associated with host plant, climate and control programs adopted by national authorities. BPS was not a key insect pest of citrus in many countries until the 1970s. The pest has been established on citrus as primary host in Asiatic areas (China, Iran and Taiwan) and then has spread within the crop expansion to different areas through the trade movement of citrus plant materials, showing a high adaptation to different climates mainly to tropical and Mediterranean regions. The pest is established where citrus is grown, in more than 90 countries across four continents. Nowadays, severe outbreaks of the pest are reported in the southern Mediterranean countries (Algeria, Egypt, France, Italy, Spain, and Tunisia), reaching major pest status. Pest impact is more noticeable in North Africa which has recorded complicated control status. Potential future research lines should be delineated for BPS control in the newly invaded citrus areas. An integrated management approach should be developed and accurately applied in citrus orchards, focusing on monitoring techniques and biological control. Bio-control, in conjunction with other IPM components and regular monitoring, will provide sustainable control of the BPS in the newly infested citrus regions.

Key words: *P. ziziphi, citrus, distribution, Mediterranean countries.*

Introduction

The Black Parlatoria Scale (BPS) *Parlatoria ziziphi* (Lucas, 1853) (Hemiptera: Coccomorpha: Diaspididae) is referred to a worldwide pest of citrus crop (Miller and Davidson, 2005). BPS was originally described in 1853 by Dr. Lucas Pierre Hippolyte as *Coccus ziziphi* based on female specimens collected on *Ziziphus pinnachristi* (Lam) from France. However, the original description of Lucas is so brief and indefinite. There is legitimate question to the correctness of the association of the host plant name and the common black citrus-infesting *Parlatoria*. Later, the species was described under the genus *Parlatoria* Targioni Tozzetti (1868) as *P. lucassi*. Ever since, it has received different synonyms (*Parlatoria lucasii* TargioniTozzetti (1868), *Parlatoria zizyphi*, Signoret (1869), *Parlatoria zizyphus* (Lucas) Cockerell (1900)) and is recognized today under the first name, *P. ziziphi* (Lucas, 1853; Balachowsky, 1953; Mckenzie, 1956; Bénassy, 1975; Garcia Morales *et al*., 2016). The BPS is well distinguished from other *Parlatoria* species at adult stage. The female body is membranous, elongate oval with an ear-like lateral lobe on each side of the head at the level of anterior spiracles (Balachowsky, 1953). It

is the only *Parlatoria* species having earlike lobes, which make its identification under microscope evident from other species. On citrus trees, the habit pattern is mostly aggregative, appearing as black compact colonies encrusted on leaves and fruits. The female scale is a sub-rectangular black cover (1.25-1.4 mm long; 0.6-0.75 mm wide) made of two previous instars exuviae, and ending with a narrow fringe of white wax on the posterior margin. Adult males are completely different from females. The scale cover is white, elongated, and flat, with large black terminal exuviae, and is approximately 1/3 the size of the female (Mckenzie, 1945 & 1956; Balachowsky, 1953; Miller and Davidson, 2005). The BPS is considered by different coccidologists as the only truly monophagous scale species of citrus crop (Miller and Davidson, 2005). Commonly known as the Mediterranean scale or the citrus parlatoria, BPS is a sucking insect feeding on plant cells by piercing and sucking the plant phloem sap through a set of highly adapted mouthparts. Feeding behavior affects the young shoots, the leaves and the fruits of citrus trees, leading to reduced vigor of the host plant, and resulted in development of yellow discoloration patches on leaves and fruits (Dekle, 1976; Miller and Davidson, 2005).
Pest status was described in almost citrus growing areas of the world through different periods since it was first recorded in the thirty years (Dekle, 1976; Garcia Morales *et al*., 2016). Mckenzie (1945) has noted BPS to be a very serious pest of citrus in various parts of the world. Beardsley and González (1975) considered BPS to be one of 43 major armored scale pests and one of five *Parlatoria* species known to damage citrus crop. Talhouk (1975) reported BPS has long been treated as a pest of serious economic importance on citrus crop, mainly in citrus growing countries (Algeria, Brazil, China, Egypt, Iran, Italy, France, Libya, Morocco, Nigeria, Puerto Rico, Spain, Taiwan, and Tunisia). Later Miller and Davidson (2005), in their book '*Armored Scale Insect Pests of Trees and Shrubs'*, defined this species a serious world pest of citrus crop.
The species has received several studies during the seventies mostly carried out in Asiatic and Mediterranean countries, treating chemical control options and some bio-ecological aspects of the pest (Garcia Morales *et al*., 2016). Few details were available on the economic losses caused by this insect, though it is listed in several countries as organism that may cause damages. In the last decade, an increase of studies is noted again particularly in the southern Mediterranean countries where about thirty documents were published. These include susceptibility of the citrus varieties to BPS, infestation spread and some chemical trials of new agro-chemical actives (Jendoubi *et al*., 2008; Berrabah, 2012; Tawfeek, 2012; Medjdoub, 2014; EPPO, 2015; Taibi *et al*., 2016; Ramos Portilla and Caballero, 2017; Jendoubi, 2018). Currently, large occurrences is reported for the species in Mediterranean countries such as Algeria, Egypt, Libya, and Tunisia where it commonly reaches the highest densities compared with other pest species occurring in the same citrus regions (Tena and Garcia Mari, 2011; Bouazza and Guenaoui, 2015; Taibi *et al*., 2016). The recent outbreak and the high worldwide spread of BPS should be studied in the different citrus areas.
The paper aims to revise the current distribution of BPS and incidence within time and regions to provide the actual pest status in the main citrus growing countries. A detailed revision of most published papers on the BPS is reported to clear up the pest status dynamic and difficult control situations recorded in the invaded countries.

BPS incidence on citrus fruit production

The BPS has many characteristics that make it particularly more economically damaging than other citrus diaspid species. The important longevity and reproductive rate, the accentuated overlapping of generations (two to seven generations per year); the high ability to survive and propagate in new environments, and the high adaptation potential to different climates (cool, hot and dry) make this species harmful for the host plants. The presence of the strong body armor, the immobility and its cryptic behavior provides an excellent protection from insecticides, auxiliaries and adverse climatic conditions (Bénassy and Soria, 1964; Salama *et al*., 1985; Quilici, 2003; ElSayed-Darwish, 2016). Furthermore, the most characteristic damage of BPS is the virtually irremovable masses of black scales on fruits during cleaning and packinghouse procedures. The visual aspect of citrus is affected, which cause rejection in most fresh fruit markets and may render them unusable and unfit for human consumption (Henderson, 2011; Tawfeek, 2012; EPPO, 2015).

Feeding damages

The main injury caused by the BPS to citrus plants occurs as a result of feeding activities and involves two processes: the penetration of plant tissues by the stylets and the removal of resources needed for plant growth. Depletion of plant sap leads to the reduction of plant vigor, premature shedding of the leaves and fruits. While penetrating the plant tissues with their piercing stylets, they also inject saliva, which appears to be toxic to the plant. The saliva often produces greenish discoloration and spotting on leaves and fruits. Heavy infestations of BPS on citrus cause premature senescence and leaf drop reducing yield. Fruit quality (poor taste and color) and production is decreased (Dekle, 1976; Miller and Davidson, 2005; Henderson, 2011). Nevertheless, documentation of BPS economic importance on citrus production in literature is rather poor. It is only stated that this organism may seriously damage citrus, which is not supported with any quantitative data on yield reduction or loss of income. BPS has shown particular preference to feeding on leaves, mainly on the upper face near the middle nerve; but fruits and branches are also attacked in case of high infestation. In Algeria and Tunisia, fruit infestation caused by the BPS varied from 33% to 64% and 87.9% on Thomson variety, 79% for the Portuguese variety and can reach 100% in case of high attack. On leaves, the species infests 84% and 96% of the canopy (Harrathi, 2008; Medjoub, 2014; Taibi *et al*., 2016).

Spread dynamic history

The BPS is probably native to Asia in Southern China, and has been transported around the world on nursery citrus plants. Nowadays, the scale insect occurs in Africa (22 countries), Asia (48 countries), Central and South America, Europe (14 countries), Oceania in Austria, and the West Indies. Otherwise, the pest has limited distribution in several countries as Lebanon, Saudi Arabia, Malaysia, Singapore, Guam, Peru and Venezuela or locally spread to some counties within a country. In the Western Hemisphere in Northern Mariana Islands, Argentina and Bermuda, it has not been recorded since 1938 (CABI, 1964; Bénassy, 1975; Talhouk, 1975; Longo *et al*., 1995; Claps *et al*., 2001; Jendoubi *et al*., 2008; Pellizzari, 2010; Tena and Garcia Mari, 2011; EPPO, 2015; Garcia Morales *et al*., 2016**;** Foldi and Germain, 2018). Recently, Ramos Portilla and Caballero (2017) reported a new introduction of the BPS on *Citrus* spp. to Colombia, since Blackburn and Miller (1984) mentioned its occurrence in America without indicating the host plant.

The BPS has become the major threat of citrus crop at different times in several countries. In 1930s, BPS had been recorded on citrus mainly in Asia, (Malaya, Philippines, Burma, India, and Thailand), Europe and other tropical and sub-tropical countries (Clausen, 1933; Ferris, 1937).
In the last seventy years, the BPS has further spread to many citrus growing countries mainly to those from Asia (China). BPS was not previously reported as a pest of major importance anywhere in the world, except in china where regular control was required. An important economic impact on citrus fruit production was observed in this country, despite all efforts conducted to limit the BPS population growth control. It was qualified as the most difficult species to control (Talhouk, 1975; Huang *et al*., 1988). Otherwise, the BPS was considered as a new pest infesting citrus trees or as a secondary citrus pest. Talhouk (1975) in his chart of the geographic distribution and economic importance of mites and insects gave more precisions about the pest status of BPS in different countries during this period. In Algeria, Tunisia, Morocco and south east of Asia, the species was present at low densities that occasionally require control measures. In Tunisia, BPS was recorded to be one of the main diaspid attacking citrus, with two other species *Chrysomphalus dictyospermi* (Morgan, 1889), and *Lepidosaphes beckii* (Newman, 1869) (Sigwalt, 1971). No studies were probably reported in Algeria or Morocco during this period. Nevertheless, in Spain, Italy, Greece, Israel, Egypt, India, and South Africa, the species was present but of little economic importance (Ipraloran, 1971; Talhouk, 1975; Dekle, 1976; Amin and Salem, 1978).
In the ninety years, after being established in Asiatic citrus areas, the BPS became a serious world pest reaching the highest densities in several countries from America, Africa, to Europe. At that time, serious measures of eradication were successfully taken in Europe and America (Florida, France, Italy, Palestine, and Spain) and in some zones in China. BPS was controlled efficiently in China, using many pesticides such as chlorpyrifos, methidathion, quinalphos, lambda-cyhalothrine, fenvalerate or cypermethrine (Huang *et al*., 1988). In Florida, the use of oil sprays combined with agro-chemicals (malathion, dimethoate or parathion), was highly recommended as a competent control solution, having reduced BPS populations under economic level (Dekle, 1976).
In 2010, the pest moved to the Mediterranean basin and it was called since that time a Mediterranean citrus pest. The infestation has been rapidly spreading northward and eastward and has remained limited to this area until now. In the recent years, the pest has persisted in the south Mediterranean basin in some African countries such as Egypt, Tunisia, and Algeria.

Current pest status in the southern Mediterranean countries

In Egypt, the insect was observed for the first time in 1937 on mandarin trees in Alexandria and near Cairo and since, the insect is spreading in citrus regions, reaching more and more high densities in citrus orchards (Hosny, 1943; Amin and Salem, 1978). In the 1980s, many authors carried out intensive studies on the bio-ecology of the pest as being a major pest of citrus orchards and causing serious damages in the country. The BPS widespread in Egypt has coincided with the citrus cultivation expansion period. Furthermore, the favorable climatic conditions have greatly contributed to the insect progress and its establishment. A regular chemical control was applied on BPS populations during the eighties in order to reduce population level below the economic threshold (El-Bolok *et al*., 1985; Salama *et al*., 1985; Sweilem *et al*., 1985). In the years since 1998, BPS populations emerged again in Egypt in commercial citrus orchards. Studies on BPS increased in the 2010s, treating the seasonal population dynamic, behavior of the pest on the host plant, and associated parasitoids in order to develop a control strategy for BPS in citrus orchards. BPS presents now localized distribution, becoming the most dominant species on citrus in Shebin El-Kom, Menoufia, and Qalubia. Infestation level varies between high to moderate (Tawfeek and Abu-Shall, 2010; Tawfeek, 2012; ElSayed-Darwish, 2016). All authors are actually increasing research on the necessity to apply integrated pest management strategies against BPS to limit the spread of this pest in citrus areas.

In Tunisia, the pest has persisted since 1938 in citrus orchards and is surviving the environmental conditions of the country. The scale insects injuring citrus trees have historically been overlooked by farmers and authorities in the country unless they become destructive pests, and difficult to control (Pagliano, 1938). In 2007, faunistic observations carried out on scale insects in the most infested citrus groves of Tunisia revealed the occurrence of BPS at high densities, having invaded a large part of northern citrus areas. Additionally, it was reported that the Tunisian citrus groves host a large community of exotic scale insects and BPS is classified in the group of notorious citrus pests (Harrathi, 2008; Jendoubi *et al*., 2008). Since ten years ago, farmers have been applying intensive chemical control programs using systemic agrochemicals but many foci of BPS and other species are still increasing. According to observations made with farmers during recent surveys, chemical treatment is frequently applied by field men late in summer in citrus groves at the appearance of black armors on leaves or fruits. Some other farmers prefer to not control this group of pests and are just cleaning fruits after harvest (Jendoubi, 2018). The chemical treatments applied in Tunisia have failed due to two main causes. The pesticide has not been applied at the correct time or the pest may have been in a life cycle stage or in a location where it was not susceptible to pesticides. Hence, populations that are present in concealed areas may be part of new infestations that developed long after the chemical was applied; that abundance and the high occurrences of BPS occurred in several commercial citrus regions of Tunisia.

In Algeria, the situation is noticeable. The BPS was ignored for a long time by farmers until they caused considerable economic damage. No studies have been reported during the eighties or in recent times. Indeed, the number of researches has increased during the last ten years, studying the ecological features of the pest, infestation characteristics, interaction with the host plant (Telemcen, Blida, Mitidja, Rouiba), but not yet the control programs (Medjoub, 2014; Belaribi and Halladj, 2015; Boukhobza, 2015; Taibi *et al*., 2016). BPS is one of the main *Parlatoria* species occurring in large number in the northern citrus Algerian regions. The scale insect commonly reaches the highest densities compared with other species occurring in the same orchard and trees. The highest infestation level on fruits reaches nearly 88% on Thomson and 79% on Portuguese citrus varieties, and can reach 100% in cases of high attack. This species is abundant in the upper surface of leaves, affecting the southern and central part of trees mostly (Medjoub, 2014; Belaribi and Halladj, 2015; Boukhobza, 2015; Taibi *et al*., 2016). These results are imprecise and incomplete to achieve an integrated control program for BPS. Further surveys and applied studies on BPS and other scale insect species present in the citrus area from Algeria are needed.

BPS establishment in the invaded citrus areas and actual management tactics

Actually, the spread of BPS native to Asia throughout the world is highly correlated primarily to the host plant distribution and the climatic conditions are secondary. Four factors could be included in the large spread of BPS in different citrus areas: the misidentification of the pest in the field with similar species at nymphal stages, the poor quarantine measures, and the limited control tools available for the BPS and their inaccurate use, and its associated distinctive bio-morphological features**.**

The probability of entry in new geographical zones and the probability of establishment for BPS populations in all invaded countries (previously discussed) are both moderate to high. However, the spread after establishment appears to be rapid, mainly in the Mediterranean basin. The BPS outbreak at high occurrences and large numbers is noticeable in Egypt, Tunisia, and Algeria. Attacks of this pest in Tunisia and Algeria are more notable than in Egypt. The particular geographic position of Tunisia and Algeria, encompassing high mountains and connection to the Mediterranean Sea has allowed the BPS populations growth and numerous exotic scale insect species in citrus orchards.

Control measures are needed to maintain existing pest populations of BPS at acceptable levels in northern African countries, to avoid the potential spread in local areas that were not previously infested, and to limit serious crop damage that have been noted previously in Asiatic or American states. Descriptions of control measures are outside the scope of this paper but they are commented on briefly. Most of control programs designed to combat the BPS have historically relied heavily on the use of broad-spectrum insecticides that have been ineffective in some cases (Rosen, 1990; Jendoubi *et al*., 2021). Nonetheless, the market nowadays has increased the legislative restrictions on the presence of insecticidal residues on fruits, making the management of this pest increasingly more complicated, especially because alternatives to chemical control are limited and associated natural enemies to the BPS are rare (Garcia Morales *et al*., 2016; HJ personnel observation, 2016).

Actually, BPS can be effectively controlled by a range of insecticides (Organophosphates, Pyrethroids, Ketoenols (spirotetramat)) combined with oil sprays and a few number of biological control agents (the parasitoids *Encarsia citrina* (Craw) and *Aphytis melinus* De Bach and the fungus *Aschersonia placenta* (Berkeley, 1873)) that have been identified in the current area of distribution. Augmentative releases of the aphelinid wasp *A. melinus* used for BPS control in Egypt resulted in a significant decrease of BPS populations; the parasitism level was 91%. The aphelinid wasp *E. citrina* marks a parasitism rate of 20-40% causing two declines of the population at the beginning of July and the end of August. Conidial suspension of *A. placenta* at 1×109 conidia/ml caused 23.73% and 27.42% mortality of BPS population 14 and 21 days post inoculation, respectively (Dekle, 1976; Huang *et al*., 1988; Harrathi, 2008; Abd-Rabou, 2009; Homrahud *et al*., 2016; Jendoubi, 2018). The natural enemies' potential for the biological control of BPS appeared to be promising in the field. Authorities and farmers have to select specifically the control strategy goal (prevention, suppression, eradication) and give to pesticide applicators the best strategy and tactics in controlling BPS populations, with the least risk to the environment.

In Tunisia, it is compulsory to manage and pick up the monitoring techniques in the field at the farmer level in order to make the treatment periods appropriate and increase the efficacy of agro-chemicals products. In Algeria, the incidence of BPS is significant in commercial citrus orchards, justifying a regular application of a rational chemical control program to keep the pest population below the economic injury level. Applied research studies should be firstly focusing on the population dynamic of the species in Algerian citrus orchards and their interactions with environment and auxiliaries in order to determine the population peaks and the appropriate treatment periods. While in Egypt, the situation is better kept under control, infestation areas are reduced with time; research areas which are in need of more work in Egypt are the biological control and integrated control strategy.

Conclusion

BPS is clearly one of the most successful invader diaspid in new citrus areas, established in 92 countries, where citrus is grown. The species has reached a large distribution in countries from Africa and Asia, showing a high adaptation potential to different climates mainly to tropical and Mediterranean climates. BPS was not a key insect pest of citrus in many countries until the 1970s. The pest has been established on citrus as primary host in Asiatic areas (China, Iran and Taiwan) and then has spread within the crop expansion to different areas through the trade movement of citrus plant materials. It has been introduced and extended into most Mediterranean countries (Algeria, Egypt, France, Italy, Portugal, Spain and Tunisia) in Europe and then has been rapidly spreading northward and eastward.

Populations have been now established in the southern Mediterranean citrus areas, reaching major pest status. BPS is currently widespread within northern African countries in Algeria, Egypt, and Tunisia where control status presents several difficulties. Inconsistent data about this pest still exist in the literature and no contribution to Integrated Pest management strategy (IPM) has been developed in the new invaded citrus growing countries by scientists or growers. Here, a starting point of references is given to researchers and pest management decision-makers. Potential future research lines should be delineated for BPS in the infested areas. More directed works in these regions should be focused on field studies adapted to actual citrus crop conditions (seasonal dynamic in citrus orchards, insect resistance) and advanced control tools (monitoring tools, biocontrol, IPM approaches, bio-models based on weather data and pest's life cycle).

Abstract

Each year, agronomists and farmers struggle with numerous questions regarding which seeds to plant, when to plant, how much input to apply to optimize yields, and when to harvest. Besides, the burden of analyzing and predicting the effects of a wide range of complex entities such as weather, disease, and varying consumer preferences is huge. The usual and yet unsolved question of food demand alarms everywhere. Although many claim that, several local crops could contribute to the global food supply, it is doubtful without further research and innovation. For decades agricultural researches, have been aiding farmers in improving agricultural systems and optimizing production. Agricultural research may include breeding improved seeds, enhanced plant protection, efficient irrigation, safe storage methods, new mechanizations, and others. In research, conducting extensive experiments to assure the credibility and quality of a product is necessary. However, in all these circumstances and research pathways, testing all possible research ideas and innovations is time-consuming and costly while the lack of sufficient and sustained funds is a key constraint in most developing countries. Hence, facilitating the diffusion of agricultural innovations and improved crop varieties in developing countries without disturbing the processes that lead to efficiency is timely and indispensable. In recent years, Machine learning techniques that can model complex inputs with complicated interactions have been widely used in agricultural activities. Thus, this article addresses and presents the importance, application, and impact of Machine learning in agricultural research, emphasizing facilitating research while reducing production costs and time.

Keywords: *Neural Network, Data, Agriculture.*

Introduction

Food consumption is growing at a higher pace than population growth, making meeting global food security demands a problem. The growing stress on food security and demand for high-quality nutritious foods, such as those derived from animal products, must be handled sustainably, without compromising environmental resources (Hobbs, 2007). Even though many people claim that several local crops could contribute extensively to the global food supply, it is doubtful that they will stand alone being adequate goods without further support from research and innovation (Calicioglu et al., 2019).

Agricultural research may be broadly defined as any research effort aiming at enhancing the yield and quality of crops and animals. For several decades agricultural research has been aiding farmers in optimizing their production to offset the ever-expanding population growth in many countries around the world through breeding programs, improved plant protection, irrigation,

storage systems, farm mechanization, efficient marketing, and better resource management (Zeigler et al., 2010).
However, in all these circumstances and research pathways, testing all possible research ideas and innovations is time-consuming and costly while the lack of sufficient and sustained funds is a key constraint in most developing countries. High-input, resource-intensive farming practices cannot provide sustainable food and agricultural production since they have resulted in huge deforestation, water scarcity, soil depletion, and high levels of greenhouse gas emissions. Innovative systems are required to maintain and enhance the natural resource base while simultaneously boosting production.
Though the lack of appropriate and long-term investments remains a key constraint Improved linkages that allow capacity building and technology flow are critical. Furthermore, many biotechnology products, such as novel crop types, are created by private firms with less commitment to public benefits. To make it easier for low-income nations to adopt agricultural biotechnologies and enhanced non-commercial staple crops without affecting the processes that lead to innovation (FAO, 2017). While there is no precise amount of agricultural research intensity, expending at least 1% of national GDP on science, technology and research is recommended. Countries in both the low-income and lower-middle-income groupings fall significantly short of this objective in the agricultural sector. Thus this article addresses and presents the importance, application, and impact of Machine learning on agricultural research with an emphasis on facilitating research while reducing production costs and time.

Materials and Methods

All around the world farms are striving to improve their efficiency to remain profitable. The constant expansion of the world population, and consequently the demand for an increasing amount of food, drives the need for efficiency (Godfray et al., 2010). To become more efficient, a farmer must make the proper decisions about when to inseminate, what to feed, and when to cure an animal, when and which seeds to plant, how much to irrigate, when to harvest — and analyze and predict the effects of a wide range of externalities such as weather, disease, changing consumer preferences among other things.
Every time, dozens of new concerns regarding optimizing agricultural production are prevalent. The majority of farmers base their technical decisions on their observations and experience. Nevertheless, acquiring experience takes time, and it is typically difficult to observe every action on a commercial farm over time along with complex variations. The application of sensors and automated decision-making has become crucial in the dairy industry, where herd sizes are constantly growing (Barkema et al., 2015).
Farmers are increasingly relying on data to obtain new insights, and they gather and analyze as much data as possible. Farms use a variety of sensors to collect various sorts of data. Motion sensors worn by cows and sensors attached to milking robots, for example, gather data on the health of cows. Because most farmers are unable to interpret raw data on their own, they rely on the functionality provided by Farm Management Information Systems (Slob et al., 2021). Farm management information systems used to be basic, but currently, some of them can handle comprehensive sensor data and provide significant decision-support capacity (Fountas et al., 2015). However, the full potential of data can only be exploited when machine learning techniques are used to assist or automate agricultural decision-making procedures.

Machine learning approaches typically involve a learning process to learn from experience or training data to do a certain task. Data employed in Machine learning contains a set of examples. Generally, an individual example is described by a set of features known as variables which may be nominal, binary, ordinal, or numeric. The performance of the ML model in a particular work is measured by various statistical and mathematical models. After the learning process, the trained model can be used to classify, predict, or cluster new data by using the skill gained through the training process (Liakos et al., 2018).

Fig 1. Typical Machine Learning Technique

Results and Discussions

Agronomy considers data analytics and machine learning to increase agricultural yields while reducing farmers' difficult work (Kim et al., 2014). Precision agriculture, also known as digital farming, is a technical method for developing high-quality agricultural output that makes use of contemporary data technology and expertise (Akhter and Ahmad, 2021).

In the agrarian sector, data analytics and machine learning approaches are playing an increasingly significant role in addressing the growing problems posed by weather and climatic variations such as temperature, rain, humidity, and other factors that negatively affect crop productivity. For a strong and expanding output, it is important to improve the accuracy of data analysis. The capacity to evaluate huge amounts of data can aid an organization in dealing with significant information that can have an impact on its operations (Russom et al., 2011).

Various traditional methods like manual detection of crop diseases and pests, calculations based on statistics to estimate the quantity and predict the production and loss of crops were generally burdensome before the advent of technology, these methods result in an error due to inspectors' lack of experience (Rumpf et al., 2010).

In the process of cultivation environmental features have the greatest impact on agricultural productivity. Crop growth and development are influenced by weather, which results in significant intra-seasonal yield fluctuation. Planting, fertilizer application, irrigation, tillage, and other crop agronomic management techniques can be employed to compensate for yield losses caused by weather. As a result, yield forecasting is a useful tool for maximizing crop output and assessing crop-area insurance contracts.

In agriculture, estimating yield performance for crop products is a major topic. In breeding programs, since it would take too long and be too expensive testing all likely hybrids generated by crossing two parents is not feasible. In breeding, hybrid performance is assessed through costly and time-consuming yield tests (Lanza et al., 1997).

Consequently, this undoubtedly indicates that there is a high demand for advanced techniques to forecast hybrid performance. A study that applied advanced machine learning approaches to develop a yield estimate model for corn hybrids found that employing machine learning models significantly reduces costs by reducing the number of hybrid breeding attempts. Moreover, results from field experiments are no longer required because results from the model can be provided in seconds. The entire breeding process is no longer time-intensive (Sarijaloo et al., 2021).

According to (Chlingaryan et al., 2018), fast advancements in sensing technology and machine learning approaches will create cost-effective and comprehensive solutions for better crop and environmental status assessment and decision-making. One of the goals of precision agriculture is to reduce the amount of herbicides used in the fields by employing site-specific weed management technologies. A Bayesian framework-based automatic decision making method for detecting weeds in maize crops was also shown to save cost and minimize pollution (Tellaeche et al., 2008).

Foughali et al. (2018) presented a unique decision support system based on sensor networks for the prevention of late blight. The model was found to be effective in combating potato late blight. The technology was able to calculate the proper amount of fungicide to be used. For the prediction of late blight, the forecast model incorporated weather-related data from weather stations as well as historical data. For the farmers, the method proved very efficient and cost-effective.

Conclusion

Because it feeds the whole population agriculture is essential to a country's economy. It links and interacts with all of the country's major enterprises in this way. In the majority of countries, agriculture is the primary source of employment. Agricultural research has profited from technology improvements, especially when it comes to combining industrial innovations into a sustainable agricultural production system. Technology has turned agriculture into a profitable business by revolutionizing every farming operation.

Contemporary application of machine learning algorithms such as evolutionary algorithms, neural networks, and others in agricultural systems have provided solutions to respective decision modeling issues. Hence it can be inferred that the adaptability, promotion, and lower costs of machine learning can greatly support in evaluating the complex relationship between the input and output of agricultural systems using analytical techniques that are characterized by non-linearity, time-variable characteristics, and a large number of unknown factors.

Abstract

Plant diseases caused by seed-borne bacterial pathogens place major constraints on vegetable crop production in Turkey and cause significant annual losses on a global scale. The aim of the present study was to investigate chemical composition and antibacterial activity of essential oil obtained from grapefruit fragrant Mint (*Mentha* x *piperita* f.sp. *officinalis* var. 'Aura') plant. Chemical composition of the essential oil was identified by Gas Chromatography coupled with Mass Spectrometer detector (GC-MS). According to the result of GC-MS analysis, 39 components were identified, accounting for 99.94% of the whole essential oil. The main components were linalool (57.86%), linalyl acetate (29.76%), α-terpineol (%3.69) and geranyl acetate (3.39%)). Antibacterial activity of essential oil was determined against five different economically important Gram-negative seed-borne plant bacterial disease agents such as bean halo blight disease agent *Pseudomonas syringae* pv. *phaseolicola*, tomato bacterial speck disease agent *Pseudomonas syringae* pv. *tomato*, tomato pith necrosis disease agents *Pseudomonas cichorii*, *Pseudomonas corrugata* and potato soft rot disease agent *Pectobacterium carotovorum* subsp. *carotovorum* by using paper disc diffusion assay. Based on inhibition zone diameter values, essential oils showed the highest antibacterial activities against *P. carotovorum* subsp. *carotovorum* (11.3 mm), followed by *P. syringae* pv. *phaseolicola* (10.7 mm), *P. cichorii* and *P. syringae* pv. *tomato* (8.7 mm). Essential oil did not displayed antibacterial activity against *P. corrugata.* Based on our results, the essential oil of mint plant collected from Hatay province has a potential to be applied as seed disinfectant against important seed-borne plant bacterial disease agents.

Keywords: *Antibacterial, Seed-borne, Essential oil, Mentha* x *piperita, Mint.*

Introduction

Plant diseases caused by certain plant bacterial pathogens are major constraints and cause huge yield losses in agriculture on a global scale. Depending on the infection stage, crop-pathogen interaction and environmental conditions, annual crop yield loss of agronomically important crops caused by certain bacterial pathogens may reach up to 5-50% (Sundin *et al.*, 2014). Currently, management bacterial diseases is mainly achieved by using cultural (such as use of clean certified seeds) or chemical treatment. Chemical control of disease relies upon the use of antibiotics (such as streptomycin) in USA or copper compounds in rest of the world and such control methods prevent bacterial multiplication but not always adequate control of seed-borne inoculum. Unfortunately, frequent use of antibiotics has led to the selection of resistant bacterial population against antibiotics. The high cost of pesticides, development of pesticides/antibiotic resistant pathogen isolates, governmental restriction on the use of antibiotics in European countries, including Turkey, and the interest of environmental consideration raise the need to find alternative control methods. Plant extracts and essential oils from several medicinal plant have been reported to possess antimicrobial activity against a wide range of fungal and bacterial plant pathogens (Burt, 2004). The biological activities of these plant oils have also been exploited in ethno-pharmacological and ethno-veterinary studies for the control of diseases and pests of humans and livestock. *Mentha* spp. (commonly known as mint) belong to the Lamiaceae family. The economic importance of *Mentha* spp. is evident from the fact that their essential oils and dried and fresh plant material are in daily use in many purposes such as confectionary, beverages, bakery, cosmetics, pharmaceuticals, and pesticides (Shaikh *et al.*, 2014). The genus Mentha, consists of about 25 species. Native from the temperate areas of the world is common in Eurasia, North America, southern Africa, and Australia, mints are widely distributed throughout. *Mentha* × *piperita* L. is cultivated several countries including USA, Morocco, Argentina, France, Hungary, Italy, and Switzerland (Chambers and Hummer, 1994). Although antibacterial activities of essential oils from different *Mentha spp* were reported on a variety of food and human pathogenic bacterial disease agents (Sivropoulou *et al.*, 1995), very few research has been conducted for the usage of essential oils from medicinal and aromatic plants against the seed-borne plant pathogenic bacteria.

Therefore, this research was carried out to evaluate the chemical composition and the antibacterial activity of essential oil from leaves of cultivated mint (*Mentha* x *piperita* f.sp. *officinalis* var. 'Aura') having grapefruit fragrant grown in a home garden in Hatay province against five different economically important Gram-negative seed-borne plant bacterial disease agents such as bean halo blight disease agent *Pseudomonas syringae* pv. *phaseolicola*, tomato bacterial speck disease agent *Pseudomonas syringae* pv. *tomato*, tomato pith necrosis disease agents *Pseudomonas cichorii*, *Pseudomonas corrugata* and potato soft rot disease agent *Pectobacterium carotovorum* subsp. *carotovorum* by using paper disc diffusion assay.

Material and Methods

Isolation of essential oils

Seedlings of grapefruit fragrant mint plant (*Mentha* x *piperita* f.sp. *officinalis* var. 'Aura' were purchased from a commercial company (N11.com) and cultivated in a local home garden in Hatay province. The essential oil was obtained from dried leaves at pre-flowering stage. A total of 25 g of plant samples was used and placed into a 1 L flask. Distilled water was then added until it covered the sample completely. Essential oils were obtained by hydrodistillation method using Clevenger-type distillation apparatus. The essential oils were dried over anhydrous sodium sulfate and stored in dark vial bottles at 4°C until analysis.

Determination of chemical composition of essential oil

The essential oil was analysed by a Thermo Scientific ISQ Single Quadrupole model gas chromatography-mass spectrometry (Kara *et al.*, 2020). The GC was equipped with a TRFAME MS column (60 m x 0.25 mm, 0.25 μm) column and helium carrier gas. The MS transfer line temperature was 250°C, the MS ionization temperature was 220°C, mass spectra were recorded at 70eV, and the mass range was from 1.2-1200 m/z. The injection port temperature was 220°C, the column and oven temperature was initially 50°C. The oven temperature program was initially held at 50°C for 3 min and then programmed from 50°C by a ramp of 3°C/min up to 220°C. Helium (99.9 %) was used as a carrier gas (1.0 ml/min). The essential oil was diluted in hexane

(2 ml cyclohexane, 5 ml essential oil). The structure of each compound was identified using mass spectra with the Xcalibur program (Wiley 9).

Test microorganisms and cultural methods

The antibacterial activity of mint essential oil was tested against bacterial disease agent *Pseudomonas syringae* pv. *phaseolicola*, *Pseudomonas syringae* pv. *tomato*, *Pseudomonas cichorii*, *Pseudomonas corrugata* and *Pectobacterium carotovorum* subsp. *carotovorum*. All of bacterial disease agent isolates were obtained from their respective host plants growing in the region. The bacterial cultures were maintained and tested on King B (KB) medium.

Determination of antibacterial activity of the essential oil

The antibacterial activity of the mint essential oil was determined by using the paper disc diffusion assay (Bozkurt *et al.*, 2020). The surface of KB plates was inoculated with 100 µl of overnight cultures of bacterial isolates. Sterile filter paper discs (6 mm in diameter) were treated with 5 µl of the essential oil and placed on the centre of the agar. The lid of each individual petri dish was replaced immediately to prevent unnecessary evaporation or interaction and sealed with parafilm and incubated at 25°C for 48 hr. In addition water amended discs was used for control treatment. Antibacterial activity of each essential oil against bacterial isolates was then determined by measuring the diameter of zones of inhibition, including the paper discs. Studies were performed in triplicate and repeated three times. SPSS statistic program was performed for all calculations, and the significance was determined by means of Duncan's Multiple Range Test ($P<0.05$).

Results and Discussion

The chemical components of essential oil from plant were identified by GC-MS analysis. Following GC-MS analysis, 39 different components were identified in essential oils, representing 99.94% of the essential oil. Among the components detected, linalool (57.86%), was found to be the major compound of the essential oil followed by linalyl acetate (29.76%), α-terpineol (3.69%) and geranyl acetate (3.39%) as major compounds in each essential oils investigated (Table 1). Several investigations have been carried out on the chemical composition of different samples of *Mentha* species from different geographical regions revealing that chemical composition and percentage varied depending upon the species and the harvesting time at different stages, and the geography as well as the extraction methods (Rohloff *et al.*, 2005). Some factors like physiological and environmental conditions, genetics and evolution also determine the chemical variability of *Mentha* essential oils (Figueiredo *et al.*, 2008). In a very recently published study, menthol (59.1%) in different *Mentha* spp., linalool (32.5-48.2%) in *M.* x *piperita* cv "Grenada", *M.* cf. x *gracilis* cv. "Ginger", and *M.* cf. x *gracilis* cv. "Aureus", cis-piperitone oxide, carvone, and menthofuran were reported to present in essential oil of *Mentha* spp. plants grown in a geographically small region of Estonia (Kapp *et al.*, 2020). However, in Korea, *M. piperita* leaves EO has different composition and include limonene (64.5 and 94.2%), 1,8-cineole (46.1%), p-menth-2-en-ol (34.5%), menthol (33.4%) and linalyl-acetate (28.2%) as main components (Yasukawa *et al.*, 1993).

The antibacterial activities of mint essential oil and the response of seed-borne bacterial disease agents to the essential oil is presented in Table 2. Differences between bacterial disease agents were significant. Grapefruit fragrant mint essential oil had the highest inhibitory activity against *Pectobacterium carotovorum* subsp. *carotovorum* corresponding to 11.33 mm in the zones of inhibition over the control (sterile water). This bacteria was followed by *Pseudomonas syringae* pv. *phaseolicola* (10.67 mm), *Pseudomonas syringae* pv. *tomato* and *Pseudomonas cichorii*

(8.67 mm) respectively (Table 2). No antibacterial activity was, however, observed against bacterial disease agent *Pseudomonas corrugata*.

Table 2. Inhibitory effect of grapefruit fragrant mint essential oil on growth of seed-borne bacterial disease agents

Bacterial species	**Inhibition zone* (mm)**
Pseudomonas syringae pv. *phaseolicola*	10.67c**
Pseudomonas syringae pv. *tomato*	8.67b
Pectobacterium carotovorum subsp. *carotovorum*	11.33c
Pseudomonas corrugata	0.0a
Pseudomonas cichorii	8.67b
Control (sterile water)	0.0a

* Diameter of inhibition zone including disc diameter of 6 mm.
** Means in the column followed by different letters are significantly different according to Duncan Multiple Range Test (P<0.05).

Previous studies were conducted to assess antimicrobial activities of essential oils from different medicinal plants belonging to Lamiaceae family against some plant pathogenic bacterial disease agents such as *Agrobacterium tumefaciens, Clavibacter michiganensis* subsp. *michiganensis, Pseudomonas syringae pv. phaseolicola, Acidovorax avenae subsp. citrulli, Pseudomonas savastonoi pv. savastonoi, Pseudomonas syringae pv. tomato* (Soylu *et al.*, 2003; Daferera *et al.*, 2003; Soylu *et al.*, 2009; Mengüllüoğlu and Soylu, 2012; Bozkurt *et al.*, 2020). In many published studies, antibacterial effects of essential oils have been mainly investigated against human pathogens, food spoilage microorganisms and dermatophytes (Burt, 2004; Saeed *et al.*, 2006; Kaap *et al.*, 2020). To our knowledge there is no research on the evaluation of the efficacy of essential oil of mint against seed-borne plant pathogenic bacterial disease agents used in this study. Earlier studies have demonstrated the ability of different species of mint essential oils to retard and inhibit the growth of various plant pathogenic bacteria such as *Agrobacterium tumefaciens*, *Clavibacter michiganensis* subsp. *michiganensis*, *Pseudomanas savastanoi pv. savastanoi*, (Ben Hsouna *et al.*, 2019; Benali *et al.*, 2020; Siddique *et al.*, 2020).

Conclusions

In conclusion, the results of this investigation clearly showed that essential oils obtained from leaves of cultivated mint seedlings growing in the region has the antibacterial potential against the seed-borne plant pathogenic disease agents. The mode of action of essential oils against bacterium is unclear, however the involvement of essential oil components may disrupt the cell membrane of the bacterium and change its permeability. Essential oils of plants belonging Lamiaceae family were rich in phenolic compounds, which are believed to be responsible for the marked antimicrobial activity.

Abstract

Black rot disease caused by *Xanthomonas campestris pv. campestris* is one of the most hazardous disease of cabbage which is economically important vegetable cultivated in Turkey. Between October and November of 2019 year, 27 fields of cabbage were surveyed in Niğde province which is the largest producer of Turkey. Plants showing V-shaped necrotic lesions with surrounding yellow halo and blackened veins collected from 15 different fields with a disease prevalence of 55.5% for isolation. Infected leaf tissue containing veins was macerated and suspension was streaked on YPGA medium. Growth of yellow and mucoid colonies was checked after incubation at 28°C for 72 h. Isolated colonies (n=20) were Gram-negative, aerobic, non-fluorescent on King's medium B (KB), oxidase negative, catalase positive, caused hypersensitive reaction on tobacco,able to hydrolyse gelatine and aesculin. Fifteen bacterial isolates representing field surveyed produced a single and 619 and 445-bp PCR amplicons with DLH120/125 and ZUP2311/2312 primers specific for *X. campestris* pv. *campestris*. A bacterial suspensions (10^8 cfu ml^{-1}) of isolates were inoculated into leaves of three week old cabbage seedlings. Typical symptoms identical to those observed on naturally infected plants in the field appeared . According to biochemical, physiological, pathogenicity and molecular studies, identity of isolates was confirmed as *X. campestris* pv. *campestris.* All isolates could able to grow on KB medium amended with 100 ppm of streptomycin sulphate and 2.5 mM of copper sulphate.

Key words: *Identification*, *Bacterial disease, Black rot, X. campestris* pv. *Campestris.*

Introduction

Cabbage (*Brassica oleracea* var. *capitata* f. *alba*) is one of the most important economical crop grown in all over the world. It is most commonly grown cruciferous plant cultivated with a great socia-economic impact for direct human consumption and antioxidant based diet. Cabbage is under the infection of several viral, fungal and bacterial diseases (Aksoy, 2007; Şevik et al., 2016; Ayyaz et al., 2018). The main yield-limiting disease of cabbage is considered as Black rot caused by vascular plant pathogenic pathogen *Xanthomonas campestris* pv. *campestris* (Pammel) Dowson (*Xcc*) (Alvarez, 2020). *X. campestris* pv. *campestris* is a gram negative, obligate aerobic, rod shaped with yellows pigmented colonies in culture (Alvarez et al., 1994), Black rot disease was first noticed in USA on cabbage. Bacterium has been sporadically isolated in all continents wherever Brassicaceae plants are produced (Bradbury, 1986). It affects and widely distributed in many parts of the world described as a principal yield-limiting and destructive disease of cabbage, cauliflower, broccoli, Brussels sprouts, kale, radish, and some weeds (Bradbury, 1986; Jensen et al., 2010). Pathogen is primarily seed borne and can be transmitted

by infected plant material, soil, plant debris and weeds (Schaad et al., 1974; Williams, 1980). Especially, weeds are very important inoculum source for pathogen conservation throughout the year (Schaad and Dianese, 1981). Bacterium generally enters the plant tissue through hydathodes on the leaf margins and invades vascular tissue under favouruable conditions. The characteristic symptoms of the disease are described as V-shaped necrotic lesions starting from leaf margins and vascular movement progress towards the middle vein resulted darkening (Janse and Wenneker, 2002). The disease severity often depends on factors such as variety of host plant, climatal conditions that crop can suffer from stunning and death of young plants can occur (Taylor et al., 2002). Up to date, several reports indicated the occurance of black rot infections caused by *X. campestris* pv. *campestris* in Turkey. Pathogen was first identified in Mediterranean Region on cabbage, broccoli and Brussels sprouts by Aysan et al. (2006). Other reportes indicated that pathogen was responsible of black rot on cabbage (Aksoy, 2007), cauliflower (Aksoy et al., 2018) and red cabbage plants (Ozturk et al., 2019) grown in Black Sea Region.
Despite Niğde province located in the Central Anatolian Region of Turkey having economic importance on cabbage with the highest production value approximately 150.000 tons on 20.000 decares land, there was no current and descriptional information for black rot disease. So, the present research aimed at surveying, isolation, identification of the casual agent *X. campestris* pv. *campestris* on cabbage plants in Niğde.

Materials and Methods

Surveys were conducted between October and November of 2019 in Sazlıca, Bahçeli, Kaynarca and Bor districts in Turkey which are the major production areas. 54 leaf samples (two plants from each field) contained V-shaped necrotic areas on the leaves were collected from 27 cabbage fields. The leaves showing signs of typical symptoms were used for bacterial isolation. Lesions containing margins of healthy and diseased tissue were aseptically cut and replaced into a steriled extraction bag added 1 ml of sterile sodium chloride (0.85%), crushed using a sterile scalpel and left to bacterial releasing for 45 minutes. The extracts were plated on plated onto YPGA plates (Laala et al., 2015) and left for incubation at 26°C for 72 hours. Single yellow and mucoid *Xcc*-like colonies were purified on King’s B (KB) plates. All isolates were stored in Luria broth liquid (LB) medium supplemented with 40% glycerol at -20°C (Raghavendra et al., 2013). KOH, Kovacs oxidase reaction, oxidative and fermentative metabolism of glucose, hydrolysis of esculine, liquefaction of gelatin and induction of the hypersensitive reaction in tobacco leaves (cv. benthamiana) tests were performed (Lelliot and Stead, 1987; Klement et al., 1990; Schaad et al., 2001). Fluorescent pigment production was evaluated on KB plates on a UV transilluminator. Acid production from carbon sources were tested using methods described by Dye (1968). Salt tolerance was tested in LB nedium containing 5% NaCl. Reference *X. campestris* pv. *campestris* isolate Xc53 previously isolated from red cabbage (Ozturk et al., 2019) was used as positive control for each test. Primer pairs DLH120/DLH125 for detection *X. campestris* (Berg et al., 2005) and ZUP2311/ZUP 2312 (Rijlaarsdam et al., 2004) for detection of *X. campestris* pv. *campestris* isolates were used in PCR assay (Table 1). Suspected colony was picked up with a sterile tip and directly placed into the PCR reaction tube prepared in 25 μL final volume including 12.5 μL of 2x master mix, 1 μL of forward primer, 1 μL of reverse primer, 1 μL of DMSO and 9.5 μL sterile water. PCR parametres were set up on a thermal cycler (Bio-Rad T100 thermal cycler, USA) a protocol was used as recommended by ISTA (2013). The PCR products were separated on 1.5 % agarose gels in 1× TAE buffer, stained with ethidium bromide, and visualized using UV transilluminator.

Table 1. Primers used for the identification of black rot isolates

Primers	Sequence (5'-3')
DLH120	CCG TAG CAC TTA GTG CAA TG
DLH125	GCA TTT CCA TCG GTC ACG ATT G
ZUP2311	GCA AAG CCC TCG TTC ACG CAT
ZUP2312	GGT GGT GTG GCC GCT CTT CTC AT

Bacterial isolates were grown on KB plates incubated for 48 hours at 26°C. Bacterial inoculum was adjuested to 10^8 cfu mL^{-1} (OD_{600} = 0.1). The edges of leaves of two weeks old cabbage seedlings were cut by disinfected scissors and inoculated with bacterial cells from colonies using sterile tips. Plants were incubated in polyethylene humid chambers for 24 hours to faciliate bacterial enterance (Jensen et al., 2010; Raghavendra et al., 2013). Reactions of the inoculated plants were evaluated after 7-20 days of inoculation. A fullfill Koch's postulates were performed by symtomatic leaves onto YPGA medium and PCR was repeated for identidication of re-isolated bacterial colonies. Different concentration of copper sulphate (0.64, 1.28 and 2.56 mM) and streptomycin sulphate (20, 50 and 100 ppm) were streaked on KB medium amended with different concentration of copper and streptomycin and incubated at 28ºC for 72 hours. Bacterial isolates were classified for presence or absence of growth performance (Lelliot and Stead, 1987).

Results and discussion

Black rot disease was observed in Sazlıca, Bahçeli, Kaynarca and Bor districts of Niğde province during October and November of 2019. More samples were collected from Kaynarca and Sazlıca districts and found to be under the infection of pathogen caused very visible and heavy disease symptoms. The disease was recorded in each of the visited district. Typical V-shaped and blackened veins on leaves were found in the fields. In same cases heavy diseased plants were observed at mature head period including disease symptoms on vascular system when plant root cut in half. Identification tests were performed on 20 isolates showed *Xcc*-like morphological colonies on the YPGA medium. The bacterial colonies were round, yellow, mucoid, convex and shiny after 72 hour incubation.

They were Gram-negative (approved with KOH test), negative for oxidase, aerobic, non-fluorescent after 48 hours of incubation on King's B medium, hydrolyzed esculin, liqufied gelatin and utilized oxidatively D (+) glucose, L (+) arabinose, D (+) trehalose and D mannose as a carbon source (Popović et al., 2013; Corzo et al., 2019). They could not grow at 36ºC and 5% NaCl containing liquid medium. They had ability to cause hypersensitive reaction on tobacco leaves. Fifteen of twenty isolates were positive for DLH120/125 and ZUP2311/2312 primers that generated 619 bp and 445 bp PCR products, respectively (ISTA, 2013; Raghavendra et al., 2013; Laala et al., 2015) (Figure 2). All isolates presented the same results like the reference isolate Xc53 (Ozturk et al., 2019).

Figure 1. A. Typical V-shaped disease symptom on cabbage leaf in the surveyed region, **B.** Colony growth of *Xcc* cultures on YPGA medium, **C.** Artifically inoculated cabbage plant with *Xcc* produced V-shaped halo on leaf

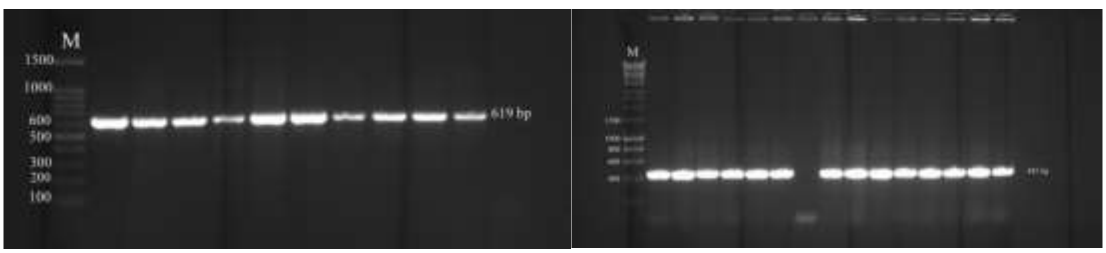

Figure 2. A. 619 bp PCR product generated by DLH120/DLH125 primer pair, **B.** 445 bp PCR product generated by ZUP2311/2312 primer pair

Fifteen isolates (NXcc1 to NXcc15) positive for PCR tests were pathogenic to cabbage plants. Typical disease symptoms were identical to those observed on naturally infected plants in the field. They initially caused small yellowish areas around the leaf in 7-10 days, followed by characteristic necrotic V-shaped lesions on the margins of leaves with chlorosis. Subsequently, blackening of vein and wilting of leaves occurred in 14–20 days (Alvarez et al. 1994; Popović et al., 2013). Plants inoculated with sterile water remained symptomless.
Reisolations were done onto YPGA and isolates showed the same colony morphology as original cultures. Pathogen was repsonsible of black rot of cabbage in the production areas of each of the Sazlıca, Bahçeli, Kaynarca and Bor districts. Pathogen is seed borne and spreads by several attemps such as movement of infected seeds, irrigation, rain splash infected plant debris left in field, weeds and mecanic damage. These factors increase the survival of pathogen in the region. It is indicated by growers even copper based products are commonly used there could not be offered an successful pathogen suppression in host plant. So, isolates were checked for copper resistance and they could grow on KB amended with 2.56 mM of copper sulphate. 100 ppm of streptomycin sulphate was also screened for pathogen survival and could not limit the growth of the isolates That can also be concluded according to the results obtained from to phenotypic tests, the isolates appear phenotypically similar.

Conclusions

Present research reports for the first presence of *X. campestris* pv. *campestris* on cabbage produced in Niğde province. Pathogenic isolates were identified by morphological, physiological, pathogenicity and molecular tests. The tests resulted identification of 15 *Xcc* isolates. The results obtained from this study provide certain information *Xcc* occurs on cabbage plants and confirms that black rot is widespread in the region. 15 of 27 visited individual fields were found to be under the infection of pathogen with a disease prevalence (55.5%). Several local varieties are dominant and preferred by growers. This local varieties are propogated by growers in their own fields and used for the next year. Especially, the fields sown by this local varieties were found to be under the infection of *X. campestris* pv. *campestris*. As indicated by Jensen et al. (2010) growers and workers observe black rot symptoms but mistakenly think it is a result of plant senescense. Certain precautions methods such as resistant/tolerant cabbage varieties, pathogen free seed and seedling material, certified pathogen-free propagative materials, alternative chemical compouds to supress pathogen viabilty in host tissue and crop rotation need to be taken by producers to prevent the spread of black rot disease in the region.

Abstract

Turkey with its geographical location and favorable climate has very rich fauna in terms of insect biodiversity, including especially agricultural plant pests. Agricultural pests destroy an estimated up to 30% of annual crop production worldwide. Keeping agricultural pests under control is very important to reduce the economic losses caused by insects in crop production. Monitoring and correct pest damage identification help us decide whether management is needed. The advanced techniques such as remote sensing and geographic information system (GIS) have become important tools for sustainable agricultural management. Recently, remote sensing and GIS techniques support a new approach for monitoring and determining the damage levels of insect pests in agriculture. The main objectives of these techniques are to collate data that help to estimate possible insect damage and make a decision for determining the most effective insect pest management. These systems have been used in collecting, mapping, analyzing the distribution of insect populations and predicting the damage of insect pests. There are several papers on the use of remote sensing and GIS techniques in agricultural pest control strategies. In this presentation, the some examples of remote sensing and GIS techniques in agriculture in the world are reviewed by focusing on monitoring and determining the damage levels of harmful insects that cause economic losses in the most common agricultural products such as hazelnuts, sunflowers, olives, cotton, cereals in Turkey.

Keywords: *GIS, Remote sensing, Insect pests, agriculture, Turkey.*

Introduction

Agricultural pests destroy an estimated 30% of annual crop production worldwide. It is very important to keep agricultural pests under control in order to reduce the economic losses caused by insects in crop production. Turkey is one of the ten largest agricultural producers in the world. Hazelnut, sunflower, olive, cotton and cereals are among the most produced agricultural products in Turkey. Turkey has a very rich fauna in terms of insect biodiversity, especially agricultural plant pests, with its geographical location and favorable climate. Recently, there has been an increasing interest in the use of remote sensing and GIS techniques in entomological studies (Dminić *et al.*, 2010; Nansen and Elliott, 2016). Remote sensing and GIS can be a rapid, accurate, and simple method for assessing pest damage on plants. Here we will focus on the most common agricultural products, their pests and the use of remote sensing and GIS techniques for monitoring insect pests in Turkey.

Agricultural crops

1. Hazelnut

Turkey is known as the homeland of hazelnut culture. Turkey is the largest producer of hazelnuts in the world with a total production area of 700 thousand hectares and approximately 600 thousand tons of product (İslam, 2018). However, insect pests constitute a major impediment to hazelnut production in Turkey. Although 150 insect and mite species have been determined from hazelnut, currently there are 7 hazelnut insects and mites could be classified as serious pests. This group includes *Curculio nucum, Gypsonema dealbana, Palomena prasina, Xyloborus dispar, Obera linearis* and *Hyphantria cunea* (Tuncer and Ecevit, 1997).

Of them, *Gypsonema dealbana, Xyloborus dispar, Obera linearis* and *Hyphantria cunea* cause damage on leaves, shoots, trunk and limbs. Due to the periodic and rapidly developing epidemic, it is not easy to estimate the damage of these pests and the actual loss. The hazelnut tree reaches 4-5 m and is usually 2-4 m tall and the appearance of a bush. The hazelnut has leaves 8-12 cm long and 6-10 cm wide. These features of hazelnut tree allow the use of remote sensing imagery as an efficient tool for identification, planning and monitoring hazelnut fields. There are several studies on the use of remote sensing and GIS techniques in hazelnut fields in Turkey (Reis and Yomralıoglu, 2006; Aydinoğlu, 2010; Taşdemir and Reis, 2011; Reis and Taşdemir, 2011; Sener *et al.,* 2013; Sarıoğlu *et al.,* 2013), but they are not related to insect damages. Multi-spectral images, acquired at a high radiometric and geometric resolution, by means of digital airborne systems or by satellite, can be useful for monitoring some diseases and insect damages of hazelnut trees (Fabi and Varvaro, 2009).

The fall webworm, Hyphantria cunea is one of the most important hazelnut pests in Turkey. Outbreaks caused by this pest that cause rapid and significant damage on leaves can be monitored by remote sensing techniques (Fig. 1). As seen in the fig.1, the insect pest damage in hazelnut fields can provide sufficient image data for remote sensing applications.

Fig 1. A hazelnut orchard severely damaged by *H. cunea* (Yaman, 2012)

In a case study, Fabi and Varvaro (2009) reports the initial results of the application of one of these systems, called "Advanced Spectroscopic Imaging System" for monitoring a bacterial disease of hazelnut by using aerial photographs taken during a decade of growing seasons, from 1996 to 2006. Furthermore, a protocol of investigation was set up, by means of vectorial GIS, in order to follow in time and in space the local spread of the bacterial disease on hazelnut trees

(Fabi and Varvaro, 2009). This study stimulates us to use Remote sensing and GIS techniques for monitoring insect pests in hazelnut fields in Turkey.

2. Sunflower

Turkey is one of the world's largest sunflower producing countries with an annual production of approximately 1.5 million metric tons and an area of approximately 569.000 ha. Sunflower is one of the most important oilseed crops in Turkey because the crude vegetable oil production is supplied by the sunflower (Konyalı, 2017). However, Turkey imports sunflower seeds, processed and raw sunflower oil for many years. Contrast, sunflower planted areas and production was decreasing in the last years. Therefore, it is necessary to increase the sunflower production areas and yield (Konyalı, 2017). On the other hand, several insect pests cause damage on sunflower leaves. In a research, Thripidae, Cicadellidae and Aphididae families were most important pests on sunflower leaves and Thripidae family was reported as the most abundant pest group (Apak *et al.*, 2017). Furthermore, a population fluctuation of these pests in sunflower fields was observed. According to that study, the highest population of Thripidae, Cicadellidae and Aphididae were observed on 19 July, 18 August and 25 August, respectively (Apak *et al.*, 2017).
There are some studies on the use of remote sensing and GIS techniques in sunflower fields in Turkey. Tunca *et al.* (2018) measured the spectral reflectance properties of sunflower using a spectroradiometer throughout the growing season. In another study, as a result of the classification of satellite images, sunflower cultivation areas were determined in the province of Edirne (Yerdelen *et al*., 2008). Narin *et al*. (2019) evaluated the performance of the Sentinel-2 satellite data in the monitoring of the phenological stages of the sunflower plant in Tokat province (Zile) in Middle Black Sea region of Turkey. Turhan *et al*. (2006) determined the effects of different salt concentrations on sunflower growth using spectral techniques and physiological-morphological characters. The number of similar studies can be increased, but we could not find articles on the use of remote sensing and GIS techniques on the monitoring of insect pests in sunflower fields in Turkey. In a study, Apak *et al.* (2017) observed a population fluctuation of insect pests in sunflower fields. It can be possible to demonstrate this population fluctuation as well as other insect pest damage by using remote sensing and GIS techniques.

3. Olive

Turkey ranks fifth among the world olive grower countries and has the potential of exporting a great majority of its production of olive fruit. In Turkey, pests are one of the most important problems in olive orchards (Bozbuğa and Elekçioğlu, 2008). In total, 8 pest species are of economic importance; *Bactoracera oleae*, *Prays oleae*, *Saissetia oleae*, *Parlatoria oleae*, *Euphyllura olivina*, *Calocoris trivialis*, *C. annulus* and *Pollinia pollini*. Of them, *Prays oleae*, one of twelve lepidopterous pest species known to occur in olive orchards in Turkey is economically important especially at the isolated olive plantations. The type of its damage depends on the attacked tissue. The damage (leaf drop) can be serious (Bozbuğa and Elekçioğlu, 2008).
There are studies on the use of remote sensing and GIS techniques in olive fields in Turkey. For example, Bolca ve Özen (2012) compared template method, a manual technique and OLICOUNT software, a semi-automatic counting modus to determine the number of olive tree presence. Kaleci et al. (2012) studied the determination of topographic characteristics of the olive field information system with remote sensing and GIS techniques. Although a variety

of insect pests can cause major damages to olive crop, the use of remote sensing and GIS techniques on olive pests are very limited. Vozikis et al. (2005) discussed the use of modern technologies (GPS, GIS and Geodata) for controlling olive tree pests. Kounatidis (2008) discussed the implementation of spatio-temporal analyses for management of the olive fly, *Bactrocera oleae* in detail. When compared the number of olive pest insect species in Turkey and the studies including these modern technologies, it is clearly seen that remote sensing and GIS techniques can be subjected to monitor olive pests in Turkey. Especially, *Prays oleae* can be subjected in these technologies because of that the type of its damage (leaf drop).

4. Cotton

Cotton has a very important place in Turkey's agriculture and economy. Turkey is among the eight countries that realize about 80% of cotton production in the World (URL-1). Cotton cultivation is carried out on an area of approximately 365.000 ha in Turkey and the annual cotton production is approximately 450.000 tons. Turkey is one of the leading countries in the world in terms of organic cotton production. In Turkey, insect pests are one of the most important problems in cotton fields. Among the several pest insects, 8 insect species are main cotton pests and they are of economic importance; *Aphis gossypii*, *Thrips tabaci*, *Empoasca decipiens*, *Asymmetrasca decedens*, *Tetranychus cinnabarinus*, *T. urticae* and *Bemisia tabaci* (Anonym, 2011).

Cotton is one of the most common plants subjected in the use of remote sensing and GIS techniques in agriculture. The use of remote sensing and GIS techniques are mostly focused on the determining the distribution of cotton fields in Turkey (Sarı *et al.*, 2007; Aydoğdu *et al.*, 2011). For example, Sarı *et al*. (2007) determined the spectral characteristics and distribution of the cotton growing areas in the West Mediterranean Region of Turkey using the digital data from the Landsat7 ETM Satellite. Contrast, the use of these technologies for monitoring cotton pests is being more popular in the World (Willers *et al*., 1999; Willers *et al.*, 2005; Verma *et al*., 2019). Verma *et al*. (2019) monitored changes in cotton acreage and alternate host crops of cotton bollworm using remote sensing and GIS. Chen *et al.* (2018) detected stress in cotton caused by aphids using leaf level hyperspectral measurements. Sudbrink *et al*. (2000) detected late-season pest damage to cotton & wild host plants of tarnished plant bug in the Mississippi Delta using remote sensing. Yang *et al.* (2011) used remote sensing for detecting and mapping whitefly (*Bemisia tabaci*) infestations. Several studies on the use of remote sensing and GIS on cotton pests stimulate us to use these technologies to determine and monitor the damage of cotton pests such as *Aphis gossypii* and *Bemisia tabaci.*

5. Cereals

Two cereals, wheat and barley, *Triticum aestivum* and *Hordeum vulgare* are very important and strategic food crops in Turkey as well as many other countries. These two crops are produced with 19 million mt and 8 million mt on approximately 9.4 million ha and 3.45 million ha in Turkey, respectively (Gül *et al.*, 2006). Wheat and barley are attacked by several insect pest species (Koçak and Babaroğlu, 2005). Sunn pests are known as a group of true bugs genera including *Eurygaster, Aelia, Carpocoris* and *Dolycoris*. Among them, *Eurygaster* species including *E. integriceps*, *E. maura*, *E. dilaticollis* and *E. austriaca* are the most important pest of cereals in Turkey. Their damage commonly results in yield losses of 20-30% in barley and 50-90% in wheat (Gül *et al.*, 2006).

There are some studies concerning the use of remote sensing and GIS in wheat and barley fields in Turkey (Özcan *et al.,* 2011; 2013; Şimşek *et al.*, 2016). However there is no study on the cereal pests in Turkey. Contrast, in the literature, several studies include the remote sensing and GIS techniques used to monitor cereal pests and their damage. There are considerable high number of studies on cereal crops (Wang *et al.* 2012; Mirik *et al.,* 2014; Bhattarai *et al.*, 2019). For examples, Wang *et al.* (2012) used the remote sensing techniques to monitor wheat stripe rust in China. Bhattarai *et al.* (2019) indicated that remote sensing data can be used to assess the areas of poor growth and health of wheat plants due to Hessian fly infestation. Contrast, numbers of such studies in Turkey is low. *Eurygaster* species, main pests of wheat and barley, can be monitored and their damages determined by the remote sensing and GIS techniques.

Conclusion

It is of great importance to monitor and estimate the damage caused by harmful insects in the agricultural areas with rapid techniques. Recently, remote sensing and GIS techniques support a new approach for monitoring and determining the damage levels of insect pests. However, a few studies have been focused on the use of remote sensing and GIS application in agriculture in Turkey. Furthermore, none of them is on the monitoring of insect damage.These limited studies stimulate us to use GIS and remote sensing applications to monitor agricultural pests and their damage. Among the most common agricultural pests in Turkey, hazelnut, grain and cotton pests are prominent for GIS and remote sensing applications.

Abstract

Plodia interpunctella (Hübner) (Lepidoptera: Pyralidae) is a common storage pest all over the world. The protection of stored products is very important both to ensure food safety and to contribute to the country economy. In addition, insect allergens emerging from foods contaminated with *P. interpunctella* pose a serious threat to human health. Different methods are used to control *P. interpunctella*. The most common of these methods is chemical control. However, chemical control is not considered as a right choice for environmentally safe, efficient and sustainable pest control. Therefore, interest in entomopathogenic organisms (EPOs) is increasing. Entomopathogenic organisms are important biological agents for the control of pest insect populations due to their common and high infection in insects. Natural enemies of *P. interpunctella* such as viruses, bacteria, protists, fungi, nematodes and parasitoids have been studied in detail. The present study includes the first records on the distribution and occurrence of protist patogens in the populations of *P. interpunctella* from 11 localities representing all Turkey between in the period 2019-2020. During the study, 3.286 of *P. interpunctella* samples including larvae, pupae and adults were dissected and searched for protist pathogens. We found three entomopathogenic protists, microsporidium, coccidian and neogergarine. The presence of the microsporidian pathogen was found in all 11 populations (33.7%), coccidian pathogen in two populations (5.55%) and neogregarine pathogen in three populations (3.12%). The distribution and occurrence of protest patogens in the populations of *P. interpunctella* were also given and discussed with literature.

Keywords: *Indian meal moth, Plodia interpunctella, entomopathogen, biological control.*

Introduction

Plodia interpunctella (Hübner) (Lepidoptera: Pyralidae) is a common storage pest all over the world. The protection of stored products is very important both to ensure food safety and to contribute to the country economy. In addition, insect allergens emerging from foods contaminated with *P. interpunctella* pose a serious threat to human health (Hossain *et al.*, 2021; Mostafiz *et al.*, 2021). Different control methods are used against *P. interpunctella*. The most common of these methods is chemical control. However, chemical control is not considered the right choice for environmentally safe, efficient and sustainable pest control. Therefore, interest in entomopathogenic organisms (EPOs) is increasing (Lacey *et al.*, 2015; Jung *et al.*, 2021). Entomopathogenic organisms are important biological agent for pest insect populations due to its common and high infection in insects. For this reason, they are known as the most reliable and promising control agents against stored product pests (Yaman *et al.*, 2019; Freitas *et al.*, 2020;

Ghoneim *et al.*, 2021). In recent years, natural enemies of *P. interpunctella;* such as viruses, bacteria, protists, fungi, nematodes and parasitoids have been studied in detail (Adarkwah and Schöller, 2012; Batta, 2016; Cowan, 1986; Knell *et al.*, 1996; Malone, 1984a; Mbata and Shapiro-Ilan, 2005; Yaman *et al.*, 2016). In this study, distribution and occurrence of pathogens in the populations of *P. interpunctella* from eleven localities representing all Turkey between the years 2019-2020 is given.

Material and Methods

Insect Samples

During the study, 3.286 specimens including larvae, pupae and adults of *P. interpunctella* were collected from eleven regions (Aydin, Bolu, Denizli, Gaziantep, Isparta, İzmir, Malatya, Ordu, Samsun, Siirt, Trabzon) of Turkey (Table 1).

Table 1. Sampling localities and dates for *Plodia interpunctella* populations

Sampling populations	Sampling Date

(AYD: Aydın, BOL: Bolu, DNZ: Denizli, GZP: Gaziantep, ISP: Isparta, İZM: İzmir, MLT: Malatya, ORD: Ordu, SAM: Samsun, ST: Siirt, TRB: Trabzon)

Microscopic Examination

P. interpunctella larva, pupa and adult samples were dissected in Ringer's solution and then prepared wet smears including host fat body, malpighian tubules, gut and hemolymph were examined for presence of protist infections under a light microscope at a magnification of 400–1000 ×. When an infection was found, the slides were air-dried and fixed with methanol, then stained with freshly prepared 5% solution of Giemsa stain. They were then washed in running tap water, air-dried and examined under a microscope (Toguebaye, 1988).

Results and Discussion

During the study, 3.286 of *P. interpunctella* samples including larvae, pupae and adults were dissected and searched for protist pathogens such as microsporidia, coccidia and neogregarines in the eleven localities of Turkey between the years 2019-2020. Protist infections were confirmed by observation of their characteristic spores/oocysts.

Three different protist pathogens, microsporidium, coccidian and neogregarine were observed in *P. interpunctella* populations. These pathogens were diagnosed as *Vairimorpha plodiae*, *Adelina* sp. and *Mattesia* sp.

While *V. plodiae* was observed in all populations of *P. interpunctella*, *Adelina* sp. in two populations (Aydın and Ordu) and *Mattesia* sp. in three populations (Bolu, Malatya and Ordu) with the infection levels, 33.7, 5.5 and 3.1%, respectively (Tables 2, 3 and 4).

Table 2. Occurrence of *V. plodiae* in *P. interpunctella* populations.

Location	Number of larvae	İnfected larvae	Number of adult	İnfected adult	Number of pupa	İnfected pupa
Aydın	62	52	15	6		
Bolu	573	293	350	82	8	5
Denizli	14	6	5	1		
Gaziantep	353	18	4	3	10	1

Total	36	2	-	-	-	-
Total infection rate (%)	5.55		-	-	-	-

Table 4. Occurrence of Mattesia sp. in P. interpunctella populations.

Location	Number of larvae	İnfected larvae	Number of adult	İnfected adult	Number of pupa	İnfected pupa
Bolu			251	17		
Malatya	252	1	8	1		
Ordu	34	1	159	2		
Total	286	2	418	20		
Infection rate (%)	0.7		4.78			
Total infection rate (%)	3.1					

Microsporidium infections in *P. interpunctella* populations have been detected in previous studies. However, no record of *Adelina* and *Mattesia* infection was presented. In this study, three different protist pathogen records from Turkey are given. Detection of these pathogens in natural populations of the pest is important in terms of biological control against *P. interpunctella*.

Conclusions

Entomopathogens can be considered as a more effective and easy method, considering the harmfull of chemicals to the environment in Integrated Pest Management (IPM) (Mantzoukas *et al.*, 2021). Although commercial preparations of entomopathogenic protists for use in biological control are limited, they may play a role as suppressive factors in natural populations of the pest. The presence of three different protists in natural populations of *P. interpunctella* is promising in terms of suppression of the pest under natural conditions. The obtained results encourage the use of protists in biological control against *P. interpunctella*.

Acknowledgement

The study was financially supported with a research project (Project no: 118O980) by the Scientific and Technological Research Council of Turkey.

Abstract

Nuts are seed kernels that are widely used in cooking or eaten as snack. They contain a high, inedible outer shell that usually needs to be cracked open to release the kernel inside. Nut products are always high in fat content and calories. The most commonly consumed nuts are: hazelnuts, peanut, walnut, almonds, cashew nuts, and pistachio nuts. Various factors can affect the quality of nut products during production, harvesting, post-harvest, and storage processes, such as: environmental factors, storage method, and corresponding storage conditions. These factors are mostly affecting the flavor, appearance, texture, color, and also the nutritional values of these products. This, in turn, affects the acceptability of the product by the consumers, as well as the marketability. Application of post-harvest quality control processes is very important to improve the quality and increase the product acceptability. Machine vision and image processing techniques are largely used as post-harvest quality control processes for classification, sorting, grading, and evaluating the quality of different agricultural products due to their consistency, objectivity, and reliability. In the current article, the general construction of the machine vision systems, application of machine vision and image processing techniques in evaluating the quality of different nut products are addressed.

Keywords: *Nuts, Almond, Hazelnut, Machine vision, Quality control***.**

Introduction

Nuts are some of the world's most popular snacks and come in many varieties, such as peanuts, pecans, pistachios, almonds, and hazelnuts. Many nuts are defined as seeds, while others are botanically defined as fruits. When eaten in moderation, nuts can be quite healthy and a fine source of protein, fat, fiber, etc. during 2020 and 2021 period over 5.3 million metric tons of tree nuts were produced worldwide (Shahbandeh, 2021). Within the type of nut trees, the production of almond (kernel basis) was the highest in the 2020/2021 production period as demonstrated in figure 1.

The harvest maturity and the procedures used for harvesting and harvest handling are factors affecting the quality of nut products. The most important nut quality factors include: color; texture (crispness), which is related to degree of dryness (moisture content); and flavor (oiliness, sweetness, absence of off-flavors due to development of staleness and rancidity). Deterioration rate is influenced by moisture content, incidence of decay-causing fungi, and insect damage (Kader, 2013). In general, Nuts in the shell have longer storage potential than shelled nuts. Since, broken pieces are more perishable than halves or whole kernels. In order to improve the quality of these products, post-harvest quality control operations need to be applied. These tasks have been largely performed using traditional approaches, which are very expensive, time-consuming, and ineffective approaches. In the current article, the general construction of the machine vision systems, application of machine vision and image processing techniques in evaluating the quality of different nut products are addressed.

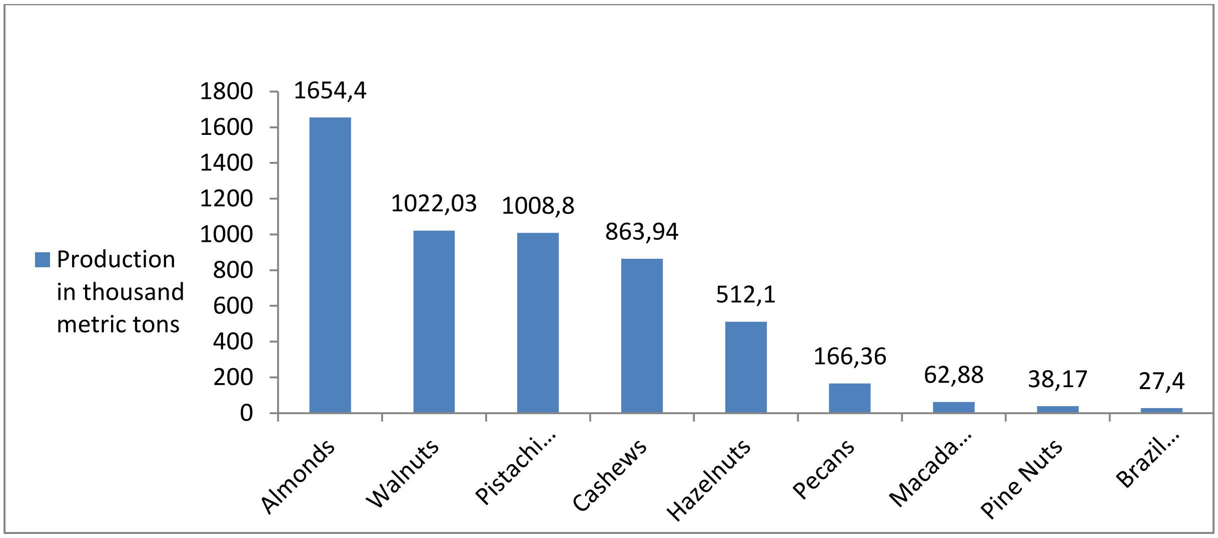

Fig. 1. Production of tree nuts worldwide in 2020/2021, by type (in 1,000 metric tons). (Statista, 2021)

Nut Quality Improvement

Improving the safety and quality of nuts is a comprehensive resource for food safety, product development and QA professionals using nuts in foods, those involved in nut growing, nut handling and nut processing, and researchers in food science interested in the area of improving the quality of these products using different methods(Casulli and Calhoun, 2013). Nut products, like many other agricultural products, require considerable amount of post harvest processing operations, such; separation, sorting, grating, defect detection and classification. Several techniques are currently used to perform these operations in order to improve the quality of nut products, like; image processing and machine vision systems. Digital image processing techniques as nondestructive quality control technique mainly derive from specific conditions in which researchers aim to mimic human vision and decision methodologies with artificial techniques in order to identify and classify objects without extracting samples from them, or permanently damaging them (Czimmermann et al., 2020).

Machine Vision System and Its Construction

Machine vision system is defined as a technology that has arisen from a union between camera and computer and try to imitate human vision in order to gather information from an object without requiring a physical interaction with that object (Sandoval et al., 2018). From other side of view (Timmermans, 1998) defined computer vision system as states that include capture, processing, and analysis of 2D images.

A typical machine vision system constructs of an image sensor, a frame grabber, lighting system, and a computer with suitable software and algorithms. An object image is captured using the image sensor, the analog signal generated by the sensor are digitized into a sequence of numbers and stored as an image into the computer, and then different type of image processing algorithms are used to extract a pattern from the image and represent the object. The extracted pattern is classified by classification algorithms which in turn may generate a signal to animate a trigger to direct the object into the required route. Figure 2 presents a block diagram of the software and hardware components and the inspection process of a typical machine vision system.

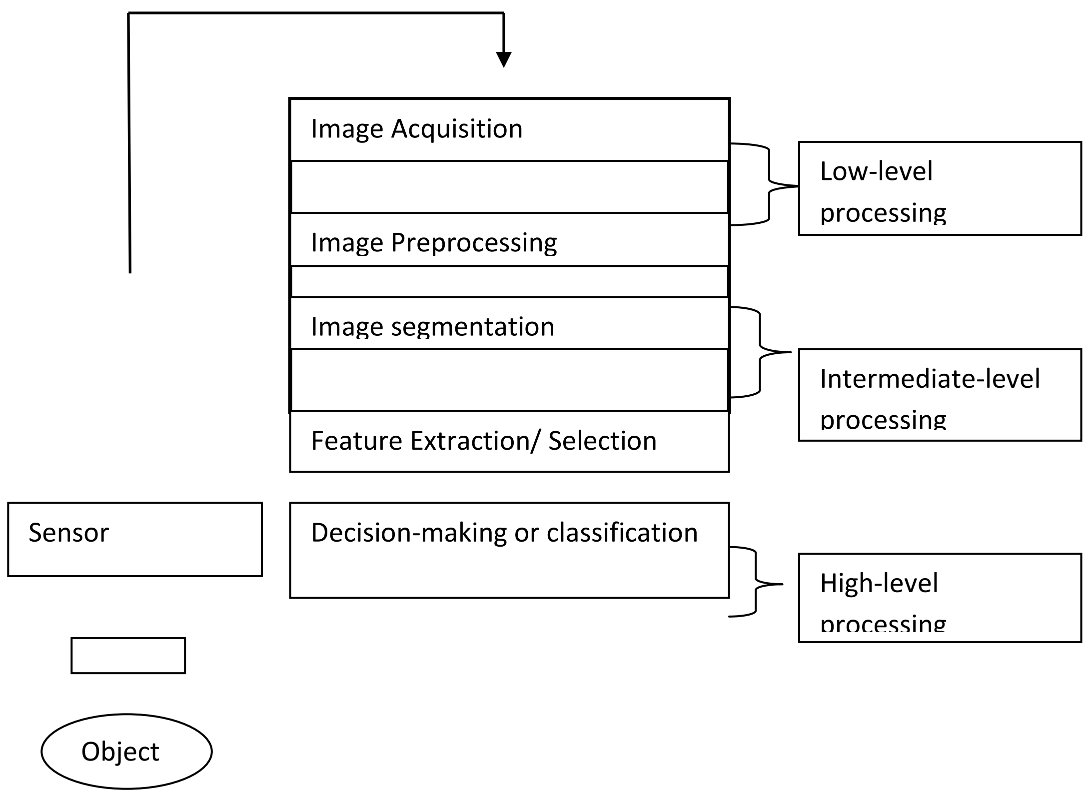

Fig.2.2 A schematic representation for inspection process by machine vision system

Machine Vision Image Acquisition

Obtaining good image of the object under inspection is the first problem in any automated task. In order to acquire all the useful information of the object, it is important to use a suitable light source to obtain the required quality of illumination required over the scene. As well as the performance of the illumination system can play an important role in the accuracy and efficiency of the machine vision system (Novini, 1995). Considering that the sensor used will receive the reflected light, the intensity of the illumination source should be limited by the sensitivity of the sensor.

The image sensor is the basic part of the imaging system within the camera for capturing images. In addition, the image sensor resolution must be taken into consideration, hence; it determines the amount of pixels from the image. There are many different sensors which can be used to generate an image, but self-scanned solid-state charge couple devices (CCD) are the most widely used image sensors (Brosnan and Sun, 2004). CCD cameras are widely used in computer vision system in industrial inspection problems in which a product moves along transport system require line-scan camera. Using these types of cameras, the image is carried out line by line as the object moves past the camera. Both the color and monochromatic cameras have been largely used in the agro-food industry, such as quality assessment, product selection, and product classification (Jhawar, 2016).

An image acquisition board or frame grabber is normally used to perform digitization task. The device is normally installed in a computer to digitize the signal received from the sensor in analog form by dividing the image into a tow dimensional grid containing picture elements defined as pixels. The analog signal of each sensor pixel is usually digitized by an 8bit resulting in a range of 0-255 for the signal (Narendra and Hareesh, 2010).

Inspection by Machine Vision Systems

Machine vision as nondestructive inspection method, is widely used in agricultural applications, including inspection and selection of fruits and vegetables (ElMasry et al., 2012).The visual aspect of the products considers an important factor for the agro-industry, since this parameter is used to determine the value of the product in the market. In addition, the appearance of agricultural products, i.e., their size, shape, and color, and the presence of stains or defects, negatively influence in the consumer perception and therefore determine the degree of acceptance prior to a purchase. The consumer also associates a certain internal quality with the appearance of the product, which affects future decisions in the purchases (Brosnan and Sun, 2004).

Machine vision inspection of agricultural and food products is more versatile than the existing optical and other traditional inspectors. Using machine vision techniques multiple-feature processing can be offered. These features can perform the signals sent by different sensors or obtained through different type of algorithms. The pattern classification algorithms implemented on a machine vision system provide multiple choices for agricultural products classification.

Mostly industrial inspection systems are designed to inspect only known objects at fixed position. The object needs to be appropriately illuminated in order to facilitate the acquisition of the previously known image features. Elias et al (2002) represent an intensive survey of machine vision applications in the industrial environment and they classified the industrial vision applications according to the inspected features of the product in four categories, namely: dimensional, structural, surface, and operational quality. They also can be classified according to the flexibility or degree of freedom of the system (DOFs), which is a measure of the ability of the inspection system to inspect independent features. DOF for any system could be increased, but sophisticated image classification approaches based on carefully selected models and algorithms must be employed. Which means that, the system can be improved to detect new types of defects if additional image processing and analysis functions are applied independently from the old ones to capture more image features.

Application of Machine Vision System in Nut Quality Evaluation

Application of machine vision system in quality evaluation begins with understanding the requirements of the application and also with the proceeds of selecting the appropriate machine vision hardware and software to solve the problem at hand. Mostly industrial inspection systems are designed to inspect only known objects at fixed position, and the object needs to be appropriately illuminated in order to facilitate the acquisition of the previously known image features.

The technology has been widely applied to determine the quality of nut products as illustrated in table 1. Recently, the technology was applied to identify hazelnut defects using RGB image analysis and color grams techniques (Giraudo et al., 2018). The half-cut RGB hazelnut images were acquired using digital camera after classified by industrial expert assessors into three reference categories, i.e. 'sound', 'rotten' and 'pest-affected'. The color grams were obtained by converting RGB images, and then Partial Least Squire Discriminant Analysis (PLS-DA) was developed and used as classification model. For better discrimination of the previously defined classes, Interval Partial Least Square Discriminant Analysis (IPLS-DA) feature selection algorithm by Nørgaard et al., (2000) was applied to select the most informative regions of the color gram signals. The whole defective hazelnuts have been also detected by Kivrak (2019) using image processing and machine learning techniques. The work was aimed to separate intact hazelnuts from damaged or imperfect ones. The images of hazelnut samples were captured by a mobile phone and processed using image tagging technique. Satisfactory results were obtained using supervised learning method.

As almonds are one of the most nutritious of all nuts and they have the highest protein content of any nut, increasing the quality of almond product by means of a new and reliable technique is a key factor in exporting and economic profitability of the final product. In order to evaluate the quality of the product, a robust method based on image processing and computational intelligence for almonds grading and classification was developed (Teimouri et al., 2015). Using artificial neural networks (ANNs) classifier, five classes of almond including normal almond (NA), broken almond (BA), double almond (DA), wrinkled almond (WA) and shell of almond (SA) were classified with very high accuracy. multiple researches have been performed to improve almond quality such; sweet and bitter almond classification (Abozar and Seyed, 2017), almond size prediction (Vidyarthi et al., 2020), and normal and broken almond classification (Teimouri et al., 2014).

Table 1. Application of machine vision system in quality inspection of nut products

Products	Application	Technology used	References
Almond	Defected, roasted, and foreign material classification	RGB Digital camera	(Delila Halac, 2017)
Almond	Pinholes detection	X-Ray imaging	(S. Kim and Schatzki, 2001)
Pistachio	Sorting different types of defects	X-Ray image histogram features	(Pearson et al., 2001)
chestnuts	Detection of insect infestation	NIR spectral tec.	(Moscetti et al., 2014)
chestnuts	defected chestnuts grading	NIR camera	(Zhan et al., 2010)
chestnuts	moldy chestnuts detection	near infrared spectra	(Zhou et al., 2009)
peanut	moldy peanut kernel detection	RGB camera, H,I,S color parameters	(Hong and Lirong, 2007)
Pecans	Damage inspection	X-Ray imaging	(Mathanker and Sunil, 2010)

Although chestnut is not widely spread around the world, it is of great importance in some countries such as China. The chestnut is one of China's important economic fruit and has rich nutrition and medicinal value. One of the most important defects that serially affect the overall quality of chestnuts is the existence of the worm-eaten chestnuts. Therefore, developing an effective, fast and accurate non-destructive testing (NDT) method for sorting chestnuts is an important process for the chestnut industry. For that reason a machine vision system was employed by Wang et al. (2011) to identify the worm-eaten chestnuts based on the edge image of the wormhole. The wormhole edges were obtained using the threshold method. The connected component of the binary images of the wormhole edge was labeled, and the first three longest components were considered as feature values of the worm channel. 100% recognition rate was obtained using back-propagation neural network model.

During the last decades, the application of machine vision technology in evaluating the quality of pistachio nuts have been increased, especially in grading and sorting systems. Recently, several researchers have conducted their efforts on developing automatic pistachio nut grading and sorting systems. Nouri-Ahmadabadi et al. (2017) developed an intelligent system based on machine vision and support vector machine (SVM) for sorting pistachio kernels. A color CCD camera was used for image capturing. HSV color space was gained from the RGB one and a feature vector containing 30 color features was extracted from the captured images. Using SVM classifier an accuracy of (99.17%) was achieved and applied in the online decision-making unit of the system.

Conclusion

This paper has summarized the important of machine vision in quality improvement and its construction. Also the application of machine vision and image processing techniques in evaluating the quality of nut products in order to increase the acceptability and marketability of these products are addressed in this article. However, there are still challenges in this topic that have to be overcome by researchers.

Abstract

Clary sage (*Salvia sclarea* L.) is an important aromatic plant cultivated to obtain essential oil throughout the world. *Salvia sclarea* L. (Clary sage) is a biennial or perennial herb between 20-120 cm tall, branched at the top, with a thick, upright stem. It has lilac, white or pale blue flowers. The plant, which develops rosette leaves in the first year, blooms the following year. Usually, flowering starts in May and continues until the end of August. Clary sage is commercially grown mainly in Russia, Bulgaria, France and Morocco, with an annual production of about 150 tons of essential oil in these countries. Clary sage essential oil is obtained from the flower parts in full bloom. The aim of the study is to determine the quality of clary sage essential oil, and mineral matter content, growing in natural environment in Central Anatolia. In this study, samples were collected from natural environment in Yozgat (0751558D-4393790K 1837 m), Central Anatolia conditions, during flowering periods in 2017. Flower parts in full bloom period essential oil ratio were found as 0.10%. The main components and its ratio of clary sage essential oil Sclareol, Sclareoloxide, and geranyl-p-cymene were determined as 37.74%, 8.33%, and 4.58%, respectively. Macro elements of flower parts Ca, K, P, and S were determined as 104.419, 432.161, 43.169, and 21.363, respectively. Micro elements Fe, Mn, Cu, B, and Na were observed 3.185, 0.867, 0.414, 0.125, 0.524, and 2.574, respectively. Heavy metals Al, Cd, Co, and N, were found as 2.91543, 0.00021, 0.00643, and 0.00508, respectively.

Keywords: *Clary sage, Salvia sclarea L., essential oil, mineral matter, Sclareol.*

Introduction

Most of the Lamiaceae family members are rich in secondary metabolites, especially essential oils. Therefore, they are of great importance in various fields such as medicine, food, cosmetics and perfumery. Sage, which is a member of this family, is the general name of the species included in the genus *Salvia* (Dweck, 2000). There are 99 species of *Salvia* genus, 51 of which are endemic, naturally spread in the flora of Turkey (Güner ve ark., 2012). Although leaves, shoot tips, flowers and partly stems of *Salvia* species, which have been important medicinal plants since ancient times, are used, the most utilized part is the leaves. *Salvia* species have a very high market potential as they appeal to a wide consumer group (food industry, pharmaceutical and chemical industry, herbalists selling as retail products) due to their characteristics (Yaseen et al., 2015). One of these species, *Salvia sclarea* L. (Clary sage), is a biennial or perennial herb with a plant height of 20-120 cm, branched at the top, a thick, upright stem. It has lilac, white or pale blue flowers. Seeds are brown, rounded triangular in shape. The leaves are petiolate, heart-shaped, and there are gray glandular hairs on the plant. The plant, which develops rosette leaves in the first year, blooms the following year. Generally, its flowering starts in May and continues until the end of August. It is classified as early (less than 170 days), medium early (170-200 days) and late (more than 200 days) according to maturation time (Yaseen *et al*., 2014; Yaseen *et al*., 2015). *S. sclarea* is an economically important species that grows naturally in many countries around the world and is also cultivated. It is a common species in the Flora of Turkey. Clary sage is grown commercially in Russia, Bulgaria, France and Morocco, and annual essential oil production is approximately 150 tons in these countries (Džamić *et al.,* 2008; Hristova *et al.,* 2013; Yaseen *et al*., 2015). The inflorescences and leaves of *S. sclarea*, known as "misk adaçayı, pamuk otu, paskulak" in our country, are used in folk medicine for abdominal pain and constipation (Lahlou, 2004). During the full flowering period, essential oils ranging from 0.01-0.40% are obtained from the inflorescences (Verma 2010, Dogan *et al*., 2015). *S. sclarea* essential oil is rich in linalool and linalyl acetate. *S. sclarea* essential oil is an important commercial oil and is characterized as a colorless, brownish yellow or pale-yellow liquid with a characteristic odor in the European Pharmacopoeia (Aćimović *et al*., 2018). One of the main components of the essential oil, sclareol is the main bioactive compound that can also be used to produce Ambrox, a chemical compound in the tetralabdanoxide class, which is considered one of the most valuable perfumes of animal origin. In addition, the essential oil is used in the food industry to produce beer, tonic drinks, liqueurs, as well as Muscat and Vermouth type wines (Gonceariuc *et al*., 2016). Although intensive studies have been carried out on the essential oil composition of *S. sclarea*, very few studies on the mineral content have been found as a result of the literature reviews. It is now known that nutrients play a vital role in general health and the treatment of diseases. These elements are present in varying concentrations and in very small amounts in different parts of plants (root, seed, leaf, etc.) (Lokhandea *et al*., 2009). The aim of this study was to determine the essential oil composition and heavy metal and mineral content of *S. sclarea*.

Materials and Methods

Plant material: S. sclarea was collected from the natural area in full flowering. Location information and general view of the species are presented in Figure 1.

Location	0751558E-4393790N
Altitude	1837m
Collected Date	30.05.2017-23.06.2017
Province	Yozgat/TURKEY

Figure 1. *Salvia sclarea*

Determination of essential oil content

After the plants were collected from natural area, the flowering aerial parts were allowed to dry in a shady environment not exceeding room temperature. The amount of essential oil in the dried plants was determined by Clevenger distillation device. An average of 50 g of dried plant sample was distilled in 700 mL of water for 3 h. Essential oil values (%, v/w) were calculated as volume over dry matter. The obtained essential oils were placed in dark-colored flasks and stored at 4 °C in a refrigerator until they were analyzed (Oke *et al*., 2009; Baj *et al*., 2015).

Gas chromatography–mass spectroscopy analysis (GC/MS)

The compounds of the essential oil were detected with GC/MS (Shimadzu, QP2010 ULTRA) in the Science and Technology Application and Research Center of Yozgat Bozok University (Turkey). The analysis was performed according to the method described by Cosge Senkal et al. (2019).

Determination of heavy metal and nutrient contents

Plant samples were dried in the shade. From each sample,1 g was weighed and put into a porcelain crucible. The samples were burned at a maximum of 550 °C until gray ash was obtained, and 3 N HCl was added to these samples. Then they were filtered using filter paper (Whatman No.1), and distilled water was added up to a final volume of 10mL (Kacar and Inal, 2010). The heavy metals and nutrients (aluminum, cadmium, cobalt, chrome, nickel, phosphorus, potassium, calcium, sulfur, iron, copper, zinc, manganese, boron, and sodium) in the samples were detected using an iCAP-Qc ICP-MS spectrometer (Thermo Scientific) at the Science and Technology Application and Research Center (Yozgat Bozok University, Turkey. (Basaran *et al*., 2017).

Results and discussion

Compounds and contents of the essential oil

The amount of essential oil in the aerial parts of S. sclarea collected in full flowering stage was 0.1% (w/w) in our study. The amount of essential oil obtained from S. sclarea varies according to flowering maturity. The amount of essential oil, which is low before flowering, reaches its highest value during the full flowering period and decreases as the flowers begin to fade (Lattoo et al., 2006). The essential oil content of this species was reported as 0.4% by Torres et al. (1997), 0.03-2.5% by Aydogan (2006), and 1.36% by Sharkhiz (2009). Also, El-Gohary et al. (2020) obtained 0.1-0.2% essential oil in flowers of S.sclarea grown under culture conditions. The values obtained from the study are within the limits reported by the researchers. The GC-MS results of the essential oil obtained from the aerial parts of S. sclarea species are given in Table 1.

Table 1. Chemical composition of essential oil from aerial parts of *S.sclarea* (%)

No	Compounds	RT[1] (min)	(%)	No	Compounds	RT (min)	(%)

[1]Retention Time

40 components were determined in the essential oil obtained from the plant. Of these components, sclareol constituted 37.74% of the essential oil. Linalyl 2-methylpropanoate (13.06%), sclareoloxide (8.33%) and geranyl-p-cymene (4.58%) were detected as other important components in the mentioned essential oil (Table 2). Farkaš et al. (2005), the essential oil obtained from S. sclarea flowers is characterized by high linalool, sclareol and linayl acetate content; Caissard et al. (2012) stated that sclareol is a high-value natural product obtained by solid/liquid extraction of sage clary sage inflorescences. The chemical composition of the essential oil obtained by water distillation from the aerial part of the plant grown under culture conditions in Iran was analyzed by GC and GC/MS and 50 components were determined. Among these components, linayl acetate (35.9%), germacrene D (13.3%), linalool (12.8%) and sclareol (9.27%) were reported to have the highest values (Sepldeh and Rowshan, 2013). Our findings are consistent with those of other researchers. However, there are some differences. It is known that many factors (genotype, ecological conditions, plant development period,

harvest/harvest time, drying, storage, working principles of the devices used, etc.) are effective on the chemical composition of essential oils. Dzumayev et al. (1995) emphasized that the chemical composition of essential oils obtained from S. sclarea varies according to the parts of the plant, the maturity of the plant, the location of the place where it is grown/collected, whether the plant is obtained from wild or cultivated conditions, the harvest year and the color of the bract leaves.

Mineral Matter and Heavy Metal Content

Some macro (Ca, K, P and S) and micro (Fe, Mn, Zn, Cu, B and Na) elements and heavy metals (Al, Cd, Co, Cr and Ni) analyzes in flowering aerial parts of *S. sclarea* were carried out and the results are presented in Table 2.

Table 2. Somme plant nutrients and heavy metal concentrations of S. sclarea (ppm)

Macrominerals		**Microminerals**		**Heavy metals**	
Ca	104.419	Fe	3.185	Al	2.91543
K	432.161	Mn	0.867	Cd	0.00021
P	43.169	Zn	0.414	Co	0.00277
S	21.363	Cu	0.125	Cr	0.00643
		B	0.524	Ni	0.00508
		Na	2.574		

Dietary minerals are accredited as an essential part of human nutrition due to their various beneficial functions. Major minerals include calcium, phosphorus, potassium, sulfur, sodium, chlorine and magnesium, and minor elements are iron, cobalt, copper, zinc, manganese, iodine, bromine and selenium (Yadav *et al*., 2017). In our study, K and Ca among the macro elements and Fe and Na among the micro elements had the highest values (Table 3). Ca, K, P, S, Fe, Mn, Zn, Cu, B and Na contents of *S.sclarea* collected during flowering period were recorded as 8844-13458 mg kg^{-1}, 22465-24267 mg kg^{-1}, 1852-3268 mg kg^{-1}, 2255-17437 mg kg^{-1}, 66.17- 198.5 mg kg^{-1}, 10.21-15.67 mg kg^{-1}, 17.34-31.99 mg kg^{-1}, 9.17-119.2 mg kg^{-1}, <0.2-6.35 mg kg^{-1}, and 45.96-168.9 mg kg^{-1}, respectively (Szentmihályi *et al*., 2004). *Salvia* species are rich in both major and minor minerals with nutritional properties. At the same time, there is great variation in mineral content among *Salvia* species. In a study conducted by Er et al. (2013), it was stated that Ca (12.402- 15.478 ppm) and S (1.034-2.257 ppm) contents of *S.halophila*, *S. tomentosa*, *S.heldreichiana* and *S. dichroantha* were found to be low compared to K (14.518-24.171 ppm) and P (1.385-1.910 ppm) levels. When our findings are compared with the literature values, it is observed that there are some differences. These differences are probably due to the development period of the plant, the organ used, genetic structure, growing conditions, climatic factors, species etc.

Determination of heavy metal contents is of great importance for the safe use of medicinal and aromatic plants collected from the natural environment (Baranowska *et al*., 2002). According to the analysis results, the heavy metal content of S sclarea was determined as Al > Cr > Ni > Co > Cd. The WHO/FDA breakpoints for "Cd, Cr and Ni" are 0.3, 0.02 and 1.63 ppm, respectively (Lone *et al*., 2003). The amounts of the three metals detected in this study are lower than the maximum allowable values

Conclusion

The chemical composition of essential oils is of great importance in determining the quality and usage areas of essential oils. The essential oil obtained from the flowering aerial parts of *S. sclarea* is rich in sclareol, an important component. Although the micronutrient content of the species is very low, it contains toxic heavy metal concentrations. There is limited research on the elemental content of *S. sclarea* in the literature. Therefore, our findings will be an important resource for future studies.

Abstract

Over the past two decades, a wide spread of rust on sunflower in the Rostov, Saratov, Krasnodar, and other regions of the Russian Federation was observed. The identification of the racial structure of *P. helianthi* populations in Russia has not been done since the early 80s of the last century. At that time, races 100 and 300 were identified in Russia. In our recent study, we identified six races among the isolates of the rust pathogen collected between 2017 and 2019. In addition to the indicated races 100 and 300, we identified, for the first time, the new races: 700, 710, 722 and 772. The aim of this study was to determine the racial identity of 160 *P. helianthi* isolates collected in the period 2018-2020 in the Rostov, Saratov, and Krasnodar regions. We used eight standard differentiating lines of sunflower: SM-90, SM 29, R-386, HAR-1, HAR-2, HAR-3, HAR-4 and HAR-5. We used also the sunflower variety VNIIMK 8883 as a differentiator susceptible to all races of the pathogen. In addition to 6 races mentioned above, we identified 11 more new races for the first time: 304, 351, 352, 364, 704, 736, 740, 741, 745, 760 and 762. Race 700 prevailed among the isolates collected in the Rostov region in 2020; we also identified single specimens of races 760, 762. Thereby, we found 17 races of *P. helianthi* on sunflower in three regions of the Russian Federation. It is possible that other races are also present here, so further research is required.

Keywords: *sunflower, rust, Puccinia helianthi, races, regions.*

Introduction

The rust pathogen is an obligate parasite of sunflower. As a result of its vital activity, the fungus dries up the leaves, which has a negative effect the productivity and quality of the seeds of the crop (Sackston, 1962; Yang *et al.*, 1986; Gulya, 1990; Gulya, Maširević 1995). Yield losses can reach 60-80 % depending on weather conditions and the stage of plant development (Sackston, 1962; Markell *et al.*, 2009). Rust is common in all countries cultivating sunflower, including Russia (Gulya, 1997; Sendall *et al*., 2006; Friskop *et al*., 2012; Qi *et al*.,2011; Vypritskaya, 2015; Detsyna *et al*. 2018) (Fig. 1).

Figure 1. The sunflower affection by rust in the Krasnodar region in 2019 (orig).

The spread of the disease is directly related to the emergence of virulent races of the pathogen. The racial composition of *Puccinia helianthi* Schwein is not constant; sexual and asexual reproduction inherent in the pathogen, along with mutations, which leads to the rapid emergence of new virulent pathotypes It is known that in the USA in 2008-2009 there were found 38 races of rust pathogen. Of these, race 336 was predominant and race 777 was the most virulent. In 2011-2012, 29 races were identified among the samples from seven US states and one province of Canada. Among them, pathotypes 300, 304, and 324 were prevalent. There were differences in the occurrence of races by year, for example, in 2011, race 300 was prevalent in the sample of isolates, while in 2012 race 304 had the prevalence. The presence of races 324, 364, 704, and 736 in the sample of isolates of 2012 also increased (Jing et al., 2015; Friskop and Markell, 2016). There have also been significant changes in the racial structure of the rust pathogen population in Argentina. Since 1985, the physiological races of *P. helianthi* with virulence codes 100 and 300 have not been found there, but pathotypes 700, 704, 740, 744, 760 have been identified (Moreno et al., 2012). Our earlier studies showed that in three regions of the Russian Federation - the Saratov, Lipetsk, and Krasnodar regions, - we found 6 races of the sunflower rust pathogen. Of these, four races, - 700, 710, 722, and 772, - are highly virulent and have been identified in the Russian Federation for the first time. We also found the old races 100 and 300 (Antonova et al., 2020). This situation could arise under the influence of a combination of factors, such as: a widespread decrease of the time of return of a crop to its former place against the background of an increase in its crop acreage, as well as global warming. The monitoring of the racial structure of populations of the rust pathogen is a necessary condition for successful breeding in Russian Federation of sunflower varieties and hybrids resistant to this pathogen.

The aim of the study: to determine the racial identity of 160 P. helianthi isolates collected on sunflower fields in the Krasnodar and Saratov regions in 2018-2020, and in the Rostov region in 2020.

Materials and methods

We collected the leaves affected by rust from the sunflower plants of different genotypes in the Krasnodar, Saratov and Rostov regions and stored them in a refrigerator (+4 -+6 ^{o}C). The seeds of differentiating lines of sunflower resistance (SM 90, SM 29, R-386, HAR-1, HAR-2, HAR-3, HAR-4, HAR-5) and variety VNIIMK 8883, which was used as susceptible to all races of the pathogen, were sown in rows in flower boxes with a soil capacity of 6 kg. The boxes were placed in a climate chamber, where the plants were grown at a temperature of 23-25 ^{o}C in the daytime and 20 °C in the night-time with a 16-hour photoperiod until the appearance of the second pair of true leaves. Watering was carried out daily. The samples of leaves affected by rust (with uredinia) were placed in a humidity chamber for 24 hours to renew sporulation. Then the spores were washed off with a brush into distilled water. The amount (106 thousands) of urediniospores in the suspension was counted by using a Goryaev camera. Their optimal concentration for the affection of susceptible sunflower plants by 100 % should be 100 to 110 thousand pieces in 1 ml of water (Slyusar, 1981). The plants that formed the second pair of true leaves were sprayed with the prepared suspension and the boxes with them were placed in a humidity chamber at a temperature of 20-21 °C for 24 hours. Then they were returned to their previous conditions until the appearance of infection signs on the leaves. The incubation period was 9 days at 25 °C. After 9 days, the infection degree of differentiators was analyzed and classified as R (resistant) or S (susceptible) according to their response. The infectious type 3 or more was classified as a susceptible reaction on a 4-point scale proposed by E.E. Geshele (Geshele, 1971).

Results and discussion

There were identified a total of 160 rust pathogen isolates collected during the period of 2018-2020 in the Krasnodar, Saratov, and Rostov regions. Each tested *P. helianthi* isolate affected the differentiators susceptible to it with a degree higher than 3-4 points (Fig. 2).

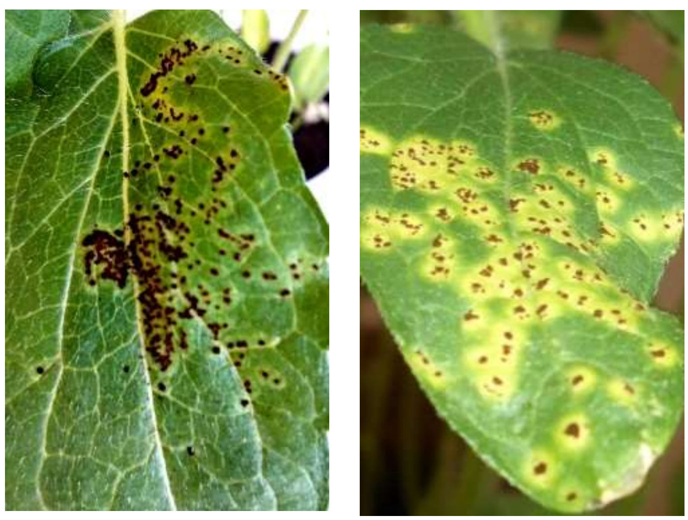

Figure 2. Uredopustules of *P. helianthi* isolate from the Rostovsky region with virulence code 700 on a leaves of differentiating line of sunflower resistance CM 90 (left) and CM 29 (right) (orig).

Among the isolates of the Saratov region collected in 2018, 5 races were identified, of which race 304 was detected for the first time. Races 300 and 700 were prevalent. Race 736 with the highest virulence code was found in a single sample (Fig. 3).

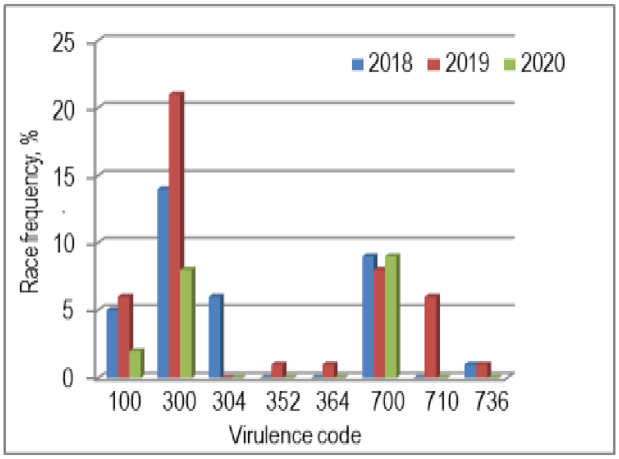

Figure 3. The distribution (%) of races of sunflower rust pathogen in isolate samples from the Saratov region, 2018-2020.

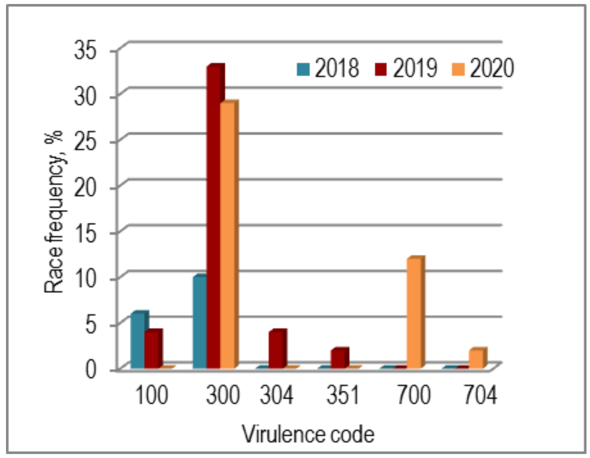

Figure 4. The distribution (%) of races of sunflower rust pathogen in isolate samples from the Krasnodar region, 2018-2020.

In the sample of isolates of 2019, a total of 7 races were identified, of which there were 3 new ones: 352, 364, and 710. Same as in the previous year, race 300 was prevalent, and race 736 was represented by one isolate. Races 700 and 300 dominated the sample of isolates of 2020. Two isolates represented race 100. The isolates collected in 2018 in the Krasnodar region were identified as races 100 and 300, with the prevalence of the latter (Fig. 4), while four races with the prevalence of race 300 as before represented the isolates of 2019. Races 100, 304, and 351 were represented by single isolates. Among these, race 351 was identified for the first time.
Among the isolates collected in the Krasnodar region in 2020, race 300 was also prevalent, but, for the first time in this region, there were identified races 700 and 704.
In the Rostov region, a strong affection of sunflower by rust occurred in 2020. In the sample of pathogen isolates collected there during this period from different sunflower genotypes, 7 races were identified, among which race 700 was prevalent (Fig. 5). For the first time in the Rostov region, there were identified races 740, 741, 745, 760, 762.

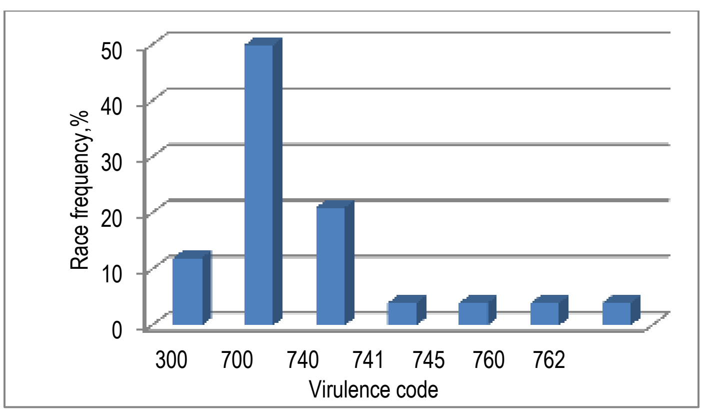

Figure 5. The distribution (%) of races of sunflower rust pathogen in isolate samples from the Rostov region in 2020.

In the combined sample of isolates from the indicated regions of the Russian Federation for 2018-2020, race 300 was prevalent (48 % of samples) (Table 1). Race 700 should also be noted (26 %). The small number of specimens of other races presented in Table 1 requires further monitoring of the frequency of their occurrence.

Table 1. The ratio of identified *P. helianthi* races among the isolates collected on sunflower in three regions of the Russian Federation in 2018-2020.

The fact that in the Russian Federation there are still races 100 and 300, identified in 1962 and 1981 of the last century (Sackston, 1962; Slyusar, 1981) can be explained by the wide cultivation of domestic varieties of both oil and confectionery sunflower in addition to hybrids of various origins. At the same time, the selection for rust resistance has not been carried out since 1983. As it is known, the physiological races of obligate parasites of agricultural crops disappear only with the removal from the cultivated range of crops of varieties and hybrids that feed them. Sunflower varieties that have not been bred for rust resistance can be called reserves for the preservation of old races of the pathogen in the Russian Federation.

In the last three decades, foreign-bred sunflower hybrids have been widely cultivated in the Russian Federation. It is logical to assume that the pathotypes of the rust pathogen in the Russian Federation will have the same triplet code as in other countries where a similar range of sunflower is grown. Thus, race 304 found in the Saratov and Krasnodar region was already present in several US states in 2011-2012 (Friskop et al., 2012). In the same period, races 700, 704, and 760 already existed not only in the United States but also in Argentina (Moreno et al., 2012). The identification of race 700 (26 % of the entire sample of isolates) in the three studied regions of the Russian Federation indicates the already significant prevalence of this pathotype in

the southern agrocenoses of Russia. In general, the racial identity of Russian isolates of the fungus is diverse, although the most virulent biotype 777 which was identified in the United States in 2008-2009 has not yet been found here.
The virulence diversity of *P. helianthi* isolates from the studied regions may be related to the growing intensification of sunflower cultivation with the widespread use of foreign-bred hybrids as sowing material, as well as with changes in climatic conditions. The races ratio in the total sample size may depend, in particular, on the number of isolates and varietal diversity of host plants from which the affected leaves were collected. The problem requires an elaborate approach to further study the ratio of rust pathogen pathotypes in the regions of the Russian Federation. Regular monitoring of the racial structure of the rust pathogen populations is required, both in the indicated regions of sunflower cultivation, and in others.

Conclusions

Thus, among the total studied sample of isolates of sunflower rust pathogen, collected in three regions of the Russian Federation in 2018-2020, we identified 17 races, races 300 (48 %) and 700 (26 %) prevailed. For the first time, there were identified 11 new pathotypes with the code numbers: 304, 351, 352, 364, 704, 736, 740, 741, 745, 760, 762.

Abstract

In order to obtain high and stable yields of tomato, one of the very important factors, is successful protection in the initial stage of the growing period against harmful insect species like Elateridae and *Gryllotalpa gryllotalpa*, which is achieved by insecticides application. The aim of the paper was to test the efficacy of insecticide tefluthrin in tomato protection against mentioned pests. The field trials were conducted in 2020 in the region of Vojvodina province at the localities Ruski Krstur (RK), Crvenka (C), Šajkaš (Š) and Budisava (B) on tomato crops, variety Amerikanac and Alparac, according to standard OEPP methods (PP 1/46; 1/152; 1/135). Insecticide based on tefluthrin (5 g a.s./kg, GR) at the rate of 12 and 15 kg/ha was applied, simultaneously with planting tomatoes. Plot size was 160 m^2 per variant and consisted of four replications. The effect of insecticide was derived based on the number of plants, from the four central rows, in the distance of 10m, as well as the number of damaged plants from Elateridae larvae and *G. gryllotalpa*. The first assessment was performed after 15 days of tomatoes planting. Efficacy (E%) of the insecticide was determined according to Abbott, while the significance of differences was evaluated by the LSD test (5%) by ANOVA. At the locality RK, insecticide treatment provided 18-27.9% higher number of plants in comparison to the control. The number of plants damaged by Elateridae and *G. gryllotalpa* was significantly reduced by insecticide use (1.5-5.3%) with regard to the control (18.9%). Efficacy of the tefluthrin was 71.9-92.1%, depending on the applied amount. Also, in the C locality, a significant reduction in the number of plants damaged by soil pests compared to the control (10.6%) was established after the use of tefluthrin (0.7-1.5%), while efficacy was in the range of 85.8-93%. At the locality Š, a significant reduction of the damaged plants percentage (0-1.5%) was registered compared to the control (8.5%), while 15 days after the treatment efficacy was in the range of 81.9-100%. A slightly lower reduction of damaged tomato plants was obtained by the use of tefluthrin in locality B where the efficiency was 72.8-83%, depending on the applied amount.

Key words: *tomato, Elateridae, Gryllotalpa gryllotalpa, tefluthrin.*

Introduction

Tomato (*Solanum lycopersicum* L.) represents one of the most common and economically important vegetables, grown in open fields and greenhouses. With an area of 20,000 ha (7% of total vegetable production) and a yield of 180,000 t, tomato is among the leading vegetable crops in the Republic of Serbia (SBS, 2018). However, average yields per hectare are low, and range around 9 t/ha. The reasons are not affected by the genetic potential of varieties and hybrids, but an inadequate and outdated growing technology, reduced and unsuitable application of mineral fertilizers and plant protection products (PPPs), as well as in unfavorable economic

circumstances (Takač et al., 2007). Application of chemical pesticides still takes the leading place in tomato protection. Intensive vegetable production with high yields is hardly sustainable without the use of pesticides. Pesticides should be used in a targeted manner, in order to control one or a group of pests, when other possible measurements have been exploited and when there is a threat of economically significant damage. In previous years, a large number of soil insecticides based on various active substances (methiocarb, chlorpyrifos, chlorpyrifos + imidacloprid, zeta-cypermethrin) were registered in the Republic of Serbia. However, after the ban of some of them, currently for the control of soil pests in vegetables, including tomato, insecticides based on tefluthrin and zeta-cypermethrin are used, with the remark that the use of zeta-cypermethrin is prohibited starting November 2021. The most destructive soil pests for tomatoes include *Gryllotalpa gryllotalpa* L. and larvae from the fam. Elateridae and Scarabeidae. European mole cricket (*G. gryllotalpa* L.) is an insect with high polyphagia which is harmful to many types of vegetables, as well to certain root crops. Also, larvae fam. Elateridae (beetles, wireworms) are one of the most important soil, polyphagous pests in agriculture. Elateridae are widespread in this region, so knowing their life cycle and adequate control is key to the survival of numerous crops. Mature larvae cause the greatest damage during hot and dry weather. The presence of wireworms is recognized by the perforated or completely bitten plants, which wither and dry. White grubs, larvae belonging to the Scarabaeidae family, periodically (every 2-3 years) attack the underground organs of tomatoes and endanger the survival of the entire plant by feeding on the roots. Other pests of tomatoes that damage the aboveground parts of tomatoes include: cotton bollworm (*Helicoverpa armigera* Hübn.), Aphids (Aphididae), tomato leafminer (*Tuta absoluta* Meyrick) and southern green stink bug (*Nezara viridula* L.) (Kereši et al., 2018).
The aim of this study was to test the effects of tefluthrin-based insecticides (5 g a.s./kg GR) for the control of soil pests under field production at four different localities, according to standard OEPP methods, as well as to determine the effectiveness of the mentioned insecticide in controlling the beetle larvae (*Agriotes* spp, Elateridae) and European mole cricket (*Gryllotalpa gryllotalpa*) in tomato.

Material and Methods

The experiments were conducted in the Vojvodina Autonomous Province (Serbia) at the four localities: Ruski Krstur, Crvenka, Šajkaš and Budisava, and were set up according to standard OEPP methods for the experimental design and data analysis (Anonimus, 2012), for the efficacy of insecticides in soil pest control (Anonimus, 2004) and for the phytotoxicity of the tested pesticides (Anonimus, 2014). The experiment was performed in 4 replications, while the type of experiment was a completely random block system. The size of the plot was 35 m² (6 rows x 0.7 x 10 m), the distance between the plants in the row was 30 cm. The application of insecticides was performed simultaneously with the planting: in Ruski Krstur and Crvenka, the planting was done on May 29, 2020., and in Šajkaš and Budisava on 05.06.2020. The PPP based on teflutrin (5 g a.s./kg GR) was applied in the amount of 12-15 kg/ha, by manual scattering of granules in previously made furrows, and immediately after that, the planting of tomatoes (American and Alparac variety) was done manually, followed by furrows burring. One assessment of the effects was performed in all tested localities, considering that the production of tomatoes was from seedlings, not from sowing. The assessment was performed 13, 15 and 16 days after planting, depending on the locality. The total number of plants was monitored, as well as the number of damaged plants from pests in the soil, in four central rows 10 m long. Standard deviation (Sd+), the significance of differences (LSD 5%) (ANOVA), relative values in relation to control (K=100%), and efficacy according to Abott were determined (Wentzel, 1963).

Results and Discussion

The results on the influence of teflutrin - based pesticide on the average number of plants per 10 m in length, as well as the number of damaged plants and the efficiency of insecticides at the tested localities are given in Tables 1-3. At the locality of R. Krstur, the average number of tomato plants per 10 m ranged from 25.8 to 33 (Table 1) in all examined variants. Regardless of the applied amount, the test plant protection product provided a significantly higher number of plants from 18.2 to 27.9% (Table 2) compared to the control. A significant reduction in the number of damaged plants from click beetles larvae and mole cricket compared to the control was found when using teflutrin in both tested amounts (Table 3). The efficiency of the tested insecticide ranged 71.9-92.1, depending on the applied amount. The average number of tomato plants at the locality Crvenka ranged from 29.0 to 33.8 in all tested variants (Table 1). The tested insecticide provided from 12.1 to 16.5% (Table 2) a higher number of plants compared to the control regardless of the amount applied. The insecticide tefluthrin applied in the recommended amounts provided a significant reduction in the number of damaged plants from click beetles larvae and mole cricket compared to the control (Table 3). The efficacy of the tested insecticide ranged from 85.8-93%.

Table 1. Average number of tomato plants per 10 m

control	100.0	100.0	100.0	100.0

K 100% - relative value compared to control.

In the field at the Šajkaš locality, the average number of tomato plants per 10 m in length ranged from 30-33.2 (Table 1). Regardless of the amount applied, the tested PPP provided from 6.7 to 10.6% (Table 2) a higher number of plants compared to the control. After the application of tefluthrin, the number of damaged plants from the larvae of the click beetle (Agriotes spp.) and the mole cricket was significantly lower compared to the control (Table 3). The efficacy of the tested insecticide ranged from 81.9 to 100%, depending on the applied amount. The average number of tomato plants at the Budisava locality ranged from 28.8 to 32.3 in all tested variants (Table 1). Regardless of the amount applied, the tested insecticide provided from 6.9 to 12.2% (Table 2) a higher number of plants compared to the control. Also in the Budisava locality as in the previous localities, the applied insecticide provided a significant reduction in the number of damaged plants from the larvae of the click beetle and the mole cricket compared to the control (Table 3).

$\bar{x}$ – average number; +Sd - standard deviation; E %- efficacy.

The application of tefluthrin-based PPP in amounts of 12 and 15 kg/ha in the localities R. Krstur, Crvenka, Šajkaš, and Budisava did not cause phytotoxicity, nor changes were registered in the form of deformations or leaf color on tomato plants of the American and Alparac varieties. Based on the available literature, there are no data on the occurrence of soil pest resistance to tefluthrin. However, in insect populations that are intensively controlled with insecticides based on tefluthrin or other insecticides from the group of pyrethroids, a change in sensitivity is possible, therefore the management of the anti-resistance strategy should be followed. Based on the study of Van Herk et al. (2008), larvae of *Agriotes obscurus* and *Limonius canus* were exposed to wheat seeds previously treated with insecticides based on imidacloprid and tefluthrin. Most larvae (> 80%) came into contact with seeds in both treatments. Teflutrin in contact with larvae (after <20 min) in all variants exhibited a repellent effect unless the larvae had previously died. Wireworm mortality was low in both variants (<50%). Hall (2003) conducted a biological test to assess the effects of tefluthrin and bifenthrin-based insecticides with the aim of controling *Melanotus communis* (Gillenhal). The tested insecticides significantly reduced the damage to the plants, which is in accordance with our study. The effect was primarily reflected as the repellent activity to wireworms of the tested PPP.

Conclusions

Based on the conducted study and the achieved results on the efficacy of product based on tefluthrin in tomato under field production with the aim of controlling the larvae of *Agriotes* spp., Elateridae and *G. gryllotalpa*, the following conclusion can be drawn:

- At the locality of Ruski Krstur, 15 days after planting, the product based on tefluthrin showed satisfactory efficacy (71.9-92.1%) and provided a significant increase in the number of plants from 18.2 to 27.9% compared to the control.
- At the Crvenka locality, 16 days after planting, the tested insecticide showed an efficiency of 85.9 to 93%, depending on the applied amount, and also provided a significant increase (12.1 - 16.5%) in the number of plants compared to the control.
- Thirteen days after planting and application of insecticides at the Šajkaš locality, tefluthrin showed high efficacy of 81.9-100%, and provided 6.7 to 10.6% more plants compared to the control.
- At the Budisava locality, 13 days after planting tomatoes and applying insecticides, efficacy ranged 72.8-83%. More plants (6.9 to 12.2%) were found compared to the control.

The insecticide tefluthrin, at all localities, provided satisfactory protection of tomato crops against the larvae of the click beetle (*Agriotes* spp., Elateridae) and the mole cricket (*G. gryllotalpa*).

Abstract

Plant protection measures, including control of weeds, are significant part of production cost. The average annual growth of pesticides world market, during the period from 2010 to 2019, had showed 2.8 % rise , its volume reached in 2019 – 55,650.00 million dollars without VAT, while the Russian market showed an increase of more than three times -10.8 %, the market volume in 2019 was 2081.00 million dollars without VAT. The continuous use of herbicides negatively affects both the economic efficiency for agricultural crops cultivation and the environmental situation. The use of differentiated plant protection technologies, in terms of herbicides application may increase the efficiency of agricultural enterprises, as well as reduce the pesticide pressure on the environment. The research work was carried out on the experimental farm of Perm Agricultural Research Institute – division of Perm Federal Research Center. The experimental plots located on heavy loamy sod-podzolic soil. The object of research was winter wheat, variety "Skipetr". The study showed the effectiveness of differentiated application of herbicides on winter wheat in the Ural region, using the in offline mode. The grain yield reached 5.63 t ha -1 after differentiated application versus 5.10 t ha -1 with conventional technique, and 4.22 t ha -1 at the control. The herbicide pressure on cultivated areas was reduced by 46 % in average, and the economic efficiency of production increased by 40 % compared to areas where overall treatment was carried out with average recommended herbicide doses.

Keywords: *differentiated plant protection, herbicide, winter wheat, precision farming, task map.*

Introduction

Production of grain crops is traditionally the basic branch of agriculture in Russian Federation. Since 2015, the annual rise of grain production in Russia has increased by 15.1 %, in average and the record harvest in 2017 was 131.3 million tons. (ROSBIZNESKONSALTING, 2021) Winter wheat cultivation promoted the most of the gross yield. With production growth, the increase in the production costs also take place. One of the significant cost items of production is the organization of plant protection system, which includes herbicidal treatment of weeds. The average annual growth of the world market of pesticides, in the period from 2010 to 2019, showed 2.8 % rise, its volume reached – 55,650.00 million dollars without VAT in 2019, while the Russian market showed an increase of more than three times-10.8 %, the market volume for 2019 was-2081.00 million dollars without VAT. (Danilov, 2020)

In the conditions of modern agriculture, an urgent task is to increase the economic efficiency of production. Conventional technologies for the use of pesticides and agrochemicals, reckon for the application of the same dose over the field unit, without taking into account the density and level of distribution of pests, diseases, weeds and cultivated plants in its individual elementary areas (Gafurov e*t al.*, 2012).

One of the underestimated ways to reduce costs, as well as to increase environmental safety, is the use of differentiated plant protection (DPP) technologies. DPP is the technique based on the discretization of a biological object, comprehensive analysis of economic harmfulness threshold of negative factor with further decision about the impact on a discrete part of a biological object.

Differentiated application of herbicides in fields with heterogeneous weed infestation reduces herbicide consumption by 30-60 %, increases their payback by 1.3-1.7 times, and reduces the anthropogenic load on the environment. (Shpaar e*t al*., 2003; Gur'yanov and Artem'ev, 2018; Takács-György and Takács, 2009)

The purpose of the study is to evaluate the effectiveness of the technology of herbicides differentiated application on winter wheat using the offline task map.

Materials and Methods

Studies were conducted in 2020 on the basis of the Perm Agricultural Research Institute - the division of Perm Federal Research Center of Ural Branch of RAS, located in Perm Region in Russian Federation. Location of the experiment site: 57°50 '13.8" N 56°18'39.5" E (Fig. 1) The soil of the experimental site is sod-podzolic heavy loam, with following parameters: humus content in the upper soil layer 1.9 %, pH_{KCl}-5.0-5.2, P_2O_5-176-203, K_20-160-169 milligrams per 1000 g of the soil.

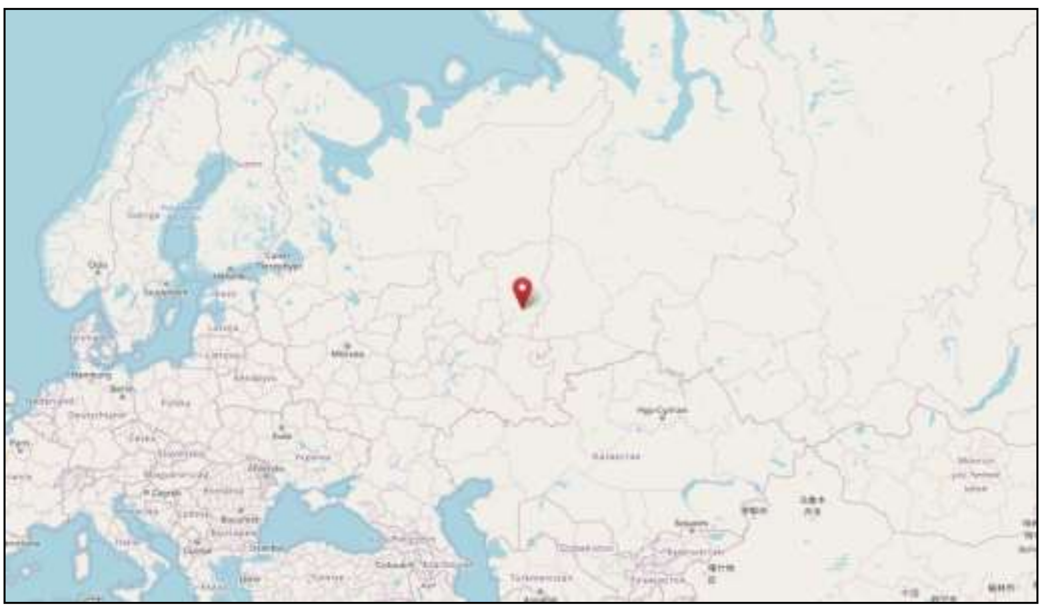

Figure 1. Location of the experiment site.

The technology of crops cultivation is generally accepted for the zone with the exception for studied questions. The predecessor was barley. Phosphorus and potassium fertilizers ($P_{60}K_{60}$) were used in autumn for pre-sowing cultivation, nitrogen fertilizer (urea) – split application (N_{30} before sowing cultivation, N_{30} - in spring as top dressing). The object of research is winter wheat *Triticum aestivum L*., cultivar "Skipetr". The seeding rate is 6 million of viable seeds per hectar. The sowing was carried out by a mechanical grain drill –John Deere 455. The sowing time was 1.09.2019.

Winter wheat "Skipetr" is characterized as a highly adaptive variety of universal type with high frost resistance. It is resistant to lodging on soils with low and medium level of fertility; the plant height is 84-96 cm, it overwinters perfectly in the phase of sprouts and seedlings. This cultivar has a very intense spring regrowth. It is also resistant to spring frosts (up to -12^{o}C).
The application of herbicides was carried out with an OP-2500 sprayer of the ARGO series with on-board computer "Bars 5" set on GAZ-66 vehicle (Fig. 3). The applied herbicide –
"Lintur" - (water-dispersible granules 0,165 kilogram per hectare (dicamba and triasulfuron)".

Figure 3. OP-2500 sprayer based on GAZ-66 vehicle

Experimental design:
1. Control, without herbicides.
2. Water treatment
3. "Lintur" overall application
4. "Lintur" differentiated application, using the task map.

Treatment placing was systematic, each treatment had three replications on the field, The area of each plot was 2.76 hectares, with 48 meters width. The total area of the experiment was 33.18 hectares.
For the purpose of precise positioning the sprayer machine on the ground the digital duplicate of real experimental field was created, where the experimental plots were showed (Fig. 4).

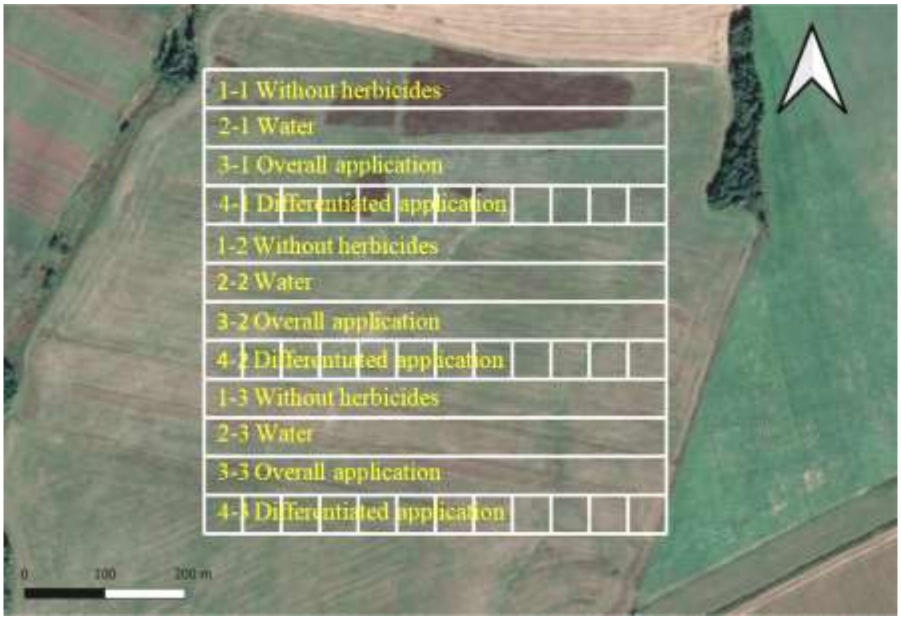

Figure 4. The diagram of the experiment options on the digital duplicate of the field.

Plots for herbicide differentiated application were additionally divided into 12 subplots, 48x48 meters each, where the weed infestation of crops was taken into account according to the numerical method for determining weed vegetation, by a continuous examination of crops and counting weeds on the calculated sites (1x1 meters). The number (A) of weed plants was calculated using the formula (1):

$$\mathrm{A} = \frac{\mathrm{a}}{S}, \qquad (1)$$

where: a - is the number of weeds encountered; S is the total registered area, m2. (Kamenskih and Samofalova, 2012; Fetyuhin e*t al.*, 2018). Analysis of the species composition of weeds was also fulfilled according Atlas of weeds (Syngenta, 2011).

Results and discussion

The weather conditions during the experiment time were following: the average daily air temperature in period "sowing – full sprouts" was 12.6^{o}C (average over the last 70 years temperature 12.5^{o}C); during tillering – 3.8 (multiyear average 11^{o}C), precipitation sum - 14 mm (multiyear average 35.2 mm) (Fig. 2). By the time of low temperatures, the plants reached the tillering phase.

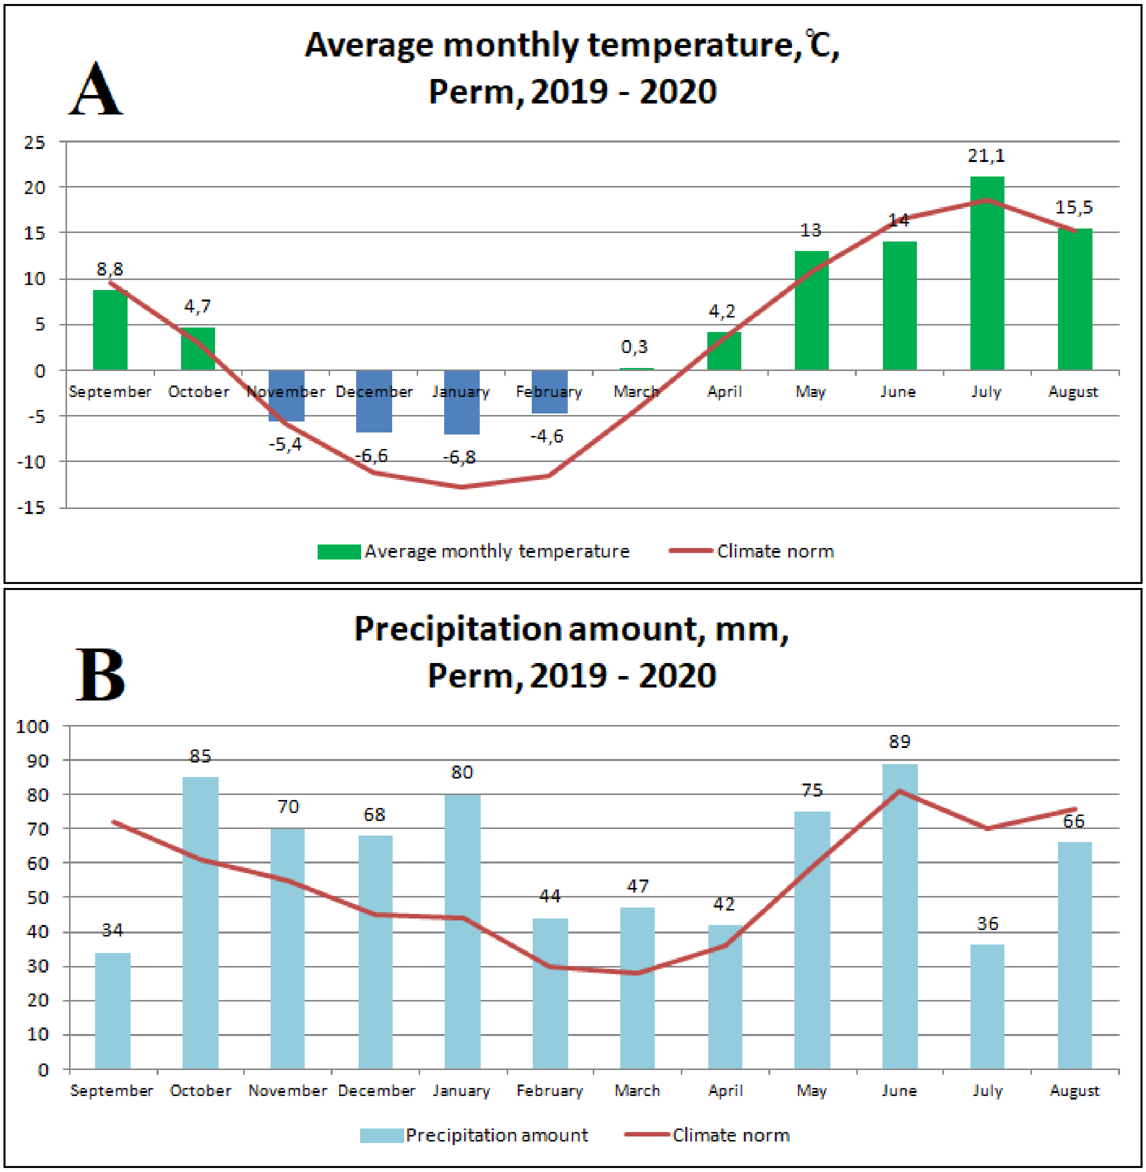

Figure 2. Agro-climatic conditions of the period 2019-2020,
A. average monthly temperature. B. precipitation amount

In the winter period of 2019-2020, the height of the snow cover reached 77 cm. The smelting of snow cover was noted in the first half of the April's decade - two weeks earlier compared with than with multiyear average.

May was characterized by unstable weather. An excess of the multiyear average emperature by 6 °C was observed in the first decade with new absolute maximum 28.2°C .The previous one was 27.7°C and was noted in 1962. In the second decade the decrease by -1...0°C was observed. The average air temperature for the month was 13°C, which is 2.3°C above the multiyear average. Precipitation sum was 127 % of the multiyear average sum. Most of it (65 mm) was noted in the third decade of May.

The summer of 2020 was generally characterized by air temperatures close to usual, with moderate precipitation deficiency. The average temperature of the summer season was higher compared with the multiyear average and 2017-2019 years. In the period from June 6 to June 11 extremely hot weather was observed with average daily temperatures within 19-24°C, that was 4-8°C higher than usual. The second and third decades were cold. The average monthly air temperature in June was 14.1°C, that was 2.5°C below the multiyear average. Precipitation sum for month was 89 mm that was slightly more compared with usual (110 %).

July was characterized by stable weather. The average monthly air temperature was 21.2°C, higher than the multiyear average by 3.1°C. Precipitation sum for the month was 36 mm – two times less compared with usual. The formation of the crop took place under conditions of increased heat and reduced moisture availability. The duration of the growing season was 342 days.

The qualitative and quantitative estimation of weeds on plots destined for differentiated application of herbicide (4-1, 4-2, 4-3), included the determination of weeds species, as well as the economic limit of harmfulness was calculated for the reasoned use of pesticides. After analyzing the results, a task map for the sprayer machine was created.

Analysis of the species composition of weeds in winter wheat crops showed that the most common were:

– dicotyledonous perennial weeds-*Convolvulus arvensis L., Taraxacum officinale Wigg*.), *Vicia cracca L*., (*Sonchus arvensis L*.);

– annual weeds-*Matricaria recutita L.,Chenopodium album L., Capsella bursa-pastoris L., Equisetum arvense L., Galeopsis tetrahit L., Viola arvensis Murr., Galium aparine L., Thlaspi arvense L., Stellaria media L., Geránium pretense.*

The share of perennials in total number of weeds was 9 %, annuals - 91 % (Fig. 5). The average indicator of weed infestation of winter wheat crops in the studied plots was 25 pcs/m^2.

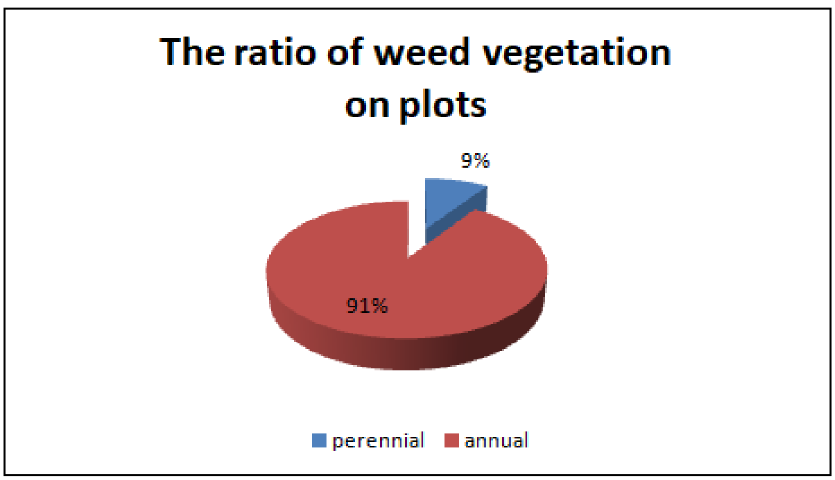

Figure 5. The ratio of weed vegetation on experimental plots.

After analyzing the weed species composition and studying the experience of using herbicides on winter grain crops (Mehmeti et al., 2018; Dvoreckij at al., 2012; Nikiforov et al., 2018), the most effective herbicide was selected - "Lintur, water-dispersible granules". Usual consumption rate of this herbicide is 0.15-0.18 kilogram per hectare, the spray liquid rate is 200-300 litres per hectare.

"Lintur, water-dispersible granules" has two active ingredients: dicamba and triasulfuron. Dicamba is a growth regulator, and triasulfuron inhibits the synthesis of essential amino acids. Both active components penetrate into plant through the root system and leaves.. The result of treatment is stunting, yellowing and necrosis of leaves and stems, with subsequent death of weeds. Symptoms appear on the 5th-7th day, and death occurs 2-3 weeks after treatment, depending on the type of weed and weather conditions. (Syngenta, 2019)

Analyzing the task map shows that the average treated area in the treatment with differentiated herbicide application was 1.46 hectares that was 46% less compared with the area of variant with overall application by the average recommended dose of the herbicide.

The economic assessment of herbicides consists from comparing the treatment cost and profit from the saved harvest. For grain crops, the income is determined only by the cost of saved crop. Herbicides prices, transportation and treatment expenses, staff salaries are taken into account in the consumable part of the assessment (Grin'ko, 2018).

Economic calculations carried out on the basis of the obtained biological crop yield of winter wheat demonstrated that with the herbicide differentiated application the profitability of the production of winter wheat "Skipetr" increased by 40% compared with the overall method. (Table 1)

Table 1. Economic efficiency of winter wheat cultivation.

Variant/ Name of indicator	**Biological crop yield ton per hectare**	**Costs per 1 hectare**	**Costs per 1 ton**	**Cost in rubles**	**Profit in rubles**	**Profitability %**
1.Control	4,22	33105,00	784,00	37600,00	4495,00	14
2.Water treatment	4,13	33066,00	801,00	36798,00	3732,00	11
3. Lintur, overall application, ,	5,1	35864,00	703,00	45441,00	9577,00	27
4. Lintur, differentiated application,	5,63	36293,00	645,00	50163,00	13870,00	38
LSD_{05}	0,31					

Conclusion

The results of fulfilled research work aimed to elaboration the technology of herbicides differentiated application on winter wheat in «offline» regime using the task map in mode allow us to make the following conclusions. Herbicides differentiated application provided the profitability rise by 40 % compared with the overall introduction with average recommended dose of herbicide. The herbicide load on the cultivated area was significantly reduced, including the herbicide consumption was reduced by 46 %. However, it is impossible to say with full confidence that these results will be applicable to other areas of winter wheat cultivation, since the species composition of weed vegetation is different. The research work requires further continuation.

Abstract

Many reactions between O_2 and phenolic compounds or ascorbic acid in the wine induce an rapidly rate of consumption of O_2. If concentration of sulfur dioxide is sufficiently high in wine, the reaction products of O_2 and the wine components are mostly avoided. The impact of addition $K_2S_2O_5$ and ascorbic acid to phenolic composition in wine was investigated. Analysis of Cabernet Sauvignon wine was made by classical vinification and maceration (21 days) inoculated with pure yeast strain *Saccharomyces cerevisiae* (BDX, Lallemand, Canada). After six months of storage, in different samples of experimental wine increasing contents of $K_2S_2O_5$ (3g/hl, 5g/hl and 7g/hl) and ascorbic acid in concentration 200mg/lwere added. Control sample without any addition was the same for both of experiments. Phenolic acids in wines wereanalyzed by UPLC H-Class System.Thestatistically significant difference between control and wine samples added by 5 and 7g/hl of $K_2S_2O_5$for derivates of benzoic acidwas observed. Addition of $K_2S_2O_5$in all of added concentrations did not significantly changed content of derivates of cinnamic acids. SO_2 has an excellent abilitystabilise hydroxycinnamic acid polyphenols such as caffeic acid when exposed to conditions of oxidation. Influence of ascorbic acid wasnot statistically significant for content of benzoic and cinnamic acidsderivatesin wine. Among phenolic acids the most susceptible to oxidation are those containing an ortho-diphenol functional group, including caffeic acid and its derivatives and compounds with a triphenol group such as gallic acid.

Keywords: *Sulfur dioxide, Ascorbic acid, Phenolic compounds, Red wine.*

Introduction

Sulfur dioxide (SO_2) has been used for centuries by winemakers as a preservative due to its antimicrobial and antioxidant properties (Waterhouse, 2016). The central role of oxygen in the process of wine maturation has been long known. In recent years, a number of studies have described the influence of oxygen exposure on wine chemical and sensory characteristics, including changes of wine aroma, color and mouthfeel (Ferreira et al., 2015). Even in wines without SO_2 additions, low amounts of total SO_2 (typically 10–20 mg/L) are present at the end of alcoholic fermentation as a result of SO_2 formation during amino acid biosynthesis. However, in most wines, the majority of SO_2 is added exogenously either before or after fermentation, often in the form of potassium metabisulfite ($K_2S_2O_5$) or as SO_2 gas. Free bisulfite can be lost following wine oxidation, either by reaction with H_2O_2 or by forming adducts with acetaldehyde or other electrophiles. SO_2 adduct formation is reversible and thus formation and dissociation reactions are happening continuously (Waterhouse, 2016). The mechanisms of wine antioxidant

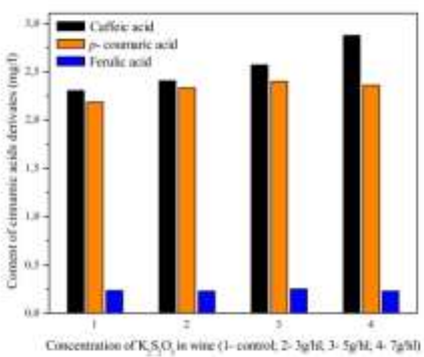
protection by SO_2 does not involve direct reaction with oxygen as long believed, but involves reaction with the quinones and hydrogen peroxide avoiding the generation of harmful hydroxyl radicals(Ferreira et al., 2015). The initial steps of oxygen consumption requires the presence of transition metal catalysts and good hydrogen donor molecules, particularly Fe(II) and *o*-diphenols. Indirect oxidation of *o*-diphenol (along with transition metals such as Cu or Fe) produces quinones and H_2O_2. Quinones are strong electrophiles that will then react with bisulfites and thus stop oxidation. If there was not enough bisulfite in the wine to bind the formed H_2O_2, Fe (II) -catalyzed Fenton reactions occurred which form aldehydes and other oxidized forms that can damage wine quality (Waterhouse, 2016). The oxidation of ascorbic acid generates dehydroascorbic acid and hydrogen peroxide. While hydrogen peroxide can lead to damaging spoilage reactions, especially in the presence of metal ions, dehydroascorbic acid is an unstable compound and is known to degrade into a wide range of products. Presence of sulfur dioxide is critical to ensure efficient scavenging of hydrogen peroxide and sulfur dioxide is recommended for use as a complementary antioxidant when utilising ascorbic acid especially in white wines (Barril et al., 2012).
Polyphenols also cannot react directly with oxygen in its normal triplet state. It is therefore proposed that transition metals, such as Fe and Cu, also play a key role in oxidative processes involving wine polyphenols. Phenols form complexes with metal ions such as Fe(III) and electron transfer occurs within the complex to reduce iron to the ferrous state and to oxidize the phenol to the semiquinone and than quinone. During that process oxygen is converted to hydrogen peroxide, which in the presence of Fe or Cu produce hydroxyl radicals. As mentioned above an action of SO_2 is to scavenge hydrogen peroxide, so preventing its destructive effect. Of the polyphenols found in wine, those containing a catechol system are the most readily oxidized, (Danilewich et al., 2007).
The combined use of ascorbic acid and sulfur dioxide therefore requires considerable care as oxidation of ascorbic acid leads to a loss of sulfur dioxide that, in turn, leads to a reduction in the main anti-microbial component. Ascorbic acid can act as a pro-oxidant leading to elevated levels of oxidative spoilage, even in the presence of sulfur dioxide (Bradshaw et. al., 2004). According to Bradshaw et. al. (2004) addition of ascorbic acid to a wine-like system resulted in an increased rate of browning of (+)-catechin, the oxidisable polyphenolic compound used in the wine model system.
The main focus of this paper is to investigate influence of addition $K_2S_2O_5$ and ascorbic acid to wine phenolic composition specifically benzoic and cinnamic acids derivates.

Material and Methods

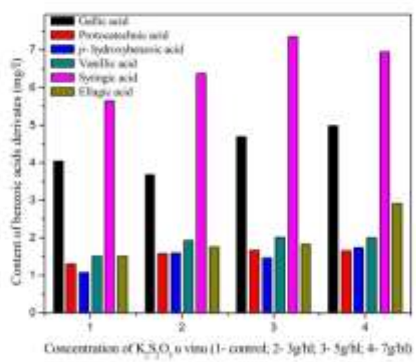
The experiments were performed in laboratory conditions on volume of 200 ml of wine, that was produced in winery on the experimental field of Agriculture faculty, Radmilovac in Belgrade. Vinification with maceration lasted 21 days with EXV enzyme preparation (Lallemand, Canada) and inoculation with wine selected yeast BDX (Lallemand, Canada) and punching down twice a day. During the destemming and crashing grapes, the must was sulphited with 10 g of $K_2S_2O_5$ per 100 kg of must. During wine maturation the level of free SO_2 was about 30mg/l. In this research that wine was control sample which was compared with same wine with addition of increasing concentrations of $K_2S_2O_5$ (3g/hl, 5g/hl and 7g/hl). Other part of experiment was related with addition of 200mg/l in same produced wine. Before addition of ascorbic acid, lever of free SO_2 was adjusted to 30 mg/l.

Results and Discussion

The statistically significant difference between control and wine samples added by 5 and 7g/hl of $K_2S_2O_5$ for derivates of benzoic acid was observed. Addition of $K_2S_2O_5$ in all of added concentrations did not significantly changed content of derivates of cinnamic acids ($p \geq 0,05$). According to Gabriele et al. (2018), the largest increase of caffeic acid was observed passing from the intermediate sulfur dioxide values to higher values, up to 150mg/l that is in agreement with our results where caffeic acid in sample with the highest SO_2 content has the highest value (2,87mg/l). In most cases, moving from 0 to 50 mg/L SO_2, which is a relatively low level of sulfur dioxide, the increase in concentration of the antioxidant compounds is less pronounced (Gabriele et al., 2018). In Merlot wine samples with addition 50, 100 i 200 mg/l SO_2 did not noticed significant difference for caffeic acid comparing with control (Tao et al., 2007). In our samples there was a slight increase in the content of ferulic and *p*-coumaric acid starting from wine with 30 mg/l SO_2 to wine with 50 mg/l SO_2. In the literature, it was found that the concentration of *p*-coumaric and ferulic acid is slightly higher in wines with a content of about 50 mg/l than in wines without added SO_2 (Garaguso and Nardini, 2015). Syringic acid concentrations as well as other benzoic acid derivatives increased with increasing SO_2 concentrations ($p \leq 0,05$). A higher concentration of syringic acid and gallic acid was found in wines with 50 mg/l than in wines that do not contain SO_2 (Garaguso and Nardini, 2015; Pateraki et al., 2014).

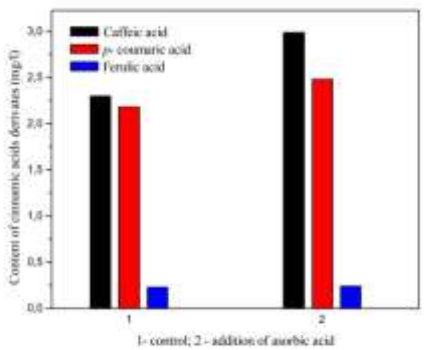


Graph 1. Impact of addition $K_2S_2O_5$ on cinnamic acids derivates.

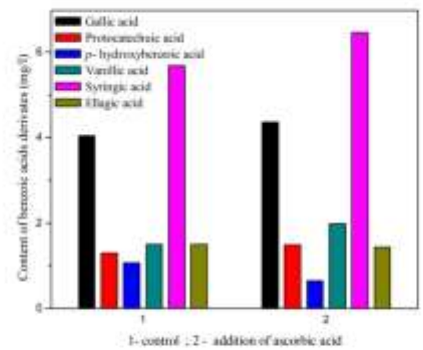


Graph 2. Impact of addition $K_2S_2O_5$ on benzoic acids derivates.

Influence of ascorbic acid was not statistically significant for content of benzoic and cinnamic acids derivates in our wines. It is assumed that the content of phenolic acids in wine samples with added ascorbic acid did not change significantly due to the presence of free SO_2, which at the beginning of the experiment in wine was ajust to 30 mg/l. According to Makhotkina and Kilmartin (2009), in a cyclic voltammetric study of wine antioxidants, it was concluded that ascorbic acid is negligible in terms of *o*-quinone reduction compared to SO_2 and glutathione. Caffeic acid quinones reacted with SO_2 the fastest compared to other quinones formed (Makhotkina and Kilmartin, 2009) and and so it can be explained unchanged or even a slight increase in the concentration of caffeic acid and other cinnamic acid derivates (*p*-coumaric acid and ferulic acid) in our wine samples where ascorbic acid and SO_2 were added. Among the benzoic acid derivates the most dominant were gallic and syringic acids in control as well as in experimental wine with ascorbic acid.



Graph 3. Impact of addition ascorbic acid on cinnamic acids derivates.



Graph 4. Impact of addition ascorbic acid on benzoic acids derivates.

Conclusion

Sulfur dioxide and ascorbic acid are all excellent reducing agents that are capable of interacting with polyphenol oxidation products. From the our results it may be concluded that sulfur dioxide in higher concentrations can readily protect phenolic acidsagainst oxidation. Addition of ascorbic acid in concentration 200mg/l did not show significant changes of cinnamic and benzoic acids derivates comparing with control sample.

Abstract

Tomato leaf miner, *Tuta absoluta* (Meyrick,1917) (Lepidoptera, Gelechiidae), a highly devastating and invasive pest attacking tomatoes either in greenhouses or in open fields, is currently spreading throughout many countries in the world. However, it may be controlled by various measures, some of which involve cultural practices such as Integrated Pest Management (IPM) and others include the use of chemicals and other synthetic products such as pheromones. In this study, toxicity and repellent effect of essential oils (safflower, lavender, sage, clove) were tested on the third and fourth larval stages of *T. obsoluta* under laboratory conditions. Three different concentrations (1%, 3%, 5%) were used for treatments. Effects of essential oils were studied using contact method. Pure water and alcohol mixture were used in the control trials. Counts were recorded as dead and live larvae at 24th, 48th, and 72nd hours after application. The experiment was carried out in three replications. The most notable result of this study was that mortality effect (100%) of safflower and clove oil on larvae at concentrations of 5%. The other essential oils had a little larvicidal effect. At the 5 ml doses, the highest mortality rate was observed at 72nd hours. Lavender oil has a 30-35% mortality rate on tomato larvae as well as a repellent effect on the larvae. However, the effect of oils should also be studied on the natural enemies of *T. absoluta*.

Keywords: *Alternative control, essential oil, tomato, Tomato leaf miner, toxicity.*

Introduction

The main pest on tomatoes is the tomato leaf miner *Tuta absoluta* (Meyrick, 1917) (Lepidoptera: Gelechiidae) originating from South America (Garcia and Espul, 1982). This pest entered Europe from the east part of Spain, at the end of 2006 (Urbaneja *et al*., 2007). It spread to other Mediterranean and European countries [Potting,2009] and it has been reported in Greece (EPPO, 2011). It was first detected in 2009 in Turkey (EPPO, 2010a, Kılıç, 2010) and caused significant economic losses in product quality and quantity, after it was spread rapidly in tomato fields, in the recent years.

The main host plant of *T. absoluta* is tomato (*Lycopersicon esculentum*), but there has also been reported several solanaceous plants, including *Solanum nigrum*, *Datura stramonium* (Garcia and Espul,1982), eggplant (*Solanum melongena*), pepper (*Capsicum annuum*) (Desneux *et al*., 2010) and potato crops as well (Pereyra and Sánchez, 2006). It has been high potential damage in tomato fields under favorable climatic conditions (EPPO, 2005).

One of the possible pathways for severe spreading of tomato leaf miner should be dependent on fruit importation and commercialization (Potting, 2009). This pest is transmitted over long distances with packages from countries contaminated with pests (EPPO, 2010b).

Struggle is not done in cases where the yield loss reaches 80-100% (Desneux *et al*., 2010). Different pest control methods (physical, culturel, trapping with pheromone and light traps, biological control, chemical or microbiological treatments) were applied (Desneux *et al*., 2010). Chemical control success rate decreases due to the endophytic behavior of the larvae and the rapid selection of resistant populations (Siqueira *et al*., 2000; Campos *et al*., 2015; Lietti *et al*., 2005, Silva *et al*., 2015; Roditakis *et al*., 2015). Chemical application methods were both harmful to the environment and very expensive.

As an alternative control method to pests, performing the studies on the effect of plant extracts, which has low risk of pest resistance development, is important in the sense of environmental and human health as well as the national economy. The number of studies on the effects of plant extracts on *T. absoluta* has been started to increase, recently (Gonçalves-Gervásio and Vendramim, 2004; Durmuşoğlu *et al*., 2011; Şenel, 2013; Adil *et al*., 2015; Bayındır *et al*., 2015; Chegini *et al*., 2017). Some essential oil showed oviposition deterrent and insecticidal activity on *T. absoluta* (Derbalah *et al*., 2012; Hussein *et al*., 2015; Campolo *et al*., 2017; Chegini and Abbasipour, 2017; Yarou *et al*., 2017). Otherwise, essential aromatic oils were used against pests seen in many plants. However, Gorski and Tomczak (2010) used citronella oil, basil oil, juniper oil, patchouli oil and eucalyptus oil in the control of *Aulacorthum solani* Kalt. on eggplant. Adverse effects of *Junglans regia, Juniperus excelsa*, *J. oxycedrus*, *Pimpinella anisum*, *Rosmarinus officinalis*, *Foeniculum vulgare* and *Laurus nobilis* essential oils were showed on the reproduction ability of cabbage aphid, *Brevicoryne brassicae* L. (Hemiptera:Aphididae) (Işık and Görür, 2009). Many essential oils from different plants such as lemon grass (*Cimbopogon winteriana*), rosemary (*Rosemarinus officinalis*), *Eulcalyptus globulus, Thymus vulgaris, Vetiveria zizanoides* and clove (*Eugenia caryophyllus*) are known for their pest control (Hussein *et al*., 2015).

For its insecticidal and repellent activities against many pests, clove essential oil has been widely studied, such as fire ants (Appel *et al*., 2004), *Diaphorina citri* (Mann *et al*., 2010), mosquitoes (Sutthanont *et al*., 2010), termites (Pandey *et al*., 2012), cockroaches (Omara *et al*., 2013), moths (Birah *et al*., 2010), weevils (Mishra *et al*., 2013) and *Cacopsylla chinensis* (Yang and Li) (Hemiptera: Psyllidae) (Tian *et al*., 2015).

For the reasons mentioned above, the study aimed to find out the effect of four different essential oils (safflower, lavender, sage and clove) on the larvae of *T. absoluta*. Hereby, increasing the use of plant extracts and oils, which has low risk of pest resistance development, will contribute to the reduction of negative effects on environmental and human health, and as a result of this, a more economical agricultural production will be carried out.

Material and Methods

The trials were carried out in 2019 in the laboratory of the Department of Entomology, Bursa Uludağ University (Turkey), Faculty of Agriculture, Department of Plant Protection.

The main material of the study consisted of tomato plant (*Solanum lycopersicum* L., Solanaceae) and the third and fourth instar larvae of *T. absoluta* collected from greenhouses nearby İzmir. Four different concentrations of the essential oils (safflower, lavender, sage and clove) were used in the experiment, including 1.00, 3.00 and 5.00% in concentrations. Also, distilled water (25 ml) +ethyl alcohol (% 96) (25 ml) was used as a control to compare with the different concentrations of the oils. All concentrations of the oils were applied by the contact or residual method by spraying.

The method used in this study was adapted from the method stated by Simon (2014). In this method, formulated essential oil was diluted in a solvent (distilled water 50%+ethyl alcohol 50%) and the solution filled in hand water spray container. In the experiments, plastic Petri dishes (10 cm diameter) with 25 small air holes were used in the upper cover. Firstly, water-soaked paper towel were placed at the bottom of Petri dishes in order to prevent the tomato leaves dry in a short time. Then the tomato leaves approximately 4 cm diameter were placed on paper towel one by one.

We separated the third or fourth instar larvae of tomato leaf miner from the leaves and transferred using a fine paintbrush on to the threatened tomato leaves. In all experiments, we surrounded the dishes by parafilm in order to avoid the larva escape. The control tomato leaves were treated only with distilled water. There were three replications for each doses of concentrations. The results were controlled after 24, 48, 72 hours and the number of live and alive individuals were noted.

The experiment was arranged in a completely randomized pot design with 3 replicates for each concentration of plant oils. The data obtained from the experiment were analyzed by ANOVA (variance analysis) method using JMP software. The LSD test was used to determine the difference between the means (Statistica, 1991).

Results and Discussion

The results of toxic effects of different concentrations of essential oils applied on *Tuta absoluta* larvae were given in Table 1. When each of the essential oils were examined separately, 5% dose of safflower and clove oils were found to be most effective. In this regard, (Casida, 1990) stated that the toxic effect of these oils might depend on its chemical composition and the level of insect sensitivity. Otherwise, Sabzalian *et al*. (2008) analyzed three different safflower plant species showed that stearic, linoleic, oleic and palmitic acids were constituting 96-99% of the total fatty acids. Similarly, Mihaela *et al*. (2013) determined that, major unsaturated fatty acids were oleic and linoleic acid. Likewise, Ramos-López *et al*. (2012) stated that linolenic and linoleic acid were found to have the insecticidal activities on *Spodoptera frugiperda*. A study conducted by Heba *et al*. (2013) showed that linoleic acid have high significant toxic effect on the two instars larva of *S. littoralis*. Ramsewak *et al*. (2001) supports this hypothesis and stated that oleic acid and linoleic acid isolated from the methanol fraction of the hexane extract of the *Dirca palustris* L. (Malvales: Thymelaeaceae) seeds cause larval mortality of the 4th instar of *Aedes aegypti* (L.) (Diptera: Culicidae) and reduced the growth of *Helicoverpa zea* Boddie (Lepidoptera: Noctuidae), *Malacosoma disstria* Hübner (Lepidoptera: Lasiocampidae), *Lymantria dispar* L. and *Orgyia leucostigma* (Smith) (Lepidoptera: Lymantriidae) larvae, likely due to the phagodeterrent action of these compounds. These results indicate that fatty acids may exhibit bioactivity on insects reported by Fatope *et al*. (2000).

The tested clove essential oil in this study showed high efficacy against *T. absoluta* and this agrees with the findings of Ebedah *et al*. (2016) who reported that treatment by clove oil caused 87.3% mortality against tomato leafminer. As well as Moawad *et al*. (2015) reported that mixed cloves, bitter orange and zinc sulfate had the highest toxic effect (97.0%). Similarly, Tian *et al*. (2015) reported that clove essential oil significantly reduced the population of *C. chinensis*. Also, lemon grass extract and essential aromatic oil have significantly insecticidal effect on *T. absoluta* (Hussein et al 2015). In addition, Campolo *et al*. (2017) reported that citrus peel essential oil nanoformulations suppress tomato moth. Another study conducted by Chegini and Abbasipour

(2017) showed that the essential oil of *Elettaria cardamomum* was toxic to *T. absoluta*. Adil *et al*. (2015) stated that after four hours of *Nigella sativa* essential oil exposure, they induced 100% of mortality of larvae and also had a strong repellent activity against the larvae of *T. absoluta*.

Table 1. Toxic effect of three different concentrations and duration of essential oils applied on *Tuta absoluta* larvae.

Oils	**Dose (%)**	**Mean Larvicidal Effect (%)**		
		24 hours	**48 hours**	**72 hours**
Clove oil	1	40 g	40 g	70 cd
	3	66 d	73 c	60 e
	5	100 a	100 a	100 a
Lavender oil	1	20 j	20 j	26.66 ı
	3	26.66 ı	40 g	26.66 ı
	5	26.66 ı	20 j	46.66 f
Sage leaf oil	1	20 j	13.33 k	26.66 ı
	3	20 j	20 j	33.33 h
	5	26.66 ı	33.33 h	46.66 f
Safflower oil	1	30 h-ı	50 f	58.33 e
	3	80 b	60 e	66.66 d
	5	100 a	100 a	100 a
Control	1	8.33 k-l	8 l	8.66 k-l
	3	8.33 k-l	9.33 k-l	10.66 k-l
	5	12.66 k-l	12.33 k-l	12.66 k-l

Toxic effects of four essential oils and different doses on *T. absoluta* larvae were shown in Figure 1. The highest mortality rate at 5% concentration of clove and safflower oil was 100%. The mortality rate of 60-70% was found in 3% doses. In sage oil, it was found that the concentration of 5% was 30-40%, the dose of 3 ml was 20-30% and the dose of 1 ml was 20%. It was found that there was no difference in lavender oil between 5 ml and 3 ml doses. The highest 30-35% mortality was observed in lavender oil. Moreover, tomato leafminer larvae have observed escape behavior to outside of the petri dishes that applied lavender oil. Similarly, Cosimi *et al*. (2009) tested essential oils extracted from bergamot, bay laurel and lavandin for repellency against *Sitophilus zeamais, Cryptolestes ferrugineus* adults and *Tenebrio molitor* larvae. In the control, mortality rates of around 10% were determined.

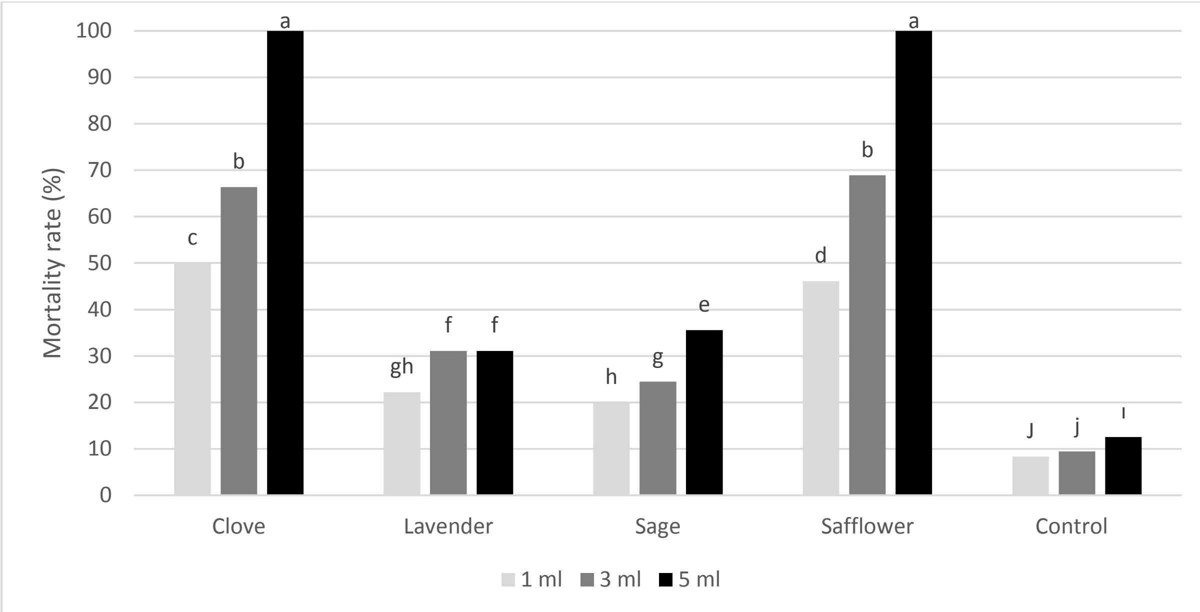

Figure 1. Toxic effects of four essential oils and different doses on *Tuta absoluta* larvae (F: 282,2679; DF: 44/90; P < 0.0001).

Toxic effects of essential oil doses and duration on *T. absoluta* larvae were given in Figure 2. Observations made in this study, the effect of duration on mortality rates was observed to be less than the effect of other parameters. At the 5 ml doses, the highest mortality rate was observed at 72nd hours and no statistically significant difference was observed at 24th and 48th hours. There were no statistically significant differences in the mortality rates at 24th, 48th and 72nd hours at 3 ml doses of oils. Mortality rate at the 72nd hour of the 1 ml dose was 35-40% and mortality rate at the 48th hour was 25-30% and at the 24th hour it was 20-25%.

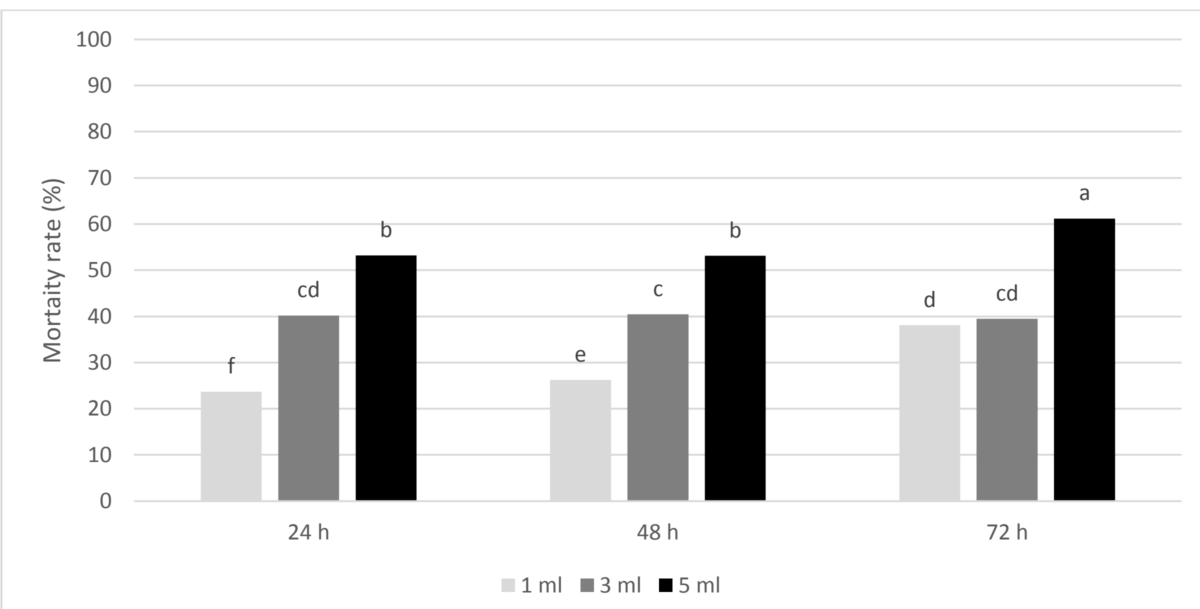

Figure 2. Toxic effects of oil doses and duration on *Tuta absoluta* larvae (F: 282,2679; DF: 44/90; P < 0.0001).

Conclusions

Generally, the extensive and unwise use of synthetic pesticides in the control programs against agricultural pests often creates major deleterious side effects. Fortunately, natural oils (safflower and clove) gave satisfactory results against *T. absoluta*, thereby; the use of thesee essential oils to protect tomato crops against this pest could thus be considered. This is why the in-vivo study of the insecticidal effect of the essential oils were necessary. It was concluded that the use of them for control mentioned tomato insect pests as alternatives to the classic pest control agents. The essential of oil lavender shows repellent activity as well as low insecticidal activity in vitro against the larvae of *T. absoluta*.

Aknowledgements

We are thankful to farmer for allowing the collection of tomato leafminer larvae from greenhouse.

OCCURRENCE OF OCHRATOXIN A IN RED WINE IN SERBIA IN 2020-2021

Marko M. JAUKOVIĆ[1]*, Anja D. VUKSAN[2]

[1]Jugoinspekt Beograd ad, Serbia
[2]Directorate for National Reference Laboratories, Serbia

Abstract

Wine production in Serbia has a long tradition and represents one of the significant branches of agricultural production. Wine produced in Serbia have for many years a reputation of good quality products. Health benefits of wine related mostly to cardiovascular diseases are well known. However, wine is also recognized as one of the main contributors to the dietary intake of ochratoxin A. Ochratoxin A is a widespread mycotoxin that is produced by several Aspergillus and Penicillium species and main mycotoxin occurring in wine. In this study, a total of 55 samples of red wine were collected from 18 producers from Serbia in the period 2020-2021. The samples were analysed for ochratoxin A (OTA) content by using an enzyme-linked immunosorbent assay Ridascreen® Ochratoxin A 30/15. The occurrence of OTA in the tested samples was 89%, with average concentration 0.47 μg kg^{-1} and maximum OTA content of 1.04 μg kg^{-1}. These results suggest very high level of occurrence of OTA in tested samples. The limit of 2.00 μg kg^{-1} imposed by Serbian legislation for OTA content in wine was not exceeded in any of the studied samples. It could be concluded that levels of OTA in wines from Serbia do not pose a risk for human health.

Key words: *wine, ochratoxin A, ELISA.*

Introduction

Ochratoxins are mycotoxins produced by several species of the fungal genera *Aspergillus* and *Penicillium*, and are among the most widely reported of the nearly 400 recognized mycotoxin contaminants of agricultural products (De Jesus et al., 2017).
Of all known variants, ochratoxin A (OTA) is the most prevalent cogener. Production of this mycotoxin was initially established with species *Aspergillus ochraceus*, *A. melleus*, *A. muricatus*, *A. petrakii*, *A. sclerotiorum* and similar. Furthermore, some species of *Penicillium* also produce OTA, of which the best known are *P. verrucosum* and *P. veridicatum* (Jović et al., 2009). Ochratoxin A (OTA) is a naturally occurring foodborne storage mycotoxin in temperate as well as in tropical areas (Devergowda et Murthy, 2009). OTA is found in a wide variety of agricultural commodities worldwide, ranging from cereal grains to dried fruits, wine and coffee (Bui-Klimke and Wu, 2015).
OTA has been shown to be potently toxic in various systems (De Jesus et al., 2018). OTA has been associated with Balkan Endemic Nephropathy (BEN) and the development of urinary tract tumors in humans (Abouzied et al., 2002; Shundo et al., 2006). Apart from a marked nephrotoxicity, ochratoxin A possesses teratogenic, immunotoxic and possibly neurotoxic properties (Burdaspal and Legarda, 2011). Some evidence exists in support of both genotoxic and non-genotoxic mechanisms by which OTA causescarcino genicity (Mally and Dekant, 2005; Pfohl-Leszkowicz and Castegnaro; 2005).

In 1993, the International Agency for Research on Cancer (IARC) classified OTA (Group B) as possible carcinogen to humans (IARC, 1993).
Among the agricultural products associated with OTA contamination, and of possible human health concern, is wine **(**De Jesus et al., 2018**)**. This product was identified as the second most important source of OTA after cereals in the European diet and among different types, red and sweet wine seemed to be the most contaminated (Miraglia and Brera, 2002).
The source of OTA contamination of wine is the raw material and therefore sanitary condition of grapes is a very important factor to avoid OTA presence in the final product (Gil-Serna et al., 2018). OTA levels in wine also depend on other factors such as latitude, environmental and weather conditions, managing conditions in the vineyards as well as on winemaking procedures (Silva et al., 2019). Many studies have been performed to unravel the most important ochratoxigenic species occurring in grapes. Several reports evidenced the contribution of Aspergillus section Nigri species to OTA contamination of grapes and their occurrence on the surface of healthy berries (Jessica Gil-Serna et al., 2018).
Wine production in Serbia has a long tradition and represents one of the significant branches of agricultural production. Therefore, the objective of this study was examination and determination of the presence of OTA in red wine in order to determine the levels of contamination. The reason for choosing only samples of red wine lays dawn in the fact that in previous years OTA was not detected in white wine samples at all.

Materials and Methods

Collection of samples

Present study examined 55 samples of red wine, collected from 18 producers from all over the Serbia in the period 2020-2021. Before analysis, the samples were stored at refrigerator (4-6ºC), protected from light.

Sample preparation

All collected samples were prepared and analyzed in accredited laboratory for testing food and feed safety „Jugoinspekt Beograd“. Samples of red wine were prepared according manufacturer's instructions. Prior to analysis, 5 ml of each sample was pipetted into a 50ml PP-tube and mixed with 20 ml of diluted ECO extractor. The mixture was shaked vigorously (manually) for 5 minutes. The extract was centrifuged for 5 minutes at 3500g, RT and 1 ml of supernatant was diluted with 1ml of ready to use wash buffer. According to manual instructions 50 µl of diluted sample was used in the test.

Ochratoxin A analysis and instrumental conditions

Determinaton and quantitive analysis of ochratoxin A was done by Enzyme Linked ImmunoSorbent Assay (ELISA) method, using RIDASCREEN® Ochratoxin A 30/15 (R-Biopharm) test kit. Multiskan FC microplate reader with absorbance range 0 - 6.000 A was used. Normal reading mode was used with reading speed t = 13 s
Analysis were performed according to manufacturer's instructions (RIDASCREEN Ochratoxin A 30/15 Art.No.:1312). Limit of detection (LoD) was set on 0,015 µg kg^{-1} while limit of

quantification (LoQ) was calculated at 0,05 μg kg^{-1} . Measuring range was confirmed from 0,05 to 25 μg kg^{-1}, while recovery rate was ranging from 94 to 116 %. The measurement is made photometrically at 450 nm. The absorbance is inversely proportional to the ochratoxin A concentration in the sample of red wine.

Statistical analysis

All obtained data were analyzed using SPSS 15.0 software (SPSS, IBM corporation, USA).

Results and Discussion

Ochratoxin A has been detected in 49 out of 55 (89%) samples of red wine, at levels ranging from 0.307 μg kg^{-1} to 1.04 μg kg^{-1}. Average concentration was 0.47 μg kg^{-1} and maximum OTA content of 1.04 μg kg^{-1}. In majority of the samples (48) OTA concentration ranged from 0.3 μg kg^{-1} to 1.00 μg kg^{-1} (Table 1). Only in 11% of examined samples OTA has not been detected. Most of the contaminated samples (18 out of 49) refer to 2020 year of the production which proves that aging has significant effect on OTA reduction in wine (Anli et al., 2011). Overall, this suggests very high level of occurrence of OTA in tested samples. High level of occurrence could be explained by the red wine making process. Maceration, which occurs just in red wine making process allows the migration of OTA from the grape to the must (Dachery et al., 2017).
Žurga et al. (2019) have found that 92% of studied samples of red wine were contaminated with ochratoxin A which is in correlance with this study (89%). Furthermore, in United States more than 85% of the samples evaluated were found to contain OTA (De Jesus et al., 2017).
The limit of 2.00 μg kg^{-1} imposed by Serbian legislation for OTA content in wine was not exceeded in any of the studied samples, which is comparable to those performed in some other studies. Belajova and Rauova (2007) have found that wines produced in Slovakia have OTA concentrations far below the proposed European limit (2.00 μg kg^{-1}). Furthermore, Žurga et al (2019) have reported that concentrations in all examinated samples of red wine were even 10 times lower than the maximum limit of contamination (2.00 μg kg^{-1}).
Although high level of occurrence was detected contamination levels were way below a provisional tolerable daily intake (PTWI) established for this toxin by JECFA (112 ng/kg bodyweight) (JECFA, 2007), which proves that wine from Serbia, consuming in reasonable amounts, are safe for consumption.

Table 1. Contamination range of analyzed samples

Year of the production	**Range of contamination (μg kg^{-1})/No. of analysed samples**		
	<0.3	0.3 – 1.00	> 1
2016	3	5	/
2017	3	5	/
2018	/	9	/
2019	/	12	/
2020	/	17	1

Conclusion

Ochratoxin A has been detected in majority of the analyzed samples. This leads to a conclusion that presence of funghi and its metabolites is natural and hardly can be avoided. Also, it was confirmed that the process of making red wine is more favorable to occurrence level of OTA. However, the levels of contamination did not exceed maximum limit imposed by the Serbian law which proves that with good agricultural practice the level of contamination can be managed. Furthermore, contamination levels were way below a provisional tolerable daily intake (PTWI) established for this toxin by JECFA which proves that wine from Serbia are safe for consumption.

ANTIBACTERIAL ACTIVITY OF MANUKA HONEY WITH DIFFERENT MANUKA FACTOR

Vesna KALABA, Tanja ILIĆ, Bojan GOLIĆ

PI Veterinary Institute of RS "Dr Vaso Butozan" Banja Luka, Republic of Srpska, Bosnia and Herzegovina
Corresponding author: vesnakalaba@yahoo.com

Abstract

Honey has been a part of myths and legends for centuries, gift from heaven, but also as the food of the Gods. The history of honey is as long and rich as the history of bees, which are one of the oldest forms of insects. To man, honey is the oldest food and known medicine. Manuka honey is the most researched medium and the first registered 'medical honey'. It is monofloral honey that comes from the nectar of the Manuka plant, *Leptospermum scoparium*, which grows like a bush or tree in New Zealand and eastern Australia. Phytochemicals derived from plants from which bees collect nectar or honey dew can have a beneficial effect on human health. Compared to other types of honey, manuka honey contains more flavonoids and phenolic acids that act as antioxidants and anti-inflammatory, antiproliferative and antimicrobial. Methylglyoxal (MGO) is up to a hundred times more abundant in Manuka honey compared to other types of honey and is considered responsible for its strong antimicrobial action. Manuka honey has different biological effects and wide application in complementary, but also in conventional medicine. It acts antimicrobial on a wide range of bacteria, including multidrug-resistant strains, thanks to its peroxide and non-peroxide activity. It is a powerful antioxidant, has anti-inflammatory, immunostimulatory, cytotoxic and antiviral, antifungal, and anthelmintic effects. The aim of this study was to examine the activity of Manuka honey of different unique Manuka factor (UMF) on bacterial cultures: *Escherichia coli*, *Staphylococcus aureus*, *Salmonella Enterica* and *Salmonella Typhimurium* and *β-hemolytic Escherichia coli* isolated from clinical material and to determine the type of action on these pathogens. The agar diffusion method was used by placing disks with a diameter of 9 mm on a solid sterile agar (Müeller-Hinton-agar-MHA) where is 50 µl of honey (original honey and diluted samples in the proportion honey: deionized water 50:50 % and 75:25 %) was dropped with a micropipette. The results confirmed the antimicrobial activity of both Manuka honey on all tested bacterial strains with a range of 19.33mm to 36.66mm for Manuka UMF 5+ and a range of 21.66mm to 34.66mm for Manuka UMF 15+.

Key words: *antibacterial properties, manuka honey, pathogenic microorganisms.*

Introduction

Manuka honey is a product of the honeybee from the New Zealand area, where the evergreen shrub tree Manuka or New Zealand tea tree (lat. *Leptospermum scoparium*) grows. New Zealanders have long used it in traditional medicine for its proven healing properties (cleansing surgical wounds, abscesses, ulcers of various etiologies, burns, while the leaves of Manuka tree were used to make tea that is good for colds, for wound healing, but also as a sedative) (Wijesinghe et al., 2008;, Bonifacio et al., 2018).
Manuka honey consists of carbohydrates, minerals, proteins, fatty acids, phenolic and flavonoid compounds. Such compounds are also found in other types of honey, but Manuka honey is

unique due to the unusually high content of methylglyoxal (MGO- present in a concentration of 38 mg/ kg to 1541 mg/kg)) which is formed from dihydroxyacetone (DHA) which is correlated with antibacterial activity (Maube et al., 2013; Aiken et al., 2012; Atrott, 2009). Manuka honey is one of the most researched honeys. It is also evaluated using a classification system known as the unique Manuka factor (UMF). The UMF score of Manuka honey is strongly correlated with MGO equivalence and antibacterial activity, but this relationship has not yet been fully studied (Kato et al., 2014;, Molan, 2008).

The unique Manuka factor (UMF) depends on the content of methylglyoxal and is the important antibacterial action of honey along with other active components including hydrogen peroxide, pH, hyperosmolarity effect, bee defensin-1, etc., which act independently or with MGO and hydrogen peroxide (Atrott, 2013; Alvarez- Suarez, 2014; Szweda, 2017; Carnwath et al., 2014)

The main bioactive substances of manuka honey and the mechanisms responsible for its biological activity are currently being studied. This research supports its increased use in dermatology and the basis for the isolation and purification of substances for the development of biopharmaceutical products with antimicrobial properties and for wound healing (Alvarez-Suarez, 2014).

Manuka honey acts on a wide range of bacteria and bacteria that are resistant to first-line antibiotics are sensitive, such as *MRSA*, *Salmonella Enterica serovar Typhi*, *Pseudomonas aeruginosa*, *Escherichia coli* and *Staphylococcus epidermidis*, *Helicobacter pylori*, *Campylobacter spp*. (Ahmed - Suarez, 2013).

During a longer period of application, a reduced susceptibility of bacteria to Manuka honey was observed, but this phenomenon was not long-term, and no mutated resistant bacteria were found. The risk is low if honey is applied over a long period of time in high concentrations (Cooper et al., 2010). The need to find new antimicrobial drugs due to the increasing occurrence of resistant and multidrug-resistant bacterial strains to previously known antimicrobial drugs has prompted the scientific community to find safe and natural (alternative) drugs (Linder et al. 2016).

The aim of this study was to examine the activity of Manuka honey of different unique Manuka factor UMF on bacterial cultures: *Escherichia coli, Staphylococcus aureus, Salmonella Enterica* and *Salmonella Typhimurium* and *β-hemolytic Escherichia coli* isolated from clinical material.

Materials and methods

Manuka honey UMF 15+ purchased in commercial sales at the Žužemberk pharmacy (Grajski trg 41, Žužemberk) and Manuka honey UMF 5+ purchased in commercial sales in New Zealand were used as material.

Test microorganisms

Bacterial cultures were used to examine the antibacterial activity: *Escherichia coli*, *Staphylococcus aureus*, *Salmonella Enterica*, *Salmonella Typhimurium* and β-hemolytic *Escherichia coli* from the collection of isolates of the laboratory for microbiology (PI Veterinary Institute of Republic of Srpska "Dr. Vaso Butozan"). Cultures were seeded in nutrient broth and incubated for 18 hours at 37^0C. Petri dishes with a suitable medium (Müeller - Hinton agar) were seeded with 100 µl of bacterial suspension with a concentration of 10^5 CFU/ml.

Test method

The agar diffusion method was used by placing 9 mm diameter disks on a solid sterile agar (Müeller-Hinton-agar-MHA). 50 µl of honey (original honey and diluted samples in the proportion of honey: distilled water 50:50% and 75:25%) was instilled on the discs with a micropipette. As a control, 50 µl of sterile distilled water was added to the discs which was used to dilute the honey samples. The plates were left in the refrigerator for 30 minutes to diffuse the sample into the medium, then incubated for 24 hours at 37°C.

For each honey sample, three replicates were performed and after incubation from 18-24h, the results were read by determining the diameter of the inhibition zone and the mean value was calculated.

Type of action

To see if the honey was bactericidal or bacteriostatic, a small piece of agar was taken from the inhibition zones and added to the nutrient broth. Incubation was performed at 37ºC/24h. If the broth has become cloudy, the effect of honey is bacteriostatic and if the broth has remained clear after incubation, the action of honey is bactericidal.

Results and discussion

The antibacterial activity of Manuka honey with two different UMFs (UMF 15+ and UMF 5 +) was tested on five bacterial strains (*Escherichia coli*, *Staphylococcus aureus*, *Salmonella Enterica*, *Salmonella Typhimurium* and *β-hemolytic Escherichia coli*) isolated from clinical material (poultry, throat swab, urine). The results are shown in Tables 1 and 2.

Table 1. Antibacterial activity of Manuka honey UMF 5+

Microorganisms	**Inhibition zones in mm**		
	Manuka honey UMF 5+ Original	***Manuka honey: distilled water 75:25%***	***Manuka honey: distilled water 50:50%***
Staphylococcus aureus	34.67±1.25	31.00±0.82	36.67±2.36
Escherichia coli	29.67±4.64	24.67±0.94	20,67±0.94
β- hemolitična Escherichia coli	26.33±2.62	20,00±2.45	22,00±2.16
Salmonella Enterica	27,33±0.94	25,67±0.47	19,33±0.47
Salmonella Typhimurium	24.00±1.41	29.33±0.94	25.00±0.00

Manuka honey UMF 5+ acted on all bacterial strains with different intensity of inhibition with a range of action from 19.33 mm to 36.66 mm. Manuka UMF 5 + showed the strongest action against *Staphylococcus aureus* in all combinations with a range of action of 36.66 mm (in the proportion of honey: distilled water 50:50%), 33.66 mm (pure honey) and 31.00 mm (in the proportion of honey: distilled water 75:25%). Pure Manuka honey had the strongest effect on *Escherichia coli*, *β-hemolytic Escherichia coli*, *Salmonella Enterica* with a range of 26.33 mm to 29.66 mm in relation to both combinations, while in the combination of honey: water 75:25% had the strongest effect on *Salmonella Typhimurium* (with a range of 29.33 mm), then honey: distilled water 50:50% (range of action 25.00 mm) and finally pure Manuka honey with a range of action of 24.00 mm.

Table 1. Antibacterial activity of Manuka honey UMF 15+

Microorganisms	**Inhibition zones in mm**		
	Manuka honey UMF 15+ original	***Manuka honey: distilled water 75:25%***	***Manuka honey: distilled water 50:50%***
Staphylococcus aureus	34.67±3.86	29.33±0.94	25.67±1.89
Escherichia coli	28.33±2.36	25.67±0.47	21,67±2.36
β- hemolitična Escherichia coli	25.33±2.05	23,67±1.25	19,00±2.94
Salmonella Enterica	28.33±2.05	24.33±0.94	20,00±1.63
Salmonella Tiphymurium	34.67±2.49	25.00±0.00	23.00±0.02

Manuka honey UMF 15+ had an inhibitory effect on the examined pathogens with a range of action from 19.00 mm to 34.66 mm. Pure Manuka UMF15 + had a stronger effect on all tested pathogens (range of action from 25.33 mm to 34.66 mm) compared to diluted honey in both proportions (honey: distilled water 50:50% and 75:25%). Also, Manuka UMF 15+ had a stronger effect on all tested pathogens in the proportion of honey: distilled water 75:25% (with a range of 22.66 mm to 33.33 mm) compared to the proportion of honey: distilled water 50:50% (range of action of 19.00 mm to 32.00 mm).

The disk diffusion method is most used for evaluation of the antibacterial activity of honey. The limiting factor is that different types of bacteria are differently sensitive to different types of honey. In addition, the agar-diffusion method evaluates the activity of honey according to the size of the growth inhibition zone, which depends on the antibacterial activity, but also on the rate of diffusion of antibacterial components through the agar. Due to relatively high molecular weight compounds that are limited in agar migration, the antibacterial activity of honey can be mistaken for low. (Kwakman, 2010; Gobin et al., 2014; Kalaba et al., 2020).

The results of the research are consistent with the results of other researchers and agree that Manuka honey with higher UMF has a stronger inhibitory effect. Manuka honey UMF 5+ contains 83mg/kg MGO, and Manuka UMF 15+ contains 250mg/kg MGO and is the reason for their stronger action in the fact that they have a higher total number of phenols that have the ability to clean free radicals (Alsara, 2009; Almasauddi et al., 2017; Lu et al., 2013; Jing et al., 2013). Also, there must be other components, which act independently or with the help of MGO and hydrogen peroxide (Tonks et al. 2007; Alvarez-Suarez, 2014). Due to the influence of various factors on the antimicrobial properties of honey it is not possible to predict exactly how much antimicrobial activity a honey will have.

The results of this study confirmed the stronger effect of Manuka honey on Gram-positive bacteria (*Staphylococcus aureus*) compared to Gram-negative bacteria (*Escherichia coli*, *Salmonella Enterica*, *Salmonella Typhimurium* and *β-hemolytic Escherichia coli*), which agrees with the results of other researchers (Irish et al., 2011; Kumar, 2014; Jing et al., 2013).

The effectiveness of the antibacterial action of honey on different types of bacteria is not the same due to different mechanisms of resistance. The outer membrane and the more complex three-layer cell membrane of Gram-negative bacteria in general causes increased resistance to some types of honey as well as to antibacterial drugs. Another mechanism of resistance involves the formation of extracellular biofilms, which represent physical barriers to antimicrobial activity (Pagès, 2009; Walsh, 2000; Hussein et al., 2012; Al-Vaili et al., 2012; Vallianou et al., 2014).

Honey has bacteriostatic and bactericidal activity in some pathogenic bacterial species such as *Escherichia coli*, *Salmonella spp.*, *Staphylococcus aureus*, etc. Bacterial growth is inhibited by

low water activity and low pH. (Almasaudi et al., 2017 ; Lu J., et al., 2014 ; Kwakman and Zaat, 2012).
To see if the honey was bactericidal or bacteriostatic, a small piece of agar was taken from the inhibition zones and added to the nutrient broth. Incubation was performed for 24 hours at 37ºC.
Both Manuka med showed bactericidal activity on *E. coli*, *β-hemolytic E. coli*, *Salmonella Enterica* and *Salmonella Typhimurium* in all replicates. Both honeys showed bacteriostatic effect on the inhibition of *Staphylococcus aureus* growth in dilution with water in the ratio honey: water 75:25 in one replication in Manuka UMF 5+ and in two replicates in Manuka UMF 15+. These results agree with the results of other researchers (Almasauddi et al., 2017; Mohapatra et al., 2011; Vallianou et al., 2014; Kalaba et al., 2020).
