
Picture 1. Bacteriostatic and bactericidal action of Manuka UMF5 + and Manuka UMF15 +

Conclusion

The results confirmed the antimicrobial activity of both Manuka honey on all tested bacterial strains with a range of 19.33 mm to 36.66 mm for Manuka UMF 5+ and a range of 21.66 mm to 34.66 mm for Manuka UMF 15+.
Both Manuka honeys were bactericidal except in one replication in *Staphylococcus aureus* with Manuka UMF 5+ 75:25% and two replicates in Manuka UMF 15+ 75:25% when the honeys were bacteriostatic.
Manuka honey is a medical honey that confirms that there is a huge potential for the application of honey in the clinical environment. However, as the factors influencing the antimicrobial activity of honey are complex and numerous, it is important to continue research not only on those honeys known as antibacterial, but also on other locally produced and unexplored honeys.

ORGANIC AGRICULTURE

CHEMICAL-PHYSICAL PROPERTIES AND QUALITY OF HONEY FROM ORGANIC GROWING FROM THE AREA OF SOUTHERN HERZEGOVINA

Abstract

Beekeeping, and thus honey production, has a very long tradition in Bosnia and Herzegovina. Due to the very favourable sub-Mediterranean climate conditions, and rich biodiversity, and especially a variety of medicinal plants, honey from the area of southern Herzegovina is a highly valued and sought-after product. On the list of 10 foods with the highest risk of counterfeiting, honey ranks sixth. This paper analyses samples of honey from organic farming from three locations in Herzegovina, namely Gornja Duboka, southeast of Stolac, Bančići (a village located between Stolac and Ljubinje) and Počitelj-brdo in the municipality of Čapljina, in order to determine their quality and originality product. The samples were analysed for the following parameters: water content, content of water-insoluble components, total ash, reducing sugar content, sucrose content, acid content, HMF content and electrical conductivity. The results of the analyses were compared with the reference values and statistically processed. The obtained results showed that all parameters, on which honey samples from all three localities were tested, were in accordance with the reference values prescribed by the Book of rules on honey and other bee products. From the obtained results of chemical and physical analyses, it can be concluded that all samples are natural, that they are not fake and that it is honey of very good quality.

Key words: *honey, location counterfeiting, parameters, chemical-physical properties, quality.*

Introduction

Honey is a mixture of relatively complex composition with over 70 chemical components been identified (Krell, 1996). Its chemical composition is influenced by agroecological, geographical, climatic conditions, as well as the characteristics of vegetation in a particular location. (Tewari and Irudayaraj, 2004). Also, the colour and taste of honey depend on the above mentioned factors (Persano Oddo and Piro, 2004). One of the most important characteristics by which its chemical composition can be described, is the variability of that composition, so it can be said that there are no two samples of honey that are completely identical. According to Mujić *et al.* (2014) the most common ingredient is invert sugar, actually a mixture of equal amounts of glucose and fructose formed by hydrolysis of sucrose and water. These authors state that the other ingredients in honey are proteins (including enzymes), minerals, vitamins, organic acids, nitrogen compounds, hydroxymethylfurfural, phenolic components, components that affect aromas. The most common are carbohydrates and water. Since different types of counterfeit honey can be found on the market, the aim of this study was to examine honey samples from three locations in southern Herzegovina for organic parameters to give a picture of the quality and originality of the product (Lazarević *et al* 2012).

Material and methods

Honey samples for this study were collected during 2019 from three locations from the areas of Stolac and Čapljina municipalities. All three locations are under influence of the sub-Mediterranean climate and are characterized as ecological areas. Samples are numbered 1, 2 and 3 as follows:

Sample 1- Spring honey; location: Gornja Duboka, southeast of Stolac at 12 km; geographical and pedological characteristics: hilly karst area with intensive forest areas in the lowlands; vegetation: sage, willow grass, dubačac, thyme, petteria and honeydew.

Sample 2 - Autumn honey; location: Bančići (village located between Stolac and Ljubinje); the apiary is located southeast of Stolac and southwest of Ljubinje; geographical and pedological characteristics: hilly area with individual karst zones; vegetation: heather, mint, white grass, ivy.

Sample 3 - Autumn honey; location: Počitelj – Gradina, municipality of Čapljina; geographical and pedological characteristics: hilly area, redness on karst; vegetation: dominant thorns, heather, sage.

The samples were tested for the following parameters:

- water content (drying method-standard procedure)
- content of water-insoluble components (gravimetric method)
- total ash (sample combustion method at 6000^{0}C)
- reducing sugar content (Fehling and Luff Schoorl method)
- sucrose content (hydrolysis and reduction method with Fehling solution)
- acid content (by neutralization method with phenolphthalein as an indicator)
- HMF content, hydroxymethylfurfural (Winkler photometric method)
- electrical conductivity (by a method of measuring electrical resistance that is reciprocal to electrical conductivity)

The analyses were performed in the laboratories of the Agromediterranean Institute in Mostar. The obtained results were compared with the maximum permitted quantities prescribed by the Book of rules on honey and other bee products in force in B&H (Official Gazette of BiH, No. 37, pp. 333 and 334), and statistically processed, using analysis of variance and Tukeytest.

Result and discussion

Tables 1 to 8 show the results of analyses for each examined parameter expressed as the mean value ± standard deviation (SD).

Table 1. Water content in honey samples (%)

Parameter	Sample 1	Sample 2	Sample 3	Reference value
Water content	**15.10 ± 0.05**	**15.30 ± 0.15**	**17.40 ± 0.04**	**20**

The stability of honey depends on the amount of contained water. In the case of increased water content, fermentation caused by osmophilic yeasts can be activated, which produces alcohol that turns into ethanoic acid and water, by oxidizing oxygen from the air, which results in a more acidic taste of honey (Zamora and Chirife, 2004). Honey that contains more than 20% of water is

more prone to fermentation. All three samples, which were the subject of the study, had a water content below the maximum allowed value.
Statistical analyses showed the existence of certain statistical significance in water content. By comparing Sample 3 to Sample 2 and for Sample 1, it indicated that significant difference was determined, while in comparison of Sample 2 with Sample 1 there was no significant difference.

Table 2. Acid content **(**milieqvkis/1000g)

Parameter	Sample 1	Sample 2	Sample 3	Reference value
Acid content	**30.10 ± 0.82**	**28.9 ± 0.77**	**26.30 ± 1.1**	**50**

The acids, which are an integral part of honey, are of quite different chemical composition. Out of all organic acids, gluconic acid is the most abundant, and tartaric, lactic, citric, acetic, oxalic, formic and malic are also present. Hydrochloric and phosphoric acids are the most abundant inorganic acids (Taranov, 2006). The acidity of honey is an indicator of its quality, and the pH is in the range of 3.2 to 6.5 (Mujić *et al.*, 2014). High acidity indicates fermentation where alcohol as a product is fermented into an organic acid. In all three tested samples, the acid content was lower than the maximum allowed. Analysis of variance showed that there was a statistical difference between the tested samples on acid content. Based on the Tukey test, the existence of significant difference in the comparisons of Sample 1 in relation to Sample 3 and Sample 2 in Sample 3 was established, while in the comparison of Sample 1 with Sample 2, no signifcant diference was determined for the examined parameter.

Table 3. Ash content (g/100g)

Parameter	Sample 1	Sample 2	Sample 3	Reference value
Ash	**0.477 ± 0.20**	**0.46 ± 0.16**	**0.587 ± 0.11**	**0.6**

When it comes to minerals, iron and aluminum predominate among all the other minerals in honey, such as potassium, sodium, calcium, phosphorus, sulfur, chlorine, magnesium. The most common microelements are copper, manganese, chromium, zinc, lead, arsenic, titanium, selenium. Out of the total mineral content, potassium is present in a percentage of 25% to 50%, and with sodium, calcium and phosphorus makes up at least 50% (Hernandez *et al.*, 2004). The higher ash content may indicate honey with addition of sugar molasses (Pohl, 2009). In all three tested samples, the ash content was below the maximum allowed value. Statistical analyses indicated that there was no statistical difference for the tested honey samples.

Table 4. Invert sugar content (g/100g)

Parameter	Sample 1	Sample 2	Sample 3	Reference value
Invert sugar	**F=33.697± 0.90 G=21.358±0.45 F+G=55.055**	**F=39.098± 0.98 G=26.860±0.62 F+G=65.958**	**F=37.839± 1.01 G=25.098±0.29 F+G=62.937**	**F +G Minimum 60**

F- Fructose, G- Glucose

The most common ingredient is an invert sugar, actually a mixture of equal amounts of glucose and fructose formed by hydrolysis of sucrose and water (Mujić *et al.*, 2014). The sweet taste of

honeycomes from carbohydrates. In addition, they affect the hygroscopicity, viscosity, density and tendency to crystallize. (Barhate *et al.,* 2003). The tendency for honey to crystallize can be determined based on the ratio of fructose to glucose. Honey is a supersaturated glucose solution and spontaneously goes into equilibrium by crystallizing excess of glucose in solution. Glucose loses water (becomes Glucose monohydrate) and turns into a crystalline form. Water, which was previously bounded to glucose, becomes free by increasing the water content in the non-crystallized parts of the honey. Due to that, honey becomes more prone to fermentation and spoilage. Fructose remains in a liquid state and forms a thin layer around glucose crystals. Honey changes colour, becomes lighter, it is no longer transparent, and changes taste (Batinić K. and Palinić D., 2014). The results showed that in Sample 1 the invert sugar content was slightly lower than the reference value, while Samples 2 and 3 were in accordance with the reference value.
Statistical analyses indicated statistical difference for the tested honey samples. Tukey test showed was performed and the existence of statistical significance in the comparisons of Sample 2 to Sample 3 and Sample 1 was proved, while in the comparison of Sample 3 with Sample 1 it can be concluded that no statistical significance was determined. Analysing the variance for glucose content of the tested honey samples, it can be concluded that there was a statistical difference for the tested honey samples. To determine the exact influence of the location on the quality of honey samples and which comparisons showed statistical significance, a Tukeytest was performed. Based on the Tukey test for glucose content, the existence of significant difference in the comparisons of Sample 2 to Sample 3 and Sample 1 was determined. Comparing Sample 3 with Sample 1 significant difference was also determined for the examined statistical parameter.
By analysing the variance for the fructose + glucose content of the tested honey samples, it can be concluded that there was a statistical difference for the tested honey samples. The influence of the location on this parameter was shown by the Tukeytest. Based on the Tukey test for F + G content, the existence of statistical significance in the comparisons of Sample 2 to Sample 3 and Sample 1 was proven. Comparing Sample 3 with Sample 1 significant difference for the examined statistical parameter was determined.

Table 5. Sucrose content (g/100 g)

Parameter	Sample 1	Sample 2	Sample 3	Reference value
Sucrose	**<0.6011**	**<0.6011**	**<0.6011**	**5**

The sucrose content of all three tested samples was the same in this case and it was slightly less than 0.6011 g/100 grams of sample, which is a satisfactory result since the maximum reference value for this parameter is 5 g/100 g of sample. Sucrose is important during the honey test because it provides an information about a counterfeit honey (feeding bees with sugar). The most of disaccharides and oligosaccharides are found in nectar and honey bees with their enzymes and organic acids reduce them to simple sugars.

Table 6. HMF content (hydroxymethylfurfural) (mg/kg)

Parameter	Sample 1	Sample 2	Sample 3	Reference value
HMF (hydroxymethylfurfural)	**35.45±0.96**	**19.9± 0.60**	**37.31± 1.0**	**40**

According to its chemical characteristics, hydroxymethylfurfural belongs to cyclic aldehydes and can be formed by dehydration of fructose and glucose in an acidic environment. The amount of HMF in honey depends on the type of honey, pH value, acid concentration, amount of moisture, as well as the exposure of honey to light, actually on the method of storage. (Spano *et al*, 2005). HMF is naturally present in honey, its content is quite low in fresh honey, it is below 1 mg/kg, while it is high in honey treated with indirect heating during processing. (10 mg/kg). The high content of hydroxymethylfurfural in honey may indicate its forgery (Mujić *et al.,* 2014).
The HMF content was highest in sample number 3, in sample number 2. The results for all three samples are satisfactory comparing to the maximum reference value for this parameter. Anova test for the HMF content of the examined samples, indicated the statistical difference. Based on the Tukey test, there was a statistical significance in the HMF content comparing Sample 3 with Sample 1 and Sample 2. Statistical significance for the examined parameter was also indicated in comparison of Sample 1 with Sample 2.

Table 7. Content of water-insoluble components (g/100 g)

Parameter	Sample 1	Sample 2	Sample 3	Reference value
Water-insoluble components	**<0.01**	**<0.01**	**<0.01**	**max 0.1g**

The content of water-insoluble components for all three tested samples was same in this case and it amounts to slightly less than 0.01 g/100 g of sample, which means that the result is satisfactory comparing to the general maximum value of 0.1 g/100 g of sample.

Table 8. Electrical conductivity (mS/cm)

Parameter	Sample 1	Sample 2	Sample 3	Reference value
Electrical conductivity	**1.63 ± 0.08**	**1.33 ± 0.07**	**1.31± 0.04**	**Max 0.8**

Electrical conductivity is a characteristic that is defined in honey as the conductivity of a 20% solution of honey in water (20% is dry matter) at a temperature of 20° C. It depends on the amount of minerals and water, as well as dissociation of acids in such a way that the higher the value of these parameters, the stronger the conductivity. It is also used as a parameter to distinguish nectar honey from honeysuckle (Lazarević *et al.,* 2012). This parameter is also used to distinguish nectar types of honey from honeysuckle, but also to classify nectar honey according to botanical origin (da Silva *et al.,* 2016, Bogdanov *et al.,* 2004). Analysis of variance for electrical conductivity indicated that there was no statistical difference for the examined honey samples.

Conclusion

Based on the obtained results, and their comparison with the maximum permitted quantities, which are regulated by the Book of rules on honey and other bee products in force in B&H, and statistical analysis, it may be concluded that all three samples are original, unadulterated honey from organic farming of very good quality and can be recommended for consumption.

RESEARCH ON THE USE OF COVER CROPS FOR THE CONTROL OF DISEASES AND PESTS IN ORGANIC VINEYARDS

Aurora RANCA*, Anamaria PETRESCU, Ionica DINA, Sergiu Ayar ENE, Victoria ARTEM

Research Station for Viticulture and Oenology Murfatlar, Romania
*Corresponding author: auroraranca@yahoo.com

Abstract

One new viticultural system capable of exploiting plant diversity was tested in the Murfatlar vineyard between November 2018 and September 2020. The experiment was set in a plot cultivated with Fetească neagră variety, in ecological system. The experiment plan consisted of four treatments, each having two sub-treatments: one treated according to the organic guidelines and the other untreated against pests and fungal diseases. The tested cover crops were a plant mix comprising *Lolium perenne* 50%, *Onobrychis* viciifolia 25%, *Trifolium repens* 25% (semi-permanent cover crops, mowed and mulched after flowering) and another mix represented by *Vicia sativa* 50%, *Sinapis* sp. 50% (mowed after flowering and incorporated into the soil) and *Tagetes sp.*, planted as seedlings under the vine row. The development of powdery mildew (as incidence and severity of symptoms on leaves and/or bunches) in the treatment with the plant mix *Vicia sativa* 50%, *Sinapis sp.* 50% made the degree of attack lower than the other treatments. On the other hand, the treatment with the plant mix *Lolium perenne* 50%, *Onobrychis viciifolia* 25%, *Trifolium repens* 25% showed mild forms of attack with *Plasmopara viticola*, *Guignardia bidwellii* and *Botrytis cinerea.* The treatment with *Tagetes sp*. had a repellent effect for the main pest of the vine, where *Lobesia botrana* registered the lowest numbers of captured adults and larvae on flowers and bunches. Regarding the production quality, the first innovative treatment obtained the best results both in 2019 and in 2020 (267 g/l and 262.8 g/l sugars respectively). Overall, there are no significant differences between the treatments in terms of grape production.

Key words: *Ecological vineyards***,** *Plant diversity, Cover crops, Fungal diseases.*

Introduction

Soil management can enhance important aspects of the vineyard ecosystem, in particular pest control and soil health. There is a growing interest in establishing cover crops that promote useful fauna, improve soil structure, suppress weeds, control pests and foliar pathogens.

Any attempt to improve biodiversity is closely linked to the impact of chemicals applied in vineyards. Thus, chemicals can be more or less toxic in terms of their effect on soil organisms and on natural predators of vine pests. Pest control, in particular, is frequently achieved through a combination of chemical applications and the actions of natural predators, but their abundance is influenced by applied agrotechnical works, including the application of pesticides (Stark & Banks 2003; Thomson & Hoffmann 2006). Identifying and adopting practices that enhance biodiversity, help reduce the need for chemical treatments and therefore promote agricultural sustainability. The term biodiversity refers to the biological diversity of an ecosystem, and its accurate measurement is difficult due to the complexity of natural systems. However, it is generally accepted that the more diversified a system is, the more resilient or self-adjusting it will be. A wide range of potential natural enemies coexist with vineyard pests and contribute to pest control through predation and parasitism. (Thomson și colab. 2007). This paper presents the results of the introduction of an innovative system, based on intercropping, which aims to improve the control of diseases and pests in organic vineyards.

Material and Methods

Location and variety

The new viticultural system capable of exploiting plant diversity was tested in the Murfatlar vineyard, within the Murfatlar Research Station for Viticulture and Oenology. The experiment spanned over 2 years, from November 2018 to September 2020. The variety cultivated in the experimental plot is Fetească Neagră (cultivated in ecological system).

Experimental design

Three experimental treatments were configured, using cover crops in comparison with a tilled conventionally control plot. Each experimental treatment had a subtreatment plot in which the first was phytosanitary treated and the other was left untreated. (table 1).

Table 1. The experimental treatments

Experimental treatments	**The used plants in cover crop**
V1 Inovativ treated 1	Mix Lolium perenne 50%, Onobrychis viciifolia 25%, Trifolium repens 25%. Semi-permanent cover crop, mowed and mulched after flowering. Applied organic phytosanitary treatments.
V1.2 Inovativ untreated 1	IDEM V1. No treatment.
V2 Inovativ treated 2	Mix of Vicia sativa 50%, Sinapis sp. 50%. mowed and incorporated after flowering. Applied organic phytosanitary treatments.
V2.1 Inovativ untreated 2	IDEM V2. No treatment.
V3 Inovativ treated 3	Tagetes sp. Under vine trunks. Applied organic phytosanitary treatments.
V3.1 Inovativ untrated 3	IDEM V3. No treatment.
V4 (Control) Traditional, bare soil treated	Tilled control plot. Applied organic phytosanitary treatments.
V4.1 (Control)Traditional, bare soil untreated	IDEM V4. No treatment.

Monitoring methods

- Phytosanitary control technique

During the season, the vineyards were inspected periodically to monitor the evolution of the disease epidemic, at least once a week.

To determine the resistance to diseases: downy mildew, powdery mildew, gray rot and grape black rot, the degree of attack was calculated for each pathogen. The frequency of attack (F) is expressed as a percentage of the total number of plants observed. The intensity of the attack (I) is given on the basis of grades, from 1 to 7, depending on the severity of which the plant is affected. Practically, the percentage was estimated by the number and area of the spots in relation to that of the leaves on a single plant, calculating the average of the figures obtained, based on which the degree of the intensity of the attack is given. In general, the rating of the intensity of the attack was assessed as follows: Degree 1 - No attack present; 2 - if 3% of the plants are attacked and there are rare spots or pustules on the leaves; 3 - if 6% of the plants have rare spots or pustules; 4 - when 12% of the plants are attacked; 5 - if 25% of the plants are attacked; 6 - if 50% of the plants have spots or pustules; 7 - when 75% of plants are attacked (Derived from Buffara et al., 2014; Derived from Caffi et al., 2010).

Knowing the frequency (F) and intensity (I) with which a disease attacks plants, the degree of attack was calculated according to the formula:

$$DA\% = \frac{F * I}{100}$$

- Grapevine moth (*Lobesia botrana*)

  A visual inspection of 100 inflorescences/bunches per treatment was performed in order to observe the presence or absence of deteriorated flowers/berries, each week, throughout the vegetation period. Particular attention was paid to grape bunches attacked by the grapevine moth during its most harmful generation (BBCH 83-85).

  Pheromone traps were used to monitor the adult density of the vine moth (*Lobesia botrana*), the economic damage threshold being established by the number of adults caught during a week. The traps were placed for all tested treatments, and the pheromone tablets were replaced at the emergence of the next generation.
- Grapes quality evaluation

  For quality and quantity assessment, standardized techniques were used, (upon OIV). Thus, physical analyzes were performed on grapes, specifying: average production/plant, mass of 100 berries, total sugar content, total acidity and malic acid.
- The statistical analysis was performed using the programs: SPSS 26.0 and XLSTAT.

Results and discussion

Following the observations and determinations that were made in the field, the severity of the attack of pathogens was established, as well as the number of affected organs (leaves and bunches).

Thus, in the wine year 2019 downy mildew, gray rot and grape black rot diseases recorded an insignificant value of the degree of attack, for all the observed treatments. This was possible due to climatic conditions that did not favor the development of these diseases. In contrast, the pathogen *Uncinula necator* - powdery mildew, recorded a significant degree of attack, especially in the case of the innovative plots and also in the untreated control treatment. The disease was manifested as an attack on the bunches.

In the wine year 2020, the pathogens *Uncinula necator* - powdery mildew and *Guignardia bidwellii* - grape black rot were mainly manifested. Downy mildew registered a moderate degree of attack, and manifested only on the leaves. Due to the dry climatic conditions, the pathogen *Botrytis cinerea* - gray rot did not manifest itself in the experimental plots.

Regarding the degree of attack of powdery mildew (*Uncinula necator*) in both study years, the untreated control treatment V4.1 registered the highest degree of attack, followed by the innovative untreated treatments V3.1, V1.1, V.2.1. For the other treated innovative treatments, where phytosanitary treatments were applied, there was a low degree of attack, being categorized as insignificant. The treated innovative treatment with the lowest attack value was V2 - *Vicia sativa* 50%, *Sinapis sp*. 50% (Figure 1).

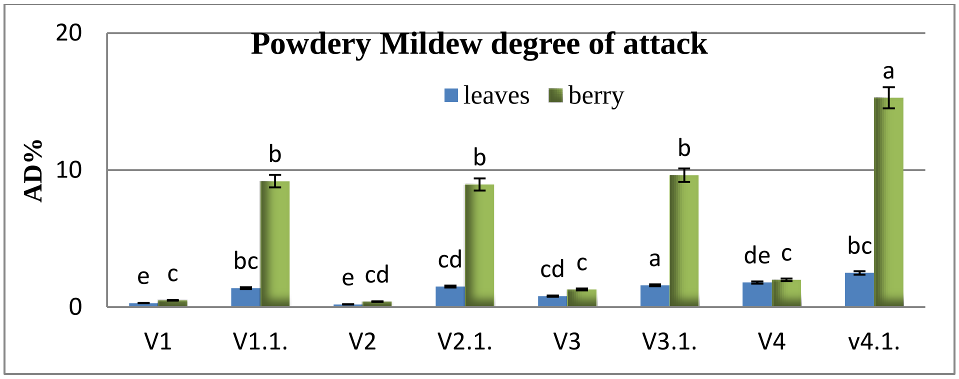

Figure 1. Degree of attack caused by *Uncinula necator* for each subtreatment

Downy mildew manifested itself on the leaves in an insignificant percentage for 2019, and in 2020 it registered a slight manifestation at leaf level. The innovative treatment that recorded the lowest degree of attack was V1 - *Lolium perenne* 50%, *Onobrychis viciifolia* 25%, *Trifolium repens* 25%, followed by V2 and V3, at short distance from V4 - control. In the case of untreated innovative treatments, the lowest degree of attack was recorded by V1.1, followed by V2.1 and V3.1, the untreated control treatment registering the highest degree of attack for both treated and untreated innovative treatments (Figure 2).

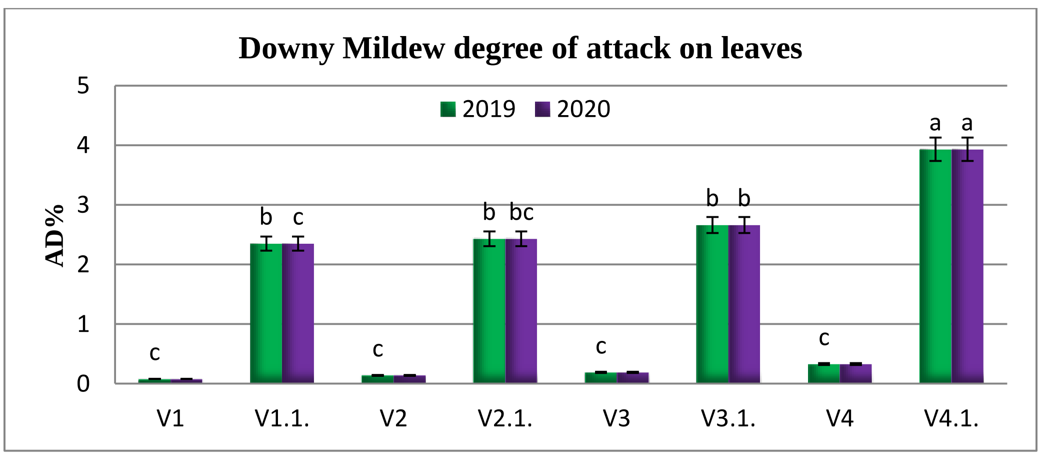

Figure 2. Degree of attack caused by *Plasmopara viticola* for each subtreatment

The attack of the grape black rot did not manifest itself in 2019, instead it was present and recorded significant values, in 2020. It had manifestations on both leaves and bunches. The untreated control treatment V4.1 being by far the most affected treatment, followed by the innovative untreated treatments V3.1, V2.1 and V1.1. In the case of the treated innovative treatments, the V3 treatment registered the highest degree of attack, followed by V2 and V1. The control treatment V4 is located between V3 and V2 (Figure 3). In the case of this pathogen, the innovative treated treatment that obtained a lower value of the attack degree is V1 - *Lolium perenne* 50%, *Onobrychis viciifolia* 25%, *Trifolium repens* 25%.

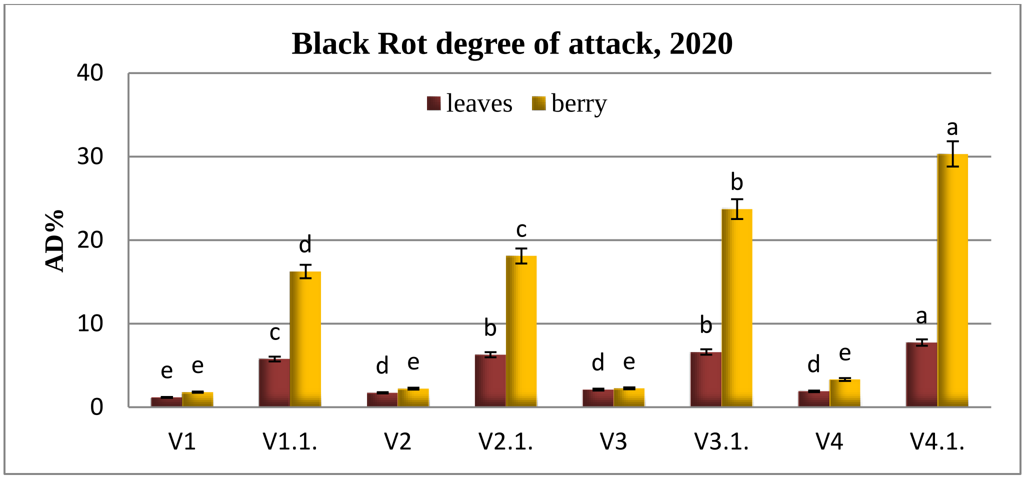

Figure 3. Degree of attack caused by *Guignardia bidwellii* for each subtreatment

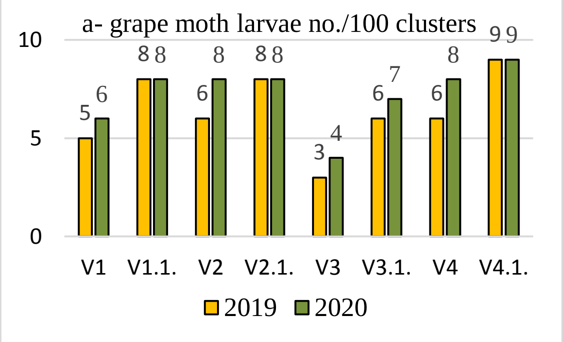
There is a clear distinction between treated and untreated treatments, however the distance in the case of untreated treatments gives us a vision and a direction towards future research.

Grapevine moth (*Lobesia botrana*)
The presence of moth larvae was identified in the experimental plots, but the economic damage threshold was not reached, for both of the years 2019 and for 2020 (10 larvae per 100 bunches analyzed). The most affected treatment was V4.1, in both years. Among the innovative treated treatments, V3 and V1 recorded the lowest number of larvae, and for the untreated ones, V3.1 and V1.1 (Figure 4 a).
The number of adults caught in 2020 recorded a value of 3080, exceeding by 75% the value recorded in the previous year, with 1762 adults. Thus, although the economic damage threshold was not attended, the pressure of the adults of this pest was very high. The flight dynamics of this pest, as seen in the graph, recorded the highest values in the untreated control treatment V4.1 - 2019 and 2020. In the case of the other innovative treated treatments, the study recorded significat differences between them and the untreated treatments. Thus, the V3 treatment registered the lowest number of adults in both 2019 and 2020, followed by the V1 and V2 treatments, and for the untreated innovative treatments, V3.1, followed by V1.1 and V2.1 (Figure 4 b)
Thus, we can see the influence of *Tagetes sp.* plants on useful fauna, which made us have a very small number of larvae and especially adults in the experimental plots. But also, the other innovative treatments have positively influenced this balance.



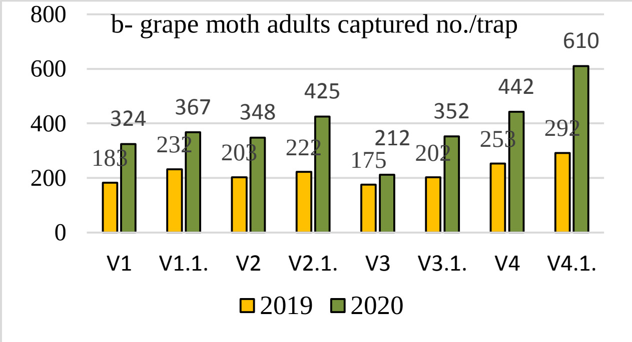


Figure 4. Larvae number (a) and dynamics of *Lobesia Botrana* adult population (b)

Regarding the **production quality**, the first innovative treatment obtained the best results both in 2019 and in 2020 (267 g/l and 262.8 g/l sugars respectively). Overall, there are no significant differences between the treatments in terms of grape production. Harvest data assessment is presented in table 2.

Average values ± standard errors (n=3). The letters in the brackets show the statistical difference among results for p<0,05. For the same compound, a common letter for 2 or more variants shows no significant difference among them.

Conclusions

Three experimental plots were tested using cover crops in comparison with control plots. Each treatment had two subtreatments, one that was phytosanitary treated and another that was not.

During the vegetation period, the vines were inspected repeatedly for epidemic control, in order to determine their resistance to the main diseases of the grapevine: downy mildew, powdery mildew, gray rot and grape black rot. At the same time, plants were inspected for the grapevine moth attack – *Lobesia botrana*.

In 2019, downy mildew, gray rot and grape black rot registered attacks below the threshold. Powdery mildew was an exception in this case, exceeding the threshold, especially for the treated treatments, as well as the untreated control plot.

In 2020, the main manifested diseases consisted of gray rot, grape black rot and downy mildew, the latter causing a moderate attack. Powdery mildew did not manifest in the experimental plots.

Summing up 2019 and 2020, the untreated 4.1 subtreatment registered the highest degree of attack, followed by the rest of the untreated plots. The treated treatments did not register severe degrees of attack.

For the grapevine moth, in both 2019 and 2020, degrees of attack exceeding the threshold were not registered.
From the perspective of production, 2019 registered higher results regarding grape quantity and quality in the treated treatments rather than the untreated treatments. In 2020, the effect of the drought and high temperatures rendered the effect produced by cover crops ineffective, thus obtaining a subpar production in comparison with the year 2019.

Abstract

Application of fluorescence spectroscopy combined with chemometrics algorithms provides rapid and non-destructive screening method in seed quality estimation, widely used in the agricultural industry and crop breeding. Fluorescence spectroscopy is a technique capable of detecting differs fluorophores among various colored maize seed cultivars and through different seed fractions. In the present study, we used the Multivariate Curve Resolution-Alternating Least Squares (MCR-ALS) algorithm to analyse the excitation-emission matrices (EEMs) of various cultivars of colored maize (*Zea mays* L.) seeds and its fractions. The EEMs were recorded as a set, with the excitation ranging from 280 nm to 330 nm and the emission spectra ranging from 300 nm to 550 nm. The MCR-ALS analysis yielded two major fluorescence components for all of the analysed samples. Both position and shape of component 1 (C1) varied among the samples. On the other hand, the position and shape were similar for component 2 (C2). C1 could be used as a marker for the discrimination of colored seeds and their fractions. The observed variations in C1 between the analysed seeds may be due to the presence of their individual fluorophores, assigned to anthocyanins, proteins, and phenolics. In conclusion, the MCR-ALS analysis of the seed emission spectra has a great potential for the rapid and non-expensive characterization of various cultivars of colored seeds.

Keywords: *maize seed, fluorescence, Multivariate Curve Resolution-Alternating Least Squares.*

Introduction

Maize (*Zea mays* L.) is considered one of the major food sources worldwide. Health benefits correlated to consumption of the whole grain are related not only to nutrients like carbohydrates, proteins, dietary fiber, vitamins, and minerals but also to the presence of various phytochemicals (Siyuan, Tong, and Liu 2018). Properties of these phytochemicals contribute to the high antioxidant activities of the maize seeds (Del Pozo-Insfran et al. 2006). It is well known that phenolic compounds, mainly phenolic acids, flavonoids, and tannins are major phytochemicals abundant in seeds, with different composition and distribution within the seed fractions (Ndolo and Beta 2014). Polyphenolics like ferulic and p-coumaric acid found in white maize as well as their derivatives, have antioxidant and anticarcinogenic effects according to reported studies. Red colored maize seeds on the other hand have higher anthocyanins content which also expresses antioxidant activity (Del Pozo-Insfran et al. 2006).

Fluorescence spectroscopy is a sensitive, non-destructive and rapid technique, which doesn't require complex sample pretreatment and preparation. It has been used in analysis of various kinds of food, such as cereals food, dairy products, wine, honey and other samples (Sádecká and Tóthová 2007). Fluorescence spectra of cereals are dependent on the species and the cultivar (Zandomeneghi 1999). Cereal food contains a large number of fluorescent molecules

(fluorophores) such as proteins, phenolics and others. The fluorescence spectrum of a food sample is complex, composed of the signals of the contributing fluorophores. In combination with suitable statistical analysis, fluorescence spectra are useful tools for various applications (Sádecká and Tóthová 2007). Applications of the fluorescence spectroscopy combined with Multivariate Curve Resolution-Alternating Least Squares (MCR-ALS) for food analyses have been reported previously in many studies (Bartolić et al. 2018; Stanković et al. 2019, 2021).
We developed methods for the measurement and analysis of emission spectra with MCR-ALS of macromolecules composed of different kinds of monomers such as proteins and polyphenols for characterization of different cultivars of pigmented maize seeds (white and red).

Material and Methods

The pigmented (white and red) maize seeds were purchased from the local market in Belgrade, Serbia. The two fractions, inner and outer, were separated using the corresponding laboratory sieves after homogenisation in a mill and subsequently with liquid nitrogen in a mortar with a pestle. Obtained powder samples were used without any further processing before the fluorescence measurements.
The front-face fluorescence measurements of the red and white maize fractions were recorded by an Fl3-221 P spectrofluorimeter (JobinYvob, Horiba, France), equipped with a 450 W Xe lamp and a photomultiplier tube. The ranges of the excitation spectra were 280 - 330 nm, while the range for the recorded fluorescence emission spectra was 300 - 550 nm. A spectral bandwidth of 2 nm was used for excitation and emission slits.
The Multivariate Curve Resolution-Alternating Least Squares (MCR-ALS) algorithm was applied to analyse the excitation-emission matrices (EEMs) of studied samples. The MCR–ALS has been used to decompose the overlapping mixture of spectral signals into individual components (Stanković et al. 2019).

Results and Discussion

The representative excitation-emission matrices (EEMs) for the inner and outer seed fractions of the various cultivars of pigmented *Zea mays* L. seeds, are presented in Figure 1 (A-D). The differences were observed in their EEMs, which could be explained by the presence of their individual fluorophores, assigned to anthocyanins, proteins, and phenolics (Sádecká and Tóthová 2007). The EEMs of white seeds (Figure 1 A and B), showed considerably weaker emission signal in the range 330 - 360 nm for the excitation 280 - 295 nm, compared to red seeds.

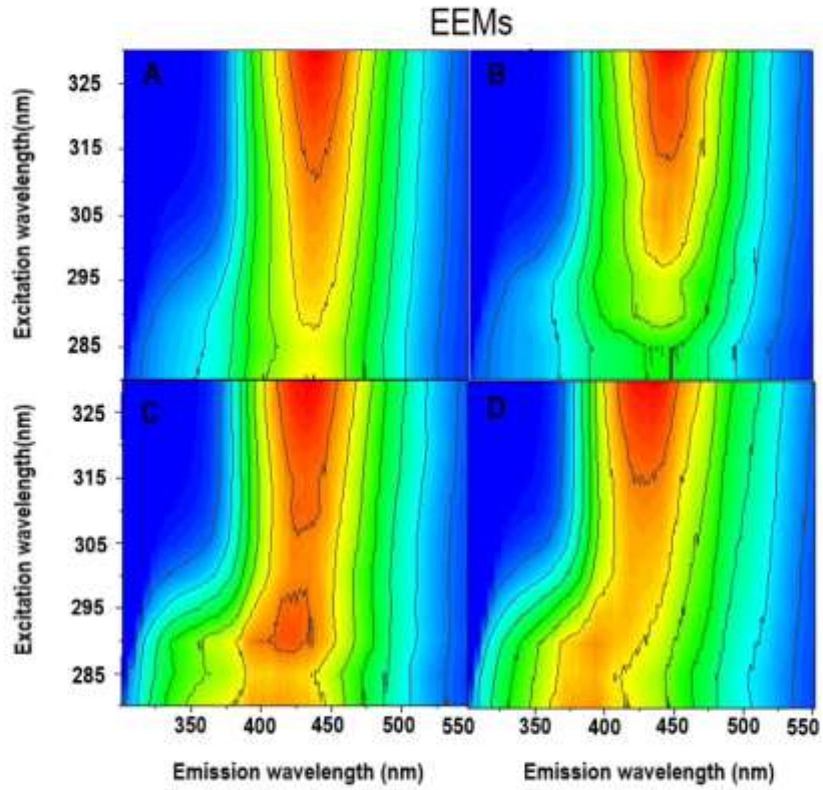

Figure 1. EEMs of the *Zea mays* L. seeds' fractions: inner (A-White and C-red) and outer (B-white and D-red).

Results of MCR-ALS analysis yielded two major fluorescence components. The position and shape of components C1 and C2 varied among the analysed samples.

As shown in Figure 2, the peak position of component 1 (C1) and component 2 (C2) were found around 360 nm and 450 nm, respectively. According to literature data, the fluorescence of the first component (C1) with the emission maximum at 360 nm originates from the aromatic amino acids present in cereal proteins (Zandomeneghi, 1999). Among the analysed samples, the C1 component of the red seeds fraction exhibited the highest relative intensity. Position of the emission maximum of C2 component, assigned to phenolic compounds, varied among the samples.

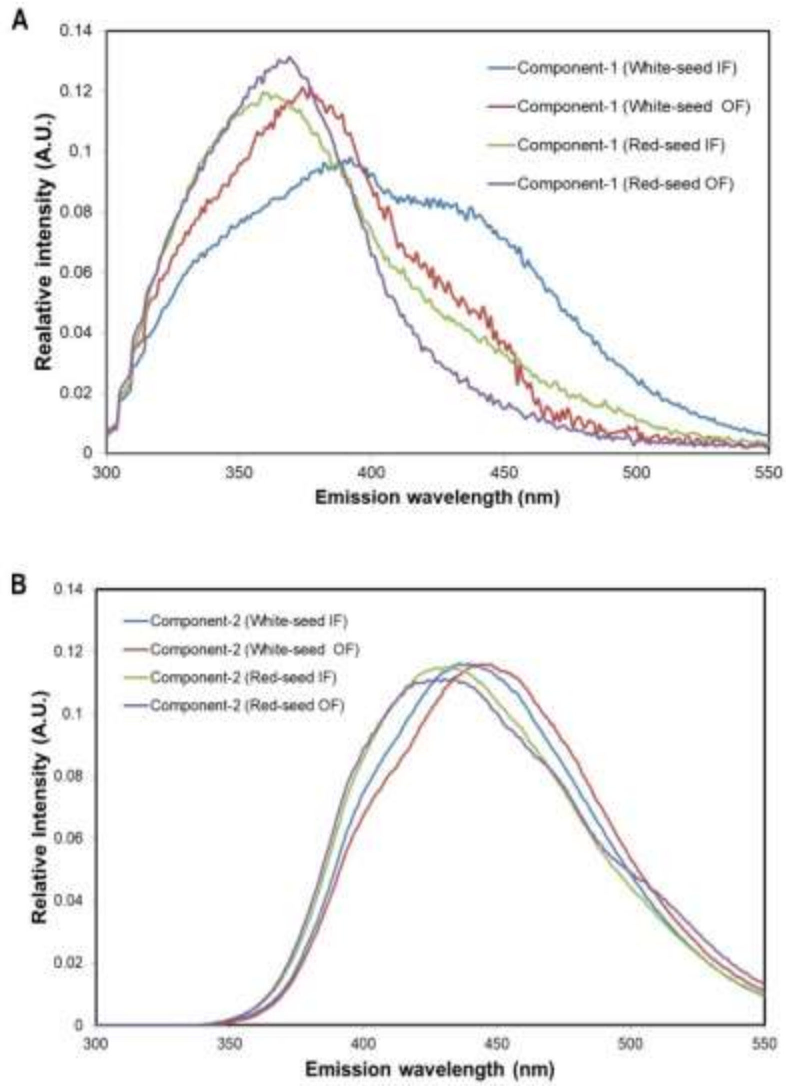

Figure 2. Emission profiles of the spectral components A) component 1 (C1) and B) component 2 (C2) obtained using the MCR-ALS method.

Conclusions

Our results imply that fluorescence spectroscopy combined with the MCR-ALS method could be applied to the rapid, simple, non-expensive characterization of various cultivars of colored seeds and their fractions. As the seed quality depends on different conditions, such as processing, storage, and others, MCR-ALS-derived components may be useful indicators for the screening of cereal seeds' health effects.

Abstract

Areas under organic plant production in Serbia have been permanently increasing. In 2019, of the total area under this type of production (21265.4 ha), the greatest share was under orchards (5324.4 ha), and cereals (21265.4 ha). Considering that organic cereal production has been growing continuously, the aim of this study was to show the range of areas under organic cereals in Serbia and to show the regional distribution for the period 2016-2019. Data were obtained from the Ministry of Agriculture, Forestry and Water Management of the Republic of Serbia. The following methods were used in the study: desk research, content analysis, comparative analyses and analyses of base and chain indices. The largest production of cereals was recorded in the region of Vojvodina (3914.3 ha), and then in the regions of southern and eastern Serbia (708.6 ha). In 2019, the organic wheat production was predominant (2264.9 ha), maize (481.6 ha) and silage maize (323.5 ha) ranked second and third, respectively, while the smallest area was under millet (only 3.3 ha). Considering that Serbia has exceptionally favourable natural conditions for cereal production, it is evident that natural potentials are not used enough, although needs for healthy, organic cereals in the world market are unlimited.

Key words: *organic production, cereals, areas.*

Introduction

An excessive, uncontrolled application of chemicals and fertilisers in conventional agriculture has resulted in numerous adverse consequences for the environment, natural resources, water and soil quality, biodiversity, soil fertility, as well as food safety and quality (Kristiansen et al., 2006). In contrast to conventional agriculture, organic farming is a sustainable system of healthy food production, without residues of pesticides and additives, and with preservation of not only human health, but, also, of the health of plants, animals, soil, agroecosystem and the entire environment (Šeremešić et al., 2010). According to the Codex Alimentarius Commission (2001), '*organic agriculture is a holistic production management system that avoids use of synthetic fertilizers, pesticides and genetically modified organisms, minimizes pollution of air, soil and water, and optimizes the health and productivity of interdependent communities of plants, animals and people*'. An insignificant percentage (<1%) of the worldwide arable land is organically cultivated. Moreover, the global population considerably consuming organically produced food is also insignificant in number. Based on these pieces of information, it is evident that organic food is intended just for niche markets. The set goals of organic farming are far from being achieved in farms throughout the world. Yields obtained in organic agriculture are relatively low (Rahman et al., 2016) and still lower than those achieved in conventional agriculture (Reganold and Wachter, 2016). However, the organic products are more profitable and environmentally friendly, equally or more nutritious and contain less or do not contain at all pesticide residues in comparison with conventionally produced food. In order to achieve objectives of the organic agriculture, farmers have to implement many practices, such as: crop rotation with the use of various crops, different combinations of plants and livestock, leguminous plants (because of nitrogen fixation), organic manure and biological control of pests. Furthermore, not only that these practices should be applied, but the local accessible resources have to be used in the best possible way. In this regard, organic systems are naturally adjusted to a given locations and limitations (Scialabba and Müller-Lindenlauf, 2010). Globally, the increase in the organic agricultural land has been evident for many years (http://www.fao.org). The same trend has been observed in Serbia: the greatest areas have been cultivated with organic fruits (5324.4 ha), followed by cereals (4788.8 ha), industrial plants (2229.6 ha), fodder plants (1797.9 ha), medicinal and aromatic plants (258.5 ha), and the smallest areas are cultivated with organic vegetables (184.2 ha) (Ministarstvo poljoprivrede, šumarstva i vodoprivrede Republike Srbije/Ministry of Agriculture, Forestry and Water Management of the Republic of Serbia, 2021).

Material and Methods

Considering the increase in the areas under organic farming in the Republic of Serbia, the production of organic fruits ranks first and is followed by organic cereal production. Using literature data referring to organic agricultural production, as well as data available from the Ministry of Agriculture, Forestry and Water Management of the Republic of Serbia, the organic cereal production in Serbia in the 2015-2019 period was analysed and graphically presented (using the Microsoft Excel 2010 program) in this study. The study encompassed the following methods: desk research, content analysis, comparative analyses and analyses of base and chain indices. The value of areas under organic cereal production in 2015 was used as a base.

Results and Discussion

Organic plant production has been increasing permanently not only in the world but also in Serbia. According to the data of the Ministry of Agriculture, Forestry and Water Management of the Republic of Serbia (2021), organic plant production was performed on the area of 21265.4 ha in 2019, while this area amounted to 15298 ha in 2015, which was an increase of 5967.4 ha or 39% for the four-year period. Although these areas increased in 2018 and 2019, the decrease of the areas was recorded in 2016 (by 6.1%) and 2017 (by 12.3%) (Table 1).
According to the 2019 reports of FiBL and FAO (http://www.fao.org), organic production took place in 187 countries on the area of 72.3 million hectares, while global sales of organic food and drink reached more than 106 billion euros. Moreover, according to the same reports, 3.1 million organic producers were registered globally and only 513 in Serbia (Ministry of Agriculture, Forestry and Water Management of the Republic of Serbia, 2021). Considering the global distribution of areas under organic farming in 2019, Oceania is a region with the most organic agricultural land (35.9 million ha), followed by Europe (16.5 million ha), Latin America (8.3 million ha), Asia (5.9 million ha), North America (3.6 million ha), while the smallest areas are in Africa (only 2 million ha). Europe is a region with a steady, long-term growth of organic agricultural land; it has over 23% of the world's organic agricultural land and is followed by Latin America (12%). Ten countries with the largest areas of organic agricultural land in 2019 were: Australia (35.69 million ha), Argentina (3.67 million ha), Spain (2.35 million ha), USA (2.33 million ha), India (2.3 million ha), France (2.24 million ha), China (2.22), Uruguay (2.14

million ha), Italy (1.99 million ha) and Germany (1.61 million ha) (Willer et al., 2021). According to Willer et al. (2021), in EU, in 2019, the organic market again grew faster than organic areas, and the EU organic food market increased to more than 41 billion euros or by 8%, whereas the farmland grew by 6%.

Table 1. Areas under organic plant production in Serbia in the 2015-2019 period

Year	Conversion period	Base indices	Organic status	Base indices	Total(ha)	Base indices
2015	7669.5	100	7628.5	100	15298.0	100
2016	6966.5	90.8	7391.4	96.9	14358.0	93.9
2017	5895.6	76.9	7527.6	98.7	13423.1	87.7
2018	6599.9	86.1	12654.7	165.9	19254.6	125.9
2019	7539.4	98.3	13726.1	179.9	21265.4	139.0

*Source: The author's presentation according to data of the Ministry of Agriculture, Forestry and Water Management of the Republic of Serbia (2021)

Organic production in Serbia varied in the analysed period from 4251.9 ha in 2015 to 4607.3 ha in 2016, so areas increased by 355.4 ha. In 2017 and 2018 areas decreased to 3661.7 ha and 3613.6 ha, respectively, while in 2019 the increase by 1175.2 ha was recorded and areas under organic production amounted to 4788.8 ha (Figure 1). Considering global cereal production in 2019, it took place on the area of 5073137 ha, ranking the first, while oilseed production on the area of 1676502 ha ranked second. The largest areas under organic cereal production are in Europe (2958165 ha), followed by Asia (1253310 ha), North America (582255 ha), Latin America (163769 ha), Africa (74344 ha) and Oceania (41293 ha) (Willer et al., 2021).

Figure 1 shows areas under organic production of nine plant species, with wheat ranking first (on average for the analysed period from 2015 to 2019) (41.4%).

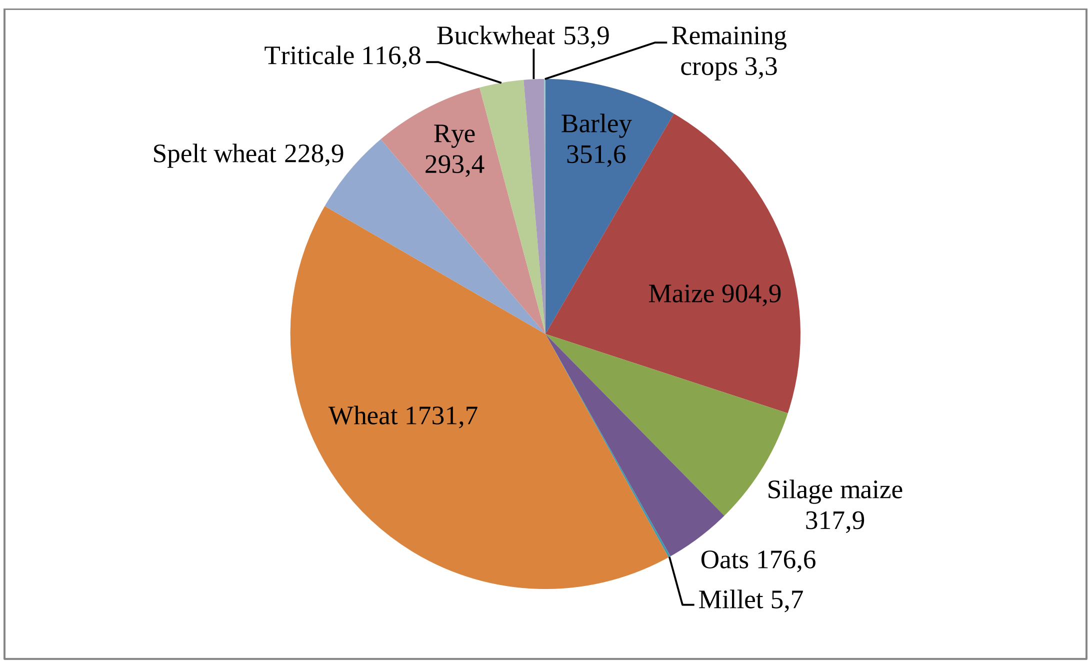

Figure 1. Areas (ha) under certain cereal crops in the organic system in Serbia (average for the 2015-2019 period)

The second largest areas were under maize (21.6%). Smaller areas were cultivated with barley (8.4%), silage maize (7.6%), rye (7%) and spelt wheat (5.5%), while less than 5% of areas were cultivated with oats (4.2%), triticale (2.8%) and buckwheat (1.3%).
Figure 2 presents the trend of areas under organic grain crops in Serbia in the 2015-2019 period.
In regard to the regional distribution of production, Vojvodina with the share of 3914.3 ha in 2019 ranked first and was followed by regions of south and eastern region Serbia, where production areas significantly varied over the four-year period.

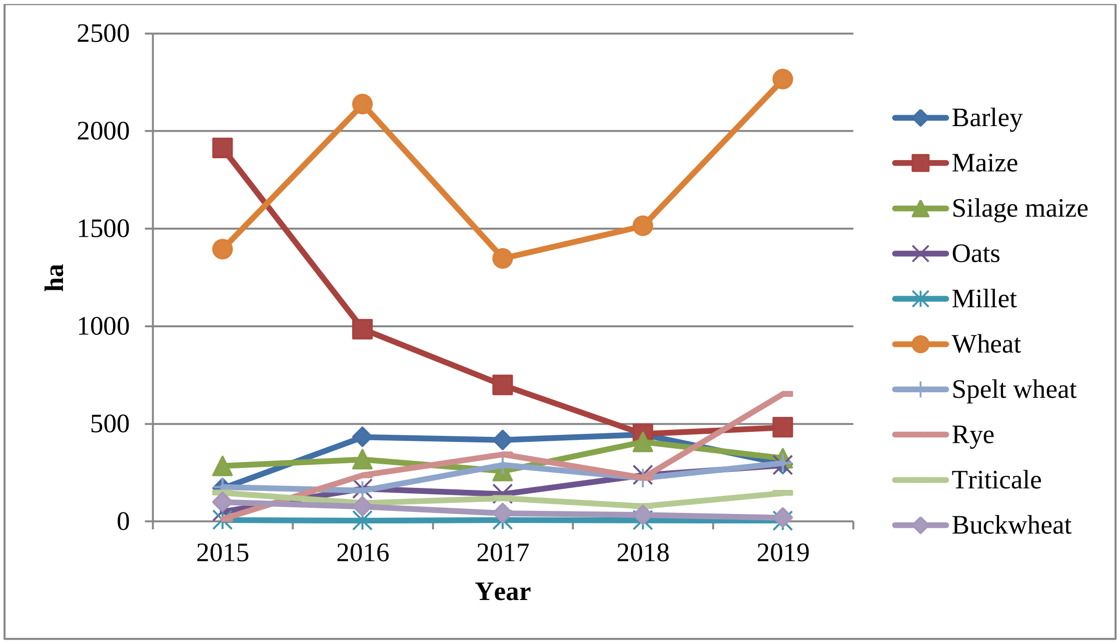

Figure 2. Areas (ha) under certain cereal crops in the organic system in Serbia in the 2015-2019 period

Namely, total of 158.8 ha under organic cereal production in 2015 increased seven times in 2016 (1182.8 ha). Then, during the following three years, these areas were reduced and amounted to only 708.6 ha in 2019 (Figure 3.). Even smaller production was registered in the region of Šumadija and western Serbia, where areas varied from 16.2 ha in 2015 to 160.4 ha in 2019. The smallest total area under organic cereal production was in the region of Belgrade and amounted to only 5.4 ha.

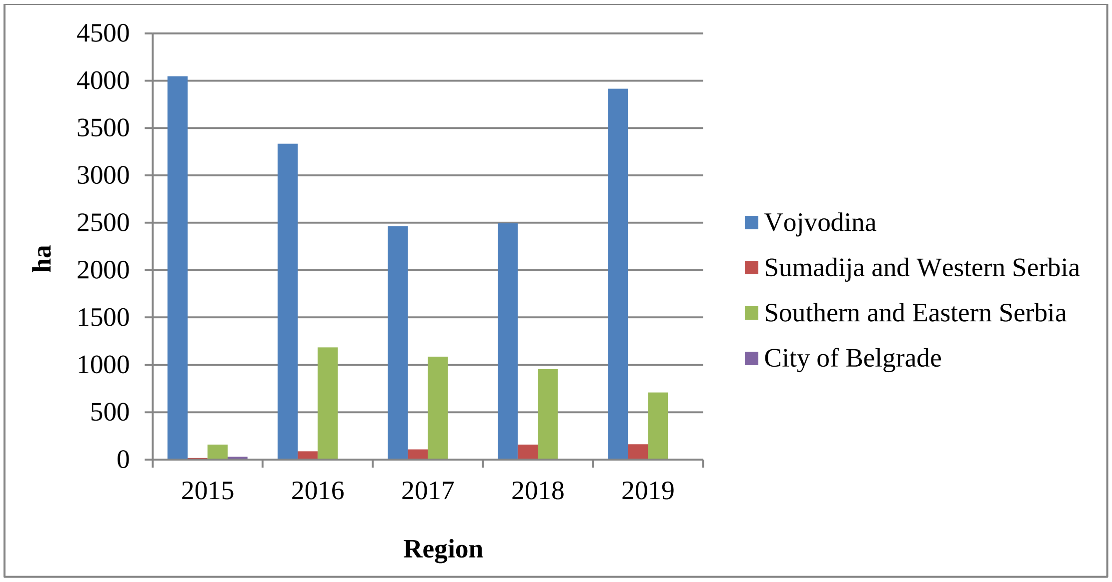

Figure 3. Areas under organic production in Serbia, over regions in the 2015-2019 period

In regard to the distribution of the global organic cereal area over a cereal type, wheat ranked first with 33.32%, and was followed by grain maize and silage maize with 14%, rice with 12.66%, oats with 11.63%, barley with 9.99%, rye with 5.47%, and millet with only 0.46% (Willer et al., 2021). The dynamics of changes in areas under certain grain crops in Serbia in the 2015-2019 period was presented by base and chain indices (Table 2).

Table 2. Dynamics of changes in areas under certain grain crops in Serbia in the 2015-2019 period

	Base indices (2015 = 100)				Chain indices			
Cereal crop	**2016**	**2017**	**2018**	**2019**	**2016**	**2017**	**2018**	**2019**
Barley	254.9	245.6	262.4	173.3	254.9	96.3	106.8	66.0
Maize	51.5	36.5	23.4	25.2	51.5	70.9	64.2	107.5
Silage maize	111.8	90.9	143.4	114.0	111.8	81.3	157.8	79.5
Oats	335.9	281.2	476.9	578.8	335.9	83.7	169.6	121.4
Millet	49.8	98.8	76.2	42.1	49.8	198.2	77.1	55.3
Wheat	153.2	96.6	108.5	162.4	153.2	63.1	112.3	149.6
Spelt wheat	89.7	164.8	126.1	170.0	89.7	183.6	76.6	134.8
Rye	2070.2	3008.6	1957.5	5730.1	2070.2	145.3	65.1	292.7
Triticale	64.1	80.7	53.3	98.8	64.1	125.9	66.0	185.5
Buckwheat	76.8	42.5	33.1	19.3	76.8	55.3	78.0	58.3

*Source: The author's presentation according to data of the Ministry of Agriculture, Forestry and Water Management of the Republic of Serbia (2021)

The drastic increase in the areas of 478.8% and 5630.1% was recorded in oats and rye, respectively in comparison to the base year (2015). A noticeable increase of approximately 70% was observed in 2019 in barley, wheat and spelt wheat. A pronounced decrease in areas were recorded in 2019 in buckwheat (by 80.7%), maize (by 74.8%) and millet (by 57.9%) in comparison to 2015. The areas of organic production of silage maize and triticale noticeably oscillated in the observed period, but were approximately the same.

Conclusions

The total area under organic cereal production in Serbia ranked second after areas under organic fruits. In regard to the regional distribution of organic production, Vojvodina encompassed the largest areas and the regions of south and eastern Serbia followed. Wheat, among nine cereal crops organically grown in the 2015-2019 period ranked first. The extreme increase in areas in relation to the base year was recorded in oats (478.8%) and rye (5630.1%), and then in barely, wheat and spelt wheat. On the other hand, the pronounced decrease in the areas was recorded in buckwheat, maize and millet. Serbia, with extremely favourable climate conditions, large areas with unpolluted land, great number of farmers, is a country with a high potential for production of organic cereals. Nevertheless, the number of farmers and the size of production areas, despite all favourable conditions, are still small.

Abstract

Butternut Squash (*Cucurbita moschata*) is grown in Serbia on relatively small areas, despite its extraordinary nutritional properties that place it among the species with significant potential for the food industry. However, in the future, due to climate change, it is expected to expand its production in our country and region, primarily due to tolerance to high temperatures and drought, but also due to significant tolerance to diseases. In order to improve the technology of growing butternut squash in accordance with organic principles, a field experiment was conducted on the two soil types i.e. two different locations, with aim to investigate the effects of application of two different fertilizers on the seed yield and seed quality. Both locations are situated in the basin of the river Velika Morava, on two different types of soil (vertisol soil type and brown forest soil). At both locations, the pre-crop was corn and the applied agro-technical measures were in accordance with the principles of organic production. The average yield of Butternut Squash seeds varied from 678,1 kg/ha, as recorded on the brown forest soil, on the control treatment without fertilization to 918.75 kg/ha as recorded on the treatment with organic fertilizer NP 1 on the vertisol. Significant differences were also observed in seed germination which ranged from 84.67% in the control treatment on the brown forest soil to 98.33% as recorded in the treatment with the organic fertilizer NP2 on vertisol.

Keywords: *fertilizers, organic production, seed quality*.

Introduction

Butternut Squash (*Cucurbita moschata*) is an annual vegetable species belonging to the *Cucurbitaceae* family with vining growth, large and dark green leaves with bright patterns and big yellow flowers. It is grown for its specifically shaped fruits with characteristic color. In a human diet, it is appreciated for its distinctive taste, high provitamin A content and low fat content (Armesto *et al*. 2020). Thanks to these properties it has a low caloric content and it is interesting for the control of body weight, as well as cholesterol and triglyceride levels in the blood (Choi *et al*., 2007). Despite its extraordinary nutritional properties that place it among the species with significant potential for the food industry, Butternut Squash is grown on relatively small areas in Serbia, mostly like a few plants in farmers own gardens, rarely as a cash crop. However, In the future, due to climate changes, it is expected to expand its production in our country and region, primarily due to tolerance to high temperatures and drought (Ara *et al*. 2013, Shen and Yuan, 2020), but also due to significant tolerance to diseases and pests (Cavanagh *et al*., 2009; King *et al*. 2010).

The exact information about the butternut squash harvested area in the world is not available. However, the area on which the pumpkins, squash and gourds were cultivated ranged from 1.561 to 2.07 million ha in the last decade. In that period the average yields of mentioned species altogether ranged from 13.07 to 14.9 t/ha (FAOSTAT DATA 2021). According to some scientific works, the yields of butternut squash ranged from 23.03 to 78.61 for different varieties grown in the Slovak republic (Andrejiova *et al*., 2018), from 19.4 to 34.9 t/ha for different crop densities (Rangarajan *et al*. 2003), from 18.9 to 31.3 t/ha for different chemical and organic fertilizers in the agroecological conditions of Iraq (Ali *et al*., 2019), from 59.4 to 79.8 t/ha for different irrigation regimes and mulching in the agroecological conditions of northern India (Mishra, 2017). However, there is a lack of data concerning butternut squash seed yields and seed quality (Sajjan and Prasad, 2009). The Republic Statistical Office of the Republic of Serbia does not have available data on surfaces, yield and production of butternut squash in Serbia (Republic of Serbia, 2021a). According to National list of registered varieties, at the moment, only two different varieties of butternut squash are registered (Republic of Serbia, 2021b).
The two most frequent soil types in the central Serbia are the vertisol and the brown forest soil. Vertisols are soils with high silt and clay content that shrink and swell extensively upon changing soil moisture conditions (thanks to its clay content). They occur worldwide under various parent material and environmental conditions. Vertisol exhibits unique morphological charachteristic such as the presence of wedge-shaped aggregates so the shrink-swell phenomena are the dominant pedogenic processes in vertisols. That causes the changes in interparticle and intraparticle porosity when the moisture content is changing. In central Serbia, field and vegetable production is very prevalent on this type of land (Coulombe *et al*. 1996, Jelić *et al*. 2011; Dugalić and Gajić, 2012).
The brown forest soils occur in Europe, North America, Russia, China and elsewhere in the world in broadleaf forests of the temperate zone and agricultural land on which the previous forests were cleared sometime in the past. They have some good productive properties for field and vegetable crops production but in Serbia they are used more frequently for the production of fruits and vines (Dugalić and Gajić, 2012; Shishkov and Kolev, 2014).
One of the most important tasks in expanding the production of butternut squash is to provide sufficient amounts of seeds for planting and apply all knowledge that can affect production improvement. To that end, the aim of this work is to determine the optimal model of fertilizer application on these two most prevalled types of land in central Serbia.

Material and Methods

The field experiments were performed at two locations with different soil types, the first one near Jagodina town on the vertisol soil type (44°01′55.23″ N 21°15′18.55″ E, 108.0 m above sea level) and the second one in Žabari municipality in Serbia on the brown forest soil (44°37′38.56″ N 21°11′21.08″ E, 222 m above sea level). The basic chemical properties of different soil types were shown in Table 1.

Table 1. Soil chemical properties at the two experimental locations

Location	pH H_2O (KCl)	$CaCO_3$ (%)	Humus (%)	Total N (%)	P (ppm)[1]	K (ppm)[1]
Žabari	6.61 (5.15)	0.0	2.30	0.115	196.3	283.0
Jagodina	7.32 (5.59)	0.0	2.92	0.15	195.8	361.4

[1-] Available P an K

The previous crop was field corn and the harvest residues were chopped and plough into the soil. A mineral fertilizer (100 kg/ha, N-46%, UREA) was added. However, at the Žabari location about a half of harvested residues were colected and removed from the experimental field. At the late autumn, additional amount of mineral fertilizer (200 kg/ha N:P - 11:52) was applied and the soil is further tilled using disc harrow.
At the mid April, examined fertilizers (8.0 t/ha of organic fertilizer NP 1 – dried chicken manure with N, P and K content of approximately 4, 4, and 4 percent; 15 t/ha of organic fertilizer NP2 – with declared N, P and K content of approximately 4, 7, and 8 percent, respectively) were applied on the marked experimental plots and incorporated in to the surface soil layer using two wheel tractor with rotary tiller. Up to 4 seeds were sown manualy on the marked places (1.5m distance betveen rows and 0.6 distance betveen plants in the row) on the April the 18th (Žabari) and April the 19th (Jagodina).
There were 9 elementary plots randomly distributed on the Žabari location and also in another location the same (Jagodina). The size of elementary plot was 6.0 x 4.2 m, consisted of 4 rows each. The surface area of each elementary plot was 25.2 m^2.
After shoot emerging, excessive plants were removed and the space betveen the rows were cultivated several times in order to supress the apearance of weeds. Weed control within rows was performed manually. All measures applied except the mineral fertilization (farmyard of acceptable quality and allowed mineral fertilizers were not available) were in accordance to the Law on Organic Production and the accompanying regulations (Republic of Serbia 2021c).
Data on climate parameters for the nearest meteorogical station (Veliko Gradište) were provided through the internet portal of the Republic Hydrometeorological Service of Serbia (RHSS 2021). However, due to the specifically modified weather conditions at the Žabari experimental field site, during some summer and autumn months, precipitation was measured with the help of a round vessel with a graded scale, and the results are shown in parentheses (Table 2).

Table 2. Temperature (T) and precipitation (P) parameters for Butternut squash crop at two locations during the trial (2020), with long-term averages

Months	Žabari				Jagodina			
	2020		1981-2010		2020		1981-2010	
	T ^oC	P (mm)*	T ^oC	P (mm)	T ^oC	P (mm)	T ^oC	P (mm)
Apr	12,2	2	11,8	55.9	12.3	23.1	11.4	52.9
May	15,8	93	17	73.6	16	81.1	16.2	78.7

Nov	6,4	15,7 (12)	6	47.3	6.4	17.3	5.9	52.9
Av/Sum	16.5	505(440)	15.8	480.3	16.6	463.4	15.06	461.6

*- values within parentesis are related to the seasonal precipitation corection for the Žabari experimental site.

The Butternut Squash fruits were harvested during the late october of 2020. Samples per each treatment replication were taken (inner rows were used for sampling in order to avoid border effects). Collected fruits were weight on the field using hand scale (the data not shown) and the seeds were taken out from each fruit. The seed yields (natural seeds without processing) were measured using the technical scale after few days of drying in the tin layers in the ventilation barn. For each seed sample (three repetitions) the percentage of germination was determined in the acredited seed laboratory. The calculated percentage of germination data were transformed by arcsine $\sqrt{(x/100)}$ prior to analysis. Two way ANOVA and further LSD-testing were performed using Statistika 7 software package for Microsoft Windows.

Results and Discussion

Conventional farming agricultural production, without farmyard application, have been practiced at both experimental sites and strong anthropogenic factor with long-term rotation of corn, wheat and meadow/clover was present. The experiment was transition to organic agricultural practice. Chemical analysis of the examined soils from Žabari and Jagodina experimental sites indicate similar values of basic parameters with smaller differences in pH values, humus and potassium content (Table 1.). On the other side, there were differences concerning temperature conditions and precipitations (Table 2.). Despite the fact that the year was with enough rainfall, severe spring drought in the pre-sowing period and after sowing on the Žabari experimental site, slowed down the germination and emerging of butternut squash plants which later affected the crop homogeneity and possibly the results of this trial. Also the precipitation schedules during the vegetation period were diverse on the both localities. However, the examined effects of locality and applied fertilizers significantly affected butternut squash seed yields and germination rate (Table 3.).

Table 3. Mean squares (MS) from ANOVA for the butternut squash seed yield and the percentage of germination on two examined localities and different treatments (Fertilizers).

Effect	d.f.	Seed Yield	Percentage of germination
Locality (L)	1	35529**	29.4*
Fertilizers (F)	2	39366**	59.1**
L / F	2	89	112.4**
Error	12	357.41	3.61

*,** – significant at the 0.05 and 0.01 levels of probability, respectively

Table 4. Butternut squash seed yields (t/ha) and the percentage of germination on two examined localities and different treatments (Fertilizers)

Locality	Fertilizers	Seed yield (t/ha)	Germination (%)
Žabari	Control	678.10	84.67
	NP1	786.50	98.33
	NP2	834.07	96.00
Jagodina	Control	762.23	96.67
	NP1	884.27	93.33
	NP2	918.73	96.67
	$lsd_{0.05}$	19.42	1.95
	$lsd_{0.01}$	27.22	2.74

During the experiment, the average butternut squash seed yield on both sites was 810.65 kg/ha, but on vertisol (Jagodina), higher average yields were achieved compare to brown forest soil (Municipality of Žabari). The highest butternut squash seed yield was achieved at the locality of Jagodina when NP2 fertilizer has been applied (918.73 kg/ha) and the lowest (678.1 kg/ha) on the control treatment on the Žabari experimental site (Table 4.).

According to results of Sajjan and Prasad (2009), *Cucurbita moschata* seed yields can be doubled using fertilizers and plant growth stimulators. The fruit yields achieved are significantly below the yields reported by Mishra (2017) and significantly below the highest yields reported by Andrejiova *et al*. (2018) (the data not shown). Knowing the approximate share of seeds in butternut squash fruit yields, our results varied in accordance with results of Rangarajan *et al*. (2003) and Ali *et al*., (2019), but were higher compare to some other research (Sajjan and Prasad, 2009).

The percentage of germination is one of the key parameters concerning seed quality. The *Cucurbita moschata* percentage of germination is usually above 90% (Valdez-Melara *et al*., 2009) and all treatments were in that range except control treatment in Žabari, probably due to presence of some fruits with sturdy and immature seeds.

Conclusions

Yields that were significantly below genetic potential indicate that agroecological conditions were not optimal despite sufficient amounts of precipitation. Based on the results of the experiment, a better choice for butternut squash seed production is vertisol. In order to enable high seed yields as well as sustainable organic production and production according to principles of organic butternut squash cultivation during the conversion period it is necessary to use high doses of organic fertilizers. The NP2 fertilizer is recommended, regardless of the type of soil on which the production is organized.

When it comes to the basic seed quality parameter, the percentage of germination, it is not possible to give definitive instructions on this issue, because despite statistically significant differences between treatments, logical conclusions cannot be made and further investigation is needed.

Acknowledgement

This study was supported by the Ministry of Education, Science and Technological Development of the Republic of Serbia (Grant number: 451-03-9/2021-14/200216). We owe gratitude to Živadin Ugrinović and Zlatibor Milenković, holders of registered agricultural farms where the field experiments have been established. Special thanks to Zora Milenković, Stojadin and Nevena Ugrinović for technical support.

Abstract

The effects of six biological plant protection products, permitted in organic production ('Extrasol F', 'Polyversum', 'Timorex gold',' Vegard', 'Ozoneem trichul', 'EcoBooster Calcium'), in addition to two herbal preparations ('LAB 3' and 'LAB 4'), were examined on germination and seed quality of *C. recutita* cv. "Banatska". The aim of study was to discover the most effective bio-product with beneficial effects on quality and health of German chamomile seeds. Seed germination testing was conducted according to the standard procedure suggested by a Rule book on seed quality control, while the seed health was examined by the filter paper method. The seeds were treated with 15 ml of bio-product solution, while the same amount of distilled water was used as a control. The experiment was conducted in triplicates, and the seeds were observed on 14^{th} day following the treatment. In comparison to control, seed germination rate was increased in following treatments: 'LAB 4' by 11%, 'Extrasol F' by 9%, 'EcoBooster Calcium' and 'LAB 3' by 2%. Based on the symptoms observed on the seed surface, presence of *Alternaria* sp. was confirmed. Compared to control, the infection of seeds was reduced by 1% in treatments with 'Vegard', 'LAB 3' and 'LAB 4'. However, doubling the concentration didn't reduce infection but reduced germination in comparison to control. Since 'LAB 4' and 'Extrasol F' affected the most germination and to a certain extent prevented seed infection, both bio-products could be recommended for safe application on chamomile seeds.

Keywords: *German chamomile*, *germination and seed health*, *biological products*, *Alternaria* sp., *organic.*

Introduction

Chamomilla recutita L. is one of the most famous medicinal plants in Serbia, belonging to the Asteraceae family. It is cultivated for its inflorescences. Once properly dried, they represent well known herbal drug *Chamomilae flos*, which is widely used in pharmaceutical and cosmetic industries. It contains 0.2-1% essential oil (*Aetheroleum chamomilae*) whose color, depending on temperture, varies from dark blue to green (Glamočlija et al., 2015). As the plant is well-known for it antiseptic, antibacterial and antiviral properties the demands for its herbal drug is continuosly increasing. Apart that German chamomille is used in various herbal preparations for plant nutrition and protection it is also used in the composting procedure (Oljača et al., 2020). Therefore, it is quite important to enable conditions for production of healthy and safe herbal raw material, free from pesticide residues, heavy metals and economically harmful pests and pathogens. In order to produce a sufficient amount of such raw material, healthy and good quality seeds of German chamomile should be used.

Apart to commonly applied conventional measures, in attempt to increase seed germination various bio-agrotechnical measures use to be examined, particularly the "bio-products". The term bio-products stands primarily for toxicologically harmless and ecologically completely acceptable products. They might not be as effective as synthetic chemicals but they use to keep the level of harmful microorganisms below the threshold of economic harmfulness and within acceptable limits (Milenković, 2015). Among them stand out, 'Extrasol F' is a bio-product composed of rhizosphere nitrogen-fixing bacteria (*Bacillus subtilis* strain Č13) intended to improve seed germination. The bio-fungicide 'Polyversum' is based on the fungus *Pythium oligandrum* and is recommended for protection of seeds from economically important phytopathogenic fungi. The active ingredient of 'Timorex gold' bio-product is a tea tree essential oil (*Melaleuca alternifolia*) dissolved in paraffin oil (15×10^{10} CFU/ml), and apart to conventional it could be also used in organic production for protection against fungal pathogens causing symptoms of gray mold and potato blight (Kołodziejczik, 2018).
The application of bio-products based on beneficial fungi, bacteria and plant extracts can prevent the appearance of phytopathogenic fungi causing decay of cultivated plants but also damping of seedlings if the plantation use to be established via nursery plants. Soil pathogens such as *Pythium debarianum*, *Fusarium* spp., *Sclerotinia* spp., *Phytophtora* spp., *Aspergillus* spp., *Alternaria* spp., *Rhizoctonia* spp. and others are mainly causing of such symptoms.
The aim of study was to examine the influence of various bio-products - biofungicides, biostimulants and bioinsecticides, and some herbal preparations on quality and health of German chamomile seeds.

Material and methods

The study was conducted in the laboratory of Agricultural Research and Development of the Institute for Medicinal Plants Research "Dr Josif Pančić" in Belgrade. The two-years old seeds of German chamomile (*C. recutita* L. Rauch.) cv. "Banatska", produced at the experimental field of the Institute, have been subjected to testings on seed germination and seed health, during 2021. The details on six bio-products (from the list of plant protection and plant nutrition products and the list of soil improvers, permitted in organic production) and two herbal preparations (created in the Institute), are provided in Table 1.

Table 1. Bio-products used in the treatments of German chamomile seed

Bio-product	Active substances		Short business name	
	name	**content**	**manufacturer**	**representative**
Extrasol F	*Bacillus subtilis* strain Č13	1×10^8 CFU/cm^3	BioGenesis, Bačka Topola and Jugo Hem, Leskovac	-
Polyversum	*Pythium oligandrum*	3% (1×10^6 - 10^7 oospore/g)	Biopreparaty, Czech Republic	Vins 2000, Belgrade
Timorex gold	tea tree oil *(Melaleuca alternifolia)*	222.5 + 194.5 g/l	Stockton Israel, Israel	Stockton, Belgrade

	+ paraffin oil			
Ozoneem trichul 1% EC	Azadirachtin	10 g/l	Ozone Biotech, India	BioGenesis, Bačka Topola
EcoBooster Calcium®	organic nitrogen fertilizer of animal and plant origin	3-3.5% total, 1.5-2% organic N, 5% organic C, CaO min. 2.5%, max. 12 C/N	Ekopatent, Vrbas	Ekopatent, Vrbas
Vegard	fertilizer and special products	amino acids 1-2%, fulvic acids 5%, humic acids 5%, other organic materials 20%	Beijing Kingbo Biotech, China	Timings, Belgrade
LAB3	herbal preparation for protection and plant nutrition	fresh aerial parts of chamomile 20%, horsetail 20%, valerian 20%, dandelion 20%, yarrow 10%, nettle 10%, comfrey 5% and liquorice 5%	Institute for Medicinal Plants Research "dr J. Pančić", Belgrade	
LAB4	herbal preparation for protection and plant nutrition	fresh aerial parts of chamomile 50% and valerian 50%	Institute for Medicinal Plants Research "dr J. Pančić", Belgrade	

Testing of bio-products on the quality of German chamomile seeds

The energy and total seed germination were examined as suggested by the Rule book on seed quality control („Official Gazette of the Socialist Federal Republic of Yugoslavia", no. 47/87, 60/87, 55/88 and 81/89, „Official Gazette of the Socialist Republic of Yugoslavia", no. 16/92, 8/93, 21/93, 30/94, 43/96, 10/98, 15/2001 and 58/2002 and „Official Gazette of the Republic of Yugoslavia", no. 34/2013). In short, the seed germination testing was conducted with 100 seeds on filter paper in Petri dishes, in triplicates. The seeds were previously treated with 15 ml of previously prepared solutions of the following single bio-products prepared in two concentrations: 'Extrasol F' (0.20 and 0.40 ml/kg), 'Polyversum' (0.50 and 1 g/kg), 'Timorex gold' (1 and 2 ml/kg), 'Ozoneem trichul' (1 and 2 ml/kg), 'EcoBooster Calcium' (0,50 and 1 ml/kg), 'Vegard' (0,50 and 1 ml/kg), 'LAB 3' (1 and 2 ml/kg) and 'LAB 4' (1 and 2 ml/kg), all being dissolved in 100 ml of distilled water. The same amount of distilled water (15 ml) was used in the control treatment. The number of germinated seeds was counted by the use of binocular loupe on 4th and 14th day from the day of setting up the experiment (ISTA, 2010).

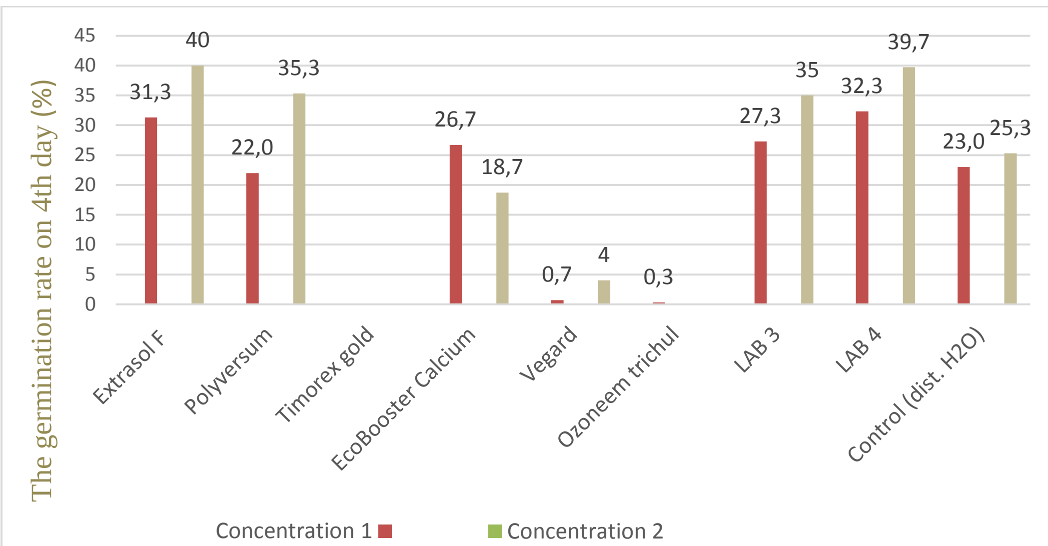
The seed health status of German chamomile

The seed health status was examined by the filter paper method. The experiment was conducted on previously sterilised (110 °C i 1h) and moistened filter paper, using 100 unsterilised seeds, in triplicates. Macroscopic and microscopic seed examinations were performed 14th day following their incubation in humidity chamber at T 20±2 °C. An Olympus CX43 microscope (Olympus, Hamburg, Germany) was used to observe the microscopic characteristics of the phytopathogenic fungi developed on the seeds, and the photographs were taken with an Axiocam ErC.5s (Zeiss, Göttingen, Germany).

Results and discussion

Comparative presentation of the efficacy of eight bio-products tested in two concentrations, on germination rate of German chamomile seeds, observed on 4th experimental day, are given in Graph 1.

Graph 1. The germination rate of German chamomile seeds observed on 4th day of the experiment (%).



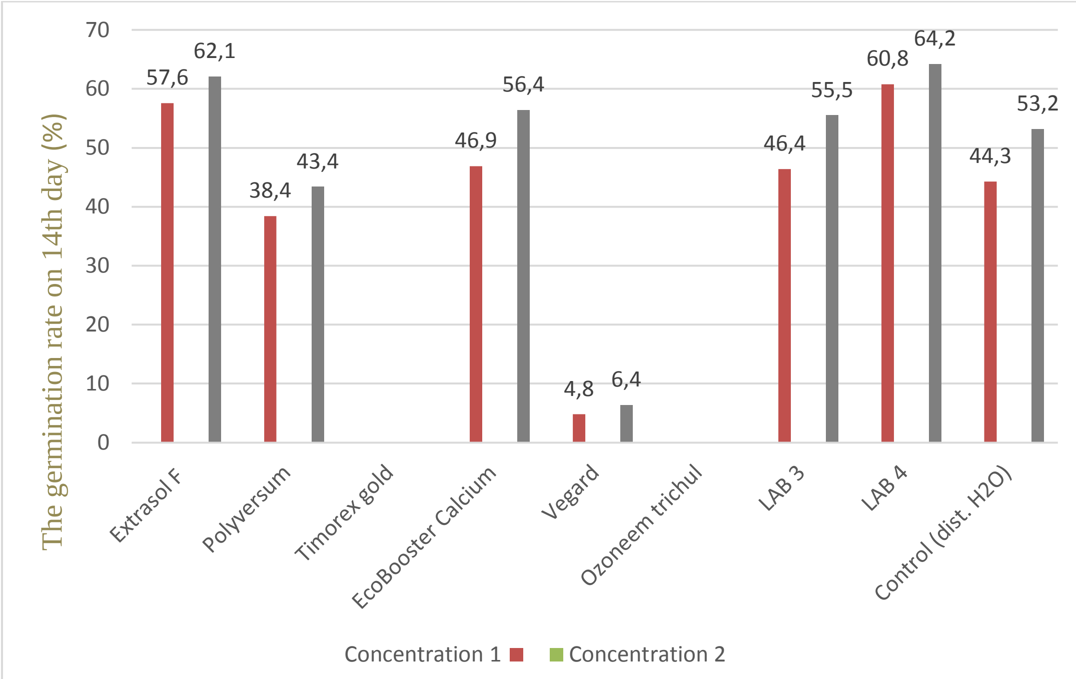
In seeds treated with the first (lower) concentrations of tested bio-products, the germination rate proved to be the highest in 'LAB 4' (averagely 32.3%) although similar results were also obtained with 'Extrasol F' (31.3%) and somewhat lesser with 'LAB 3' (27.3%).

The seeds treated with the second (higher) concentration of bio-product, generally had higher EG values (on average by 3.8%) compared to those achieved by the first concentration. In the treatment with second (higher) concentration of bio-product, the highest germination rate was achieved with 'Extrasol F' (40.0%) followed by 'LAB 4' (39.7%), although 'Polyversum' did not lag behind them a lot (35.3%).

The product 'Extrasol 55' stopped the development of economically significant plant diseases in grain crops (Jevtić et al., 2005), while the product of 'Polyversum' significantly affects on the germination rate of bean and soybean seeds (Horoszkiewicz-Janka et al., 2013).

Comparative presentation of the efficacy of eight bio-products tested in two concentrations, on the total germination of German chamomile seeds, observed on 14th experimental day, are given in Graph 2.

Graphs 2. The total germination of German chamomile seeds observed on 14th day of the experiment (%).



In the treatments with two concentrations of bio-products, the highest total of germination was achieved with 'LAB 4' (60.8% and 64.2%) followed by 'Extrasol F' (57.6% and 62.1%), while 'EcoBooster Calcium' had an effect (46.9% and 56.4%). The bio-products 'Timorex gold' and 'Ozoneem trichul' did not effect on seed germination. Filipović et al. (2014) showed that herbal preparation 'LAB 1' is shown beneficial effect on the EG and TG of two medicinal plant species, white origano (*Origanum heracleoticum* L.) and marjoram (*Origanum vulgare* L.). The biofungicides 'Extrasol F' and 'Polyversum' applied in the recommended concentrations (0.20 ml/kg and 0.50 g/kg, respectively), had an effect on fennel seed germination 73.3% and 64.7% (Filipović et al., 2021).

Comparative presentation of the efficacy of eight bio-products tested in two concentrations, on the occurence of German chamomile seeds pathogens, observed on 14th experimental day, are given in Graph 3.

Graphs 3. The occurence of pathogens on German chamomile seed observed on 14th day of the experiment (%).

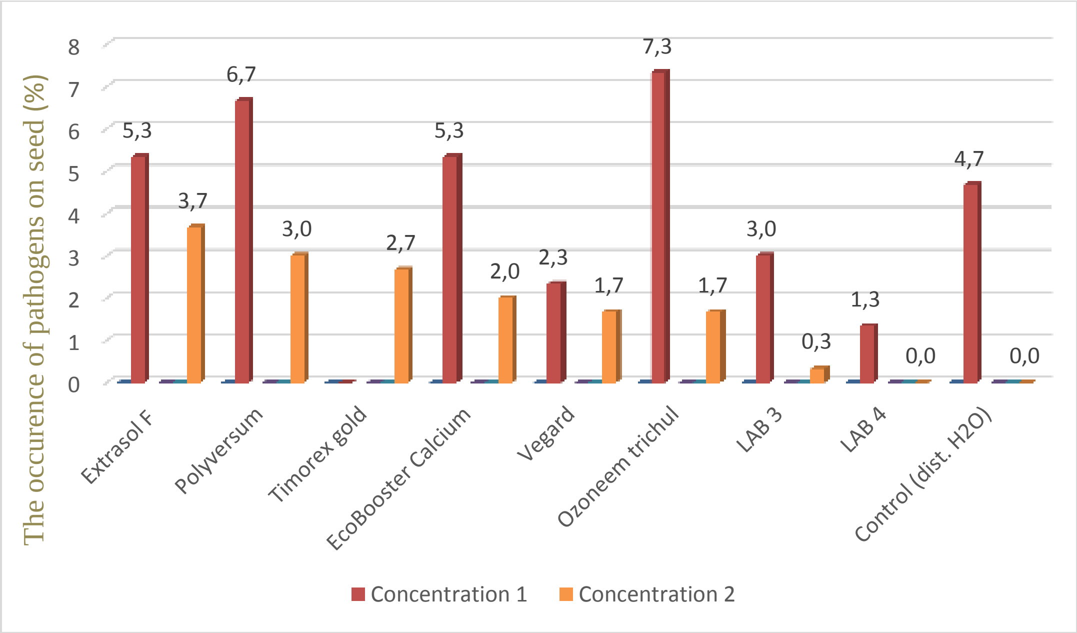


Photo 1. The symptoms of dark mycelia on the seed surface

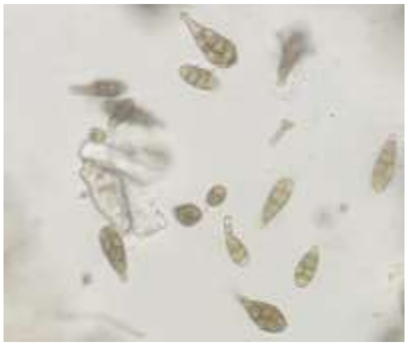

Photo 2. *Alternaria* sp.

Macroscopic examinations revealed the symptoms of dark mycelia on the seed surface, while the microscopic confirmed the presence of *Alternaria* sp. 'Timorex gold' in a lower concentration was prevented the occurence of seed infection, while the most infected seeds were recorded in the treatment with bioinsecticide 'Ozoneem trichul' (7.3%). In the treatment with higher concentration of 'LAB 4', the pathogens of genus *Alternaria* did not appear on the seed. Similar effect was achieved with 'LAB 3' (0.3%). The occurence of *Alternaria* sp. on the seed was confirmed after the treatment with 'Extrasol F' (3.7%), 'Polyversum' (3.0%) and in the control treatment (3.0%). In the research Filipović et al. (2021), the phytopathogenic fungi on fennel seed identified as *Alternaria* sp. The bio-products 'Extrasol F' and 'Polyversum' in the recommended concentrations (0.2 ml/kg i 0.5 g/kg) affected on reduce infected seeds. The higher concentrations did not reduce occurence of infected seeds.

Conclusions

The several bio-products showed positive effect on germination and reduction of pathogens on tested German chamomile seed cv. „Banatska". Bio-products 'LAB 4', 'Extrasol F' and 'EcoBooster Calcium' could be recommended for improvement of the germination rate and total seed germination of German chamomile seeds, while the 'Timorex gold' and 'LAB 4' could be recommended for the safe use in prevention of the seedborne diseases of *Ch. recutita* cv. „Banatska".

Abstract

The aim of this study is to investigate phenotypic variability of yield components for seven different durum wheat genotypes (Windur, Žitka, KG Olimpik, KG-28-6, KG-3405-03, KG-43-33-1, and KG-44-3-1), which were grown during two years (2012/2013 and 2013/2014) at certified organic trial located in Mršinci, the Municipality of Čačak, Serbia. The field experiment was conducted in a randomized block design with three replications with plot of 5 m² on the soil belonging to the loamy clay type. Experiment was carried out by the organic technology of farming production of durum wheat.
For analysis of plant height and spike characteristics, 60 plants in full maturity stage were used (20 plants per replication). The primary tiller of plant was used for analyzed plant height, spike length and number of spikelets per spike.
Plant height, on average, ranged from 76.0 cm (Olimpik) to 92.1 cm (KG-3405-03), spike length from 6.9 cm (KG-44-3/1) to 8.2 cm (Windur) and number of spikelets per spike from 19.3 (Žitka) to 22.5 (Windur). Variability for plant height was similar for both of years (CV=3.6%, 3.9%, respectively), but for spike length (CV=5.5%, 6.6%, respectively) and for number of spikelets per spike (CV=5.4%, 6.2%, respectively) was lower in the first than in the second year.
Through variance analysis, a highly significant difference in mean values for all investigated components was established. Phenotypic analysis of variance indicated that ecological factors had higher impact in relations to genetic factors on expression of all three investigated traits.

Keywords*: durum wheat, organic production, plant height, spike characteristics, variability.*

Introduction

Durum wheat (*Triticum dururn* Desf.) is still globally considered a minor wheat crop and typically much of the research effort on durum is often conducted in conjunction with studies of bread wheat. Only a few regions in the world are capable of producing durum that meets the high standards for end-use suitability (Beres et al., 2020). In Serbia, there are generally conditions for growing durum wheat, although climatic conditions can be limiting factors for durum production. The production of winter varieties can be risky due to low frost resistance of durum wheat, especially in years with frost without snow cover. If spring varieties are grown, it is necessary to perform earlier sowing and provide the irrigation system, because high

temperatures and drought stress can significantly reduce the grain filling period, plant height, spike characteristics, yield components and yield (Pour-Aboughadareh et al., 2020).
Genotypes under organic agriculture need a high phenotypic plasticity to adapt to different and changing climatic conditions, should be more tolerant to abiotic and biotic stresses, need a proper root system to enable efficient nutrient taking and, therefore, produce high enough yields with less/low input (Pagnota et al., 2020). Durum wheat varieties do not only differ in their agronomic traits, but also in their response to diseases and insects (DePauw and Ruan, 2018). In organic production of durum wheat, among the principles with the greatest impact on disease management are selection of a resistant variety and crop rotation (Knox, 2018). Choice of cultivar can impact grain yield, grain quality, and the type of management practices that might be needed to optimize performance and profitability for a given environment. The interest of consumers and the food industry in organic products requires work on creating cultivars suitable for cultivation in the system of organic production.
The aim of this paper is to analyze the variability of durum wheat genotypes in organic production based on their behavior in different ecological conditions during the growing seasons.

Materials and Methods

Seven genotypes of winter durum wheat [Windur (Germany), Žitka, KG Olimpik, KG-28-6, KG-3405-03, KG-43-33-1, and KG-44-3-1 (Serbia)] were grown during two growing seasons (2012/2013 and 2013/2014) at certified organic trial parcel which is located in Mršinci, in the Municipality of Čačak, Serbia (20°30' E, 43°48' N, 220 m a.s.l.).
The field experiment was conducted in a randomized block design with three replications with plot of 5 m² on the soil which belongs to the loamy clay type. Experiment was carried out by the organic technology of scientific farming production of durum wheat. Soybean in the first and potato in the second year were used as the preceding crops. Sowing was done on November 6, 2012, and in October 25, 2013 with 600 seeds per square meter. The treatment of the crops during the growing season respected the principles of the organic farming.
For analysis of plant height and spike characteristics, 60 plants were used in full maturity stage (20 plants per replication). The primary tiller was used for analyzed plant height, spike length and number of spikelets per spike. The following parameters were computed: the average value ($\bar{x}$), the standard deviation (SD), the coefficient of variation (CV), the analysis of variance (ANOVA) and components of variance (σ^2). The significant differences between the average values were estimated by LSD-test values. The ANOVA was done according to a random block system with two factors using the MSTAT-C program (Michigan State University, 1990).

Results and Discussion

Plant height on average ranged from 76.0 cm in cultivar Olimpic to 92.1 cm for KG-3405-03, which plant height differed significantly to other genotypes. Variability on average was similar for both investigated years (3.6%, 3.9%, respectively). The highest plant height in the first year had cultivar Žitka (89.43 cm), while in the second year genotype KG-3405-03 (99.27 cm) had the highest plant height. Analysis of SD and CV showed that the examined genotypes showed low variability for plant height. Genotype KG-28-6 and Windur showed the highest variability of plant height in the first year (7.1%, 5.3%, respectively) and genotypes Windur and KG-44-3/1 in the second year (5.9%, 5.4%, respectively). Analysis of variance showed highly significant differences between genotypes and genotype-year interaction, while differences between years were significant (Table 1). In the total variance of this trait, the largest share of variance belonged to genotype-year interaction (64.18%) and genotype (25.99%). These results are in agreement with previous research (Falaki and Mohammed, 2011).

Means followed by different letter (s) within the columns differ significantly at 5% level of probability using LSD.

Spike length is an important component of wheat plant yield, which along with other components, significantly affects yield. In this study, the spike length of durum wheat genotypes ranged on average from 6.9 to 8.2 cm (KG-44-3/1, Windur, respectively). Variability of this component was higher in the second (6.6%) than in the first investigated year (5.5%). On average for all genotypes, the length of spike was similar in both years, about 7 cm, which means that this trait showed homogeneity over the years (Table 2). These results are in agreement with previous research reported by Matković et al. (2015) who also established average value of spike length at observed genotypes about 7 cm in organic production of durum wheat. Analysis of variance for spike length showed highly significant differences between genotypes and years as well as its interactions. In the total variance of this trait, the largest share of variance belonged to genotype-year interaction (80.22%) and year (10.63%). These results agree with previous research in durum wheat (Gorjanović and Kraljević-Balalić, 2006) and spelt wheat (Zečević et al. 2018). The number of spikelets per spike is shown in table 3. On average, this trait varied from 19.3 (Žitka) to 22.5 (Windur). Genotype KG-44-3/1 had also 22 spikelets per spike. On average for all genotypes, the number of spikelets per spike differed by only one per year (21 and 22). Similar results obtained by Gorjanović and Kraljević-Balalić (2006) who found 21-22 spikelets per spike.

Table 2. Mean values, variability and ANOVA for spike length in durum wheat

Genotype	Year						Average
	2012/2013			2013/2014			
	$\bar{x}$ (cm)	SD	CV (%)	$\bar{x}$ (cm)	SD	CV (%)

On average, two sterile spikelets per spike were recorded, at basal and top position of spike. Wheat yield can be increased by decreasing the sterile basal and top spikelets, which can be achieved with appropriate plant density and by supplying sufficient nutrients, mainly nitrogen (Li et al., 2016). Analysis of variance revealed highly significant differences between the analyzed genotypes, years and genotype-year interaction. In the total variance of this trait, the largest share of variance belonged to the genotype-year interaction (53.45%) and then to the genotype (13.54%), table 3.

In organic durum wheat production, productivity of plants is lower than in conventional production because of low input of fertilization and protection against diseases and insects. Weeds are one of the largest contributors to wheat yield loss. Weed control and nitrogen supply are among the most important factors for durum yield and quality, especially in years with excess precipitation and low temperature during reproductive development of durum wheat in organic production system (Campiglia et al. 2015, Zečević et al., 2019). Resistance to disease continues to be a major factor in the maintenance or improvement of durum wheat yields, especially leaf rust, yellow or stripe rust and stem rust (Eversmeyer and Kramer, 2000).

Means followed by different letter(s) within the columns differ significantly at 5% level of probability using LSD.

Conclusion

In this study, it was found that durum wheat genotypes behave differently in organic production for the tested plant traits. Differences between genotypes were significant for plant height and spike traits. The variability was low for all examined traits. Genotype-year interaction was expressed for all three examined traits (plant height, spike length and number of spikelets per spike). The largest impact of total variance belonged to the genotype-year interaction, above 50% for all investigated traits.

The analyzed genotypes possess low variability of the examined traits in different ecological conditions, which were expressed during the two vegetation seasons. These genotypes can be used as parents in breeding durum wheat for organic and conventional production.

Abstract

Pepper (*Capsicum annuum* L.), is one of the most important types of farmed vegetables. This plant is of huge economic significance in our country. It has been grown and used for a long time. The basic system of farming peppers is a conventional method of agricultural production which aims to achieve maximum production in both quality and quantity while keeping the expenses as low as possible. However, the conventional system has shown its disadvantages through adverse effect on peoples' health, the environment and its biodiversity. Organic production aims to produce safe food of high quality which production would be sustainable. The aim of this paper is to look into the possibilities, but first of all the advantages, of organic pepper production. Pepper is a very bold vegetable. It contains significant amounts of sugar, protein, minerals and vitamins. New technologies often have unintended consequences. High-yielding varieties, which require large amounts of water, artificial mineral nutrients and other agricultural chemicals, have caused environmental problems in many parts of the world. In some cases, high-yielding varieties have been shown to be less resistant to diseases and pests than traditional varieties. This requires greater use of pesticides, the excessive use of which has poisoned the soil and negatively affected biodiversity.

Key words: *peppers, agricultural production, organic production, high quality food.*

Introduction

Pepper (Capsicum annuum L.) is one of the oldest plant species in the world. It originated in South America, and in the fifteenth century the Spaniards brought it to Europe. Since it adapts and develops easily and quickly, it is estimated that there are about 50,000 species of cultivated peppers in the world.

In the Republic of Serbia, paprika is a whole surface plant and according to the procedures that are found after tomatoes. The application of a conventional system of cultivation and the use of modern greenhouses and hothouses have ensured that the fruit of fresh peppers will be available in the coming years. Mass consumption of pepper can be announced by its extraordinary nutritional and culinary properties. Also, they require a conventional system of agricultural production, significant contributions are made and the crop is economically very profitable.

The rules of organic farmers in the Republic of Serbia are defined by the Law on Organic Production of the Republic of Serbia, as well as the adopted standards and records of the European Union. In the period from 2010 to 2015, there was a significant increase in the area under organic products, amounting to 15,298 ha (Simić, 2017). According to the MAFWM, in the Republic of Serbia the area consists of only 1.3% of the area in relation to the total area under organic product. As for paprika, there is no precise data on the area on which it is grown, but it is known that the largest plantations with organic production plant are located in Vojvodina (Kikinda, Sombor, Fruška gora, Novi Sad, Zrenjanin, Bečej).

In the world, pepper has 1,600,000 ha, with an average height of 14.0 t/ha. It is mainly grown in the temperate zone and sporadically in the tropics. The largest producer in the world is China (20.0 t/ha), and the highest average yield is achieved by Spain (40.0 t/ha Gvozdenović, 2010).

In the structure of European production, our country participates with 4.4% and is in seventh place. Pepper is grown on 21,000 ha, with an average yield of 8.3 t/ha (Gvozdenović, 2010).

The areas on which the production is based are located in the plains of Vojvodina and in the basins and river valleys of central and southern Serbia. According to the procedures of surface culture, it is located in another place, next to tomatoes.

Pepper is an intensive culture and creation of high incomes per unit area. It is grown outdoors and outdoors. The price is completely used in technological (use) or physiological (botanical) maturity, fresh and processed. Pepper is a very bold vegetable. It contains significant amounts of sugar, protein, minerals and vitamins. The fruit contains 92% water, 6 g of carbohydrates, 0.99 g of protein, 0.3 g of fat and 1.2 g of fiber. It is especially rich in vitamin C, which has approximately 150 to 250 mg in botanically ripe fruits (Popović, 1991). Vitamins P, B1 and B2 and beta carotene, provitamin vitamin A are also available in peppers. The carotenoids capsatin and capsorbin give the fruit a red color (Lazić, 2008).

Organic agricultural production

New technologies often have unintended consequences. High-yielding varieties, which require large amounts of water, artificial mineral nutrients and other agricultural chemicals, have caused environmental problems in many parts of the world. In some cases, high-yielding varieties have been shown to be less resistant to diseases and pests than traditional varieties. This requires greater use of pesticides, the excessive use of which has poisoned the soil and negatively affected biodiversity. Also, the increasing mass genetic manipulation of cultivated plants and the elimination of diversity in order to maintain uniformity (monoculture), have contributed to the conventional cultivation system as an industrial process, in which plants and domestic animals are small factories (Kovačević, 2010).

Organic agricultural pepper production

Relation to land For planting peppers, flat soils are best, on which soil moisture and light conditions are uniform. A slight slope, up to 5%, is desirable for easier drainage of excess water. The optimal pH for growing peppers is 5.5-6.5, but it can also be grown on soils with a pH of 4.6-7.5 (Lazić, 2008). Pepper requires light and sandy soils, rich in organic matter. If the soil is not loose, a larger amount of sand is added to it.

Relation to temperature Since pepper is a thermophilic plant species, the optimal temperature for plant growth and development is 22-25 ºC. At the time of germination, flowering, formation and ripening of fruits and seeds, paprika requires 3-4 ºC higher temperature than stated. The soil temperature should be 3-4 ºC lower than the air temperature.

Relation to light Paprika is a heliophilic plant, short-lived. It does not tolerate shade and is successfully grown only in a period with plenty of light. For early varieties of peppers, a denser set of plants is desirable.

Nutrients Pepper has a great need for nutrients. Burnt manure is applied in autumn or spring just before planting. The manure is spread over the entire surface of the land, with slight loosening of the pitchforks. In this way it remains as mulch on the surface of the soil. 40% of compost manure was obtained from fresh manure by composting. On average, burnt manure contains 0.50% N, 0.25% P2O2, 0.60% K2O and 20% organic matter. The content of microelements is 10-20 mg / kg of boron, 150-200 mg of manganese, 15-20 mg of copper, 70-95 mg of zinc, 1-2 mg/kg of molybdenum and 13 mg/kg of cobalt, and creatine is present as a biostimulator, indole acetic acid and others (Lazić, 2011).

Compost is the most common basic organic nutrient. It can also be used for mulching (mulching) the soil. Different materials can be used for composting, and based on that, the compost was divided into compost manure, earthworm, compost from plant industrial waste and organic waste from the household.

In organic agriculture, other organic fertilizers can be used, provided that they have an organic certificate (earthworm, ash, peat, poultry manure).

Material and Methods

The experiment was set up in the village of Otanj near Požega, on the family farm. The plot is located at an altitude of 400 meters, with a slope of 1%.

Two greenhouses were used for the experiment, each measuring 40 × 8 m, which means that the total area of the plantations is 6.4 ares. The construction of the greenhouse is covered with polyvinyl chloride foil (PVC), which transmits up to 90% of the visible part of the spectrum and 80% of the ultraviolet part, and does not transmit the infrared part of the spectrum. The greenhouse has a built-in system for artificial watering according to the "drop by drop" system. Spring water is used for irrigation.

The following parameters were obtained by soil analysis:

- pH 6.05
- pH KCL 5.34
- humus 6.89%
- N 0.340%, P2O5 11.20 mg/100 and K2O 34.10 mg/100.

The medium-early variety of paprika Claudius (Claudius F1 500) was used for cultivation. The type is white babure, with a sharp tip. The fruits are very large (200 - 250 g) and sweet taste. Thanks to the well-developed root system and strong above-ground part, it is successfully grown even in weaker conditions. It is primarily recommended for growing in unheated greenhouses and in intensive production in the open field.

For the needs of the experiment, it was decided to grow peppers in one greenhouse according to the principles of conventional, and in the other greenhouse according to the principles of organic agricultural production. In both greenhouses, the basic tillage was done in the fall, and the pre-sowing preparation was done in the spring, a month before the plants were transplanted.

Based on the analysis of the soil, the need for nutrients was determined. Basic fertilization was done in the fall, just before tillage. Manure was applied in both greenhouses, with the application of mineral NPK fertilizer (400 kg/ha, formulations 1:2:3) in the system of conventional production.

Planting of plants was done in April, at a distance of 45 cm between rows and 25 cm in a row, at a depth of about 10 cm.

The first feeding was done fifteen days after transplanting the plants. The second feeding was in the phase of mass flowering and formation of the first fruits. For feeding peppers in the classical production system, KAN 27% N + 4.8 MgO was used, in the amount of 15 g/m^2. In organic production, the preparation Trianum P (Trihoderma harzianum T-22) was applied, by fertigation through a drip system, in the amount of 0.5 kg / ha. The application of Trianum P achieves a symbiotic relationship between this useful fungus and its roots. The reaction is the secretion of various aleopathic substances (hormones, vitamins, enzymes, phytoalexins, salicylic acid) that increase the resistance of the aboveground parts of the plant, but also various volatile and non-volatile antibiotic substances, which act on dangerous bacterial diseases.

Until the mass flowering, the plants were irrigated in the amount of 10-20 L/m^2, and with the formation of fruits, irrigation was every 5-7 days with 20-30 L/m^2.After watering and fertilizing, the plants were dug up.

The protection program was in line with the monitoring and occurrence of diseases and pests. A protective belt of velvet and basil plants has been planted around the greenhouse. At the beginning of the vegetation period, the plants were treated with copper preparations. An insecticide whose active substance is acetamiprid was used to control aphids in conventional production. In the organic production system, the plants were preventively treated with nettle macerate and garlic tea.

Results and Discussion

By measuring the mass of harvested paprika fruits, it was noticed that the fruits differ in weight, on average by about 30 g. The average value of the mass of paprika fruit in the conventional production system was 220-230 g, and in the organic about 200 g. The shape and color of the fruit were uniform in both cultivation systems. It was noticed that the fruits from the system of organic production had a more intense smell and taste.

Based on the comparison of the obtained results, it can be concluded that in the production plantation of peppers with the classical cultivation system, a higher yield per unit area is achieved. However, it is a known fact that the prices of organic primary and processed products, depending on the type, point of sale and season, have increased by about 50-300% compared to the prices of the same conventional products.

Conclusions

In relation to the total areas under organic agricultural production in the Republic of Serbia, organic pepper production is represented mainly on smaller areas (1.3%). Paprika belongs to the group of vegetables whose cultivation is the most profitable. One of the possibilities for increasing income per unit area is organic agricultural production. In order to successfully grow peppers in a protected area according to organic principles, preventive measures must be applied more strictly compared to the conventional production system. The fruiting period is shorter and the yield per unit area is lower. Disease and pest control is one of the key problems due to the significantly smaller number of pesticides available. Initial investments in this type of production are higher compared to conventional production, but in the long run they pay off. In the production process, energy consumption is significantly lower. The products obtained are of better quality and stay fresh longer. They are a protected trademark and are several times more expensive than products obtained by conventional means. Organic vegetable production is not a return to rural agriculture, but it is a modern form of agriculture and represents a complete management system. Organic agricultural production requires a great understanding of producers, primarily about the need to protect the human environment and the production of safe and biologically valuable products, without pesticide residues and other chemical substances.

ORGANIC FARMING AND POLICIES APPLIED IN TURKEY

Aybüke KAYA*

Abstract

Agricultural activities are among the current topics in every period. Agriculture is indispensable in terms of its contribution to community nutrition. It is important for people to live a healthy life and to improve their living conditions. Organic farming is known as environmentally friendly in respect of agricultural sustainability. It preserves the ecological balance as it is applied within certain rules. The aim of study is to assess the organic farming potential of Turkey. In addition, it is to examine the state supports applied in this regard. Organic farming started with intensive agricultural supports in the European Union and Turkey. However, it could not show rapid development in Turkey. Today, there are serious increases in the growing area and production amount of organic products. Organic farming method is applied for many products in Turkey. In recent years, it has increased especially in feed crops, grains and nuts. In addition to organic herbal products, organic animal products have also increased. The number of farmers involved in organic crop production was 53,782 in 2019. In addition, there are 170 farmers engaged in organic animal production in Turkey. Organic farming also has an important role in world trade. Turkey has an organic product export value of over $ 200 million in 2019. Producers and consumers should be informed about this. In the future, organic farming activities are expected to increase in Turkey.

Keywords: A*griculture, environment, health, sustainability, market.*

Introduction

The rapidly increasing world population brings with it the demand for foodstuffs. However, it is impossible to increase the amount of land required for the current production. For this reason, production is tried to be increased with yield obtained from the unit area. However, as well as increasing productivity is important, the health of humans and other living things is also important (Kaya and Bay, 2020). The ecological destruction arising from the increased use of chemical inputs due to the rapid population growth and increasing food demand has caused increasing demand for organic products (Ayla and Altıntaş, 2017). Healthy life in a sustainable environment is possible with accessible food production. It is a method that cares about the environment and human health. Organic farming is an agriculture method that aims to evaluate the future of human and ecosystem as an indivisible whole with healthy plant and animal production (Akkurt et al., 2018). It is also an environmentally, socially and economically sustainable farming system (Willer et al., 2019). According to 2016 data in the world, it is known that organic production is made by 2.7 million producers in an area of 57.8 million hectares in 178 countries (Willer and Lernoud (Ed.), 2017). Organic farming in Turkey has started in line with demands from EU countries in 1985. Today, it has reached a sectoral status with more than 200 products that can be classified as herbal products, processed food and other organic products (Öztürk and Islam, 2014; Kaya and Bay, 2020). According to the report published by IFOAM

(International Federation of Organic Agriculture Movements) and FIBL (Research Institute of Organic Agriculture) Research Institute; the economic magnitude of the organic market globally is around $81.6 billion. Whereas the organic market share among the EU countries is around $27.1 billion. This would mean that one thirds of global organic market network belonged to the EU countries (Merdan, 2019). The number of farmers engaged in organic farming in Turkey is higher than the 80.000 in recent years (Kaya and Bay, 2020). Consumer demand for organic farming and food products has naturally increased the number of farmers who adopt organic farming (Demiryürek, 2011). However, Turkey's possible to be processed into products to the world market. Turkey has a competitive advantage. It has advantages such as geographical location, climate characteristics, product variety, soil quality, and high labor force working in agriculture. (Özbağ, 2010). The aim of this study is to evaluate the potential of organic farming in Turkey. In addition, it is to examine the state supports applied in this regard.

Material and Methods

Data from the Turkish Statistical Institute were used in the study. In addition, national and international studies were used. The change in Turkey's organic agriculture data has been examined over the years. In this context, organic products, number of farmers, cultivation area and production amount were evaluated in Turkey. In addition, the amount of support paid has been examined in Turkey. The supports are determined as unit price by the Ministry of Agriculture and Forestry.

Results and Discussion

Values related to Turkey's organic farming potential are given in Table 1. Organic crops have increased in Turkey in recent years. The data showed fluctuations over the years. While the number of organic products grown in 2005 was 205, it increased to 235 in 2020. There is an increase in the number of products by about 15%. In addition, organic farming producer has increased significantly. While there were 14 401 farmers in 2005, it has reached 52 590 farmers in 2020. Between 2005 and 2020, the number of farmers engaged in organic production has increased more than 3 times. In addition, the production area among the ails mentioned has almost doubled. While there was 203 811ha organic production area in 2005, it became 382 665 hectares in 2020. Turkey's organic product production potential has almost quadrupled in the same period (Table 1).

Table 1. Organic crop production in Turkey

Year	Number of crops	Number of farmers	Index (2005=100)	Area[1] (ha)	Index (2005=100)	Production (ton)	Index (2005=100)
2005	205	14 401	100	203 811	100	421 934	100
2010	216	42 097	292	510 033	250	1 343 737	318
2015	197	69 967	486	515 268	253	1 829 291	433

(1) Natural harvest areas are included.

The development and change of organic farming in Turkey can be seen in Figure 1. There has been a significant increase in organic farming in recent years. The area of organic farming has also increased in Turkey. However, the amount of production and the number of farmers increased more than area (Figure 1).

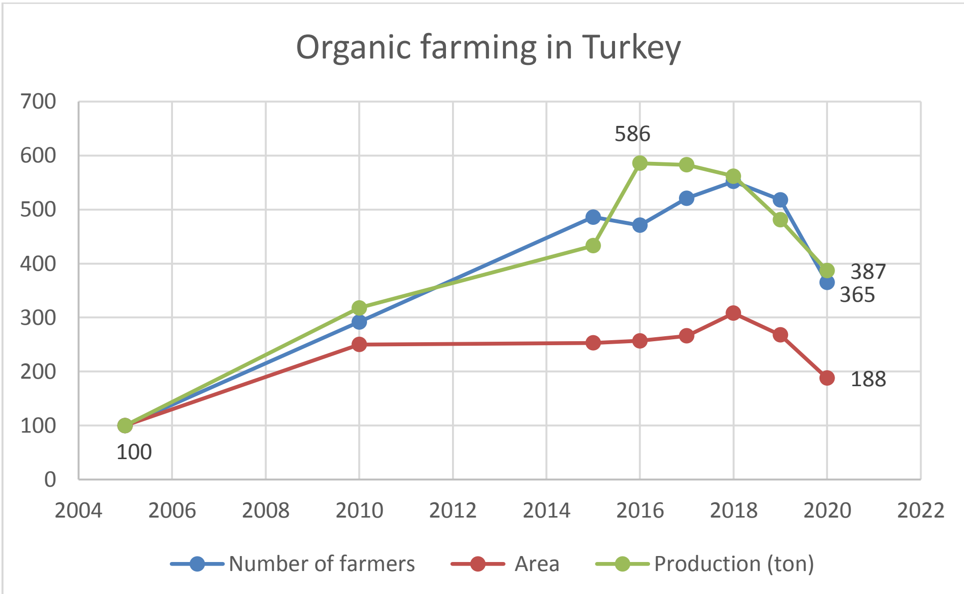

Figure 1. Change of organic farming data between 2005-2020

In 2019, there are 170 farmers within the scope of organic animal production. Egg chickens, ovine, bovine, carnivorous chickens are grown organically. In 2019, 865 781 animals were raised organically, and 819 tons of meat were obtained from these animals in Turkey. In addition, 5394 tons of organic milk was produced. On the other hand, 179 781 501 eggs were obtained from the reared laying hens. Beekeeping is also among the livestock activities. There are 249 farmers growing organic bees in Turkey. In addition, there are 50 100 hives. Organically, 577 tons of honey is obtained from these bees (TUIK, 2021a). Based on production guidelines, organic livestock farming has set itself the goal of establishing environmentally friendly production, sustaining animals in good health, realising high animal welfare standards and producing high quality products (Atasever and Adıgüzel, 2006).

Today, the increase in environmental and health problems increases the importance of healthy foods. Support for environmental policies should be increased. Many products are supported within the scope of agricultural policies in Turkey. Organic farming producers are also supported within the scope of the applied basin-based support system.

Organic farming support unit prices were obtained from the Ministry of Agriculture and Forestry. There are supports that encourage organic farming. These supports are given according to different categories. The supports are determined at 100 TL/da for the 1st category. It was determined as 70 TL/da for the 2nd category, 30 TL/da for the 3rd, and 10 TL/da for the 4th, respectively. In addition, there are beekeeping supports within the scope of organic livestock. In this context, the unit price of the beehive was determined as 10 TL/da. Not only organic plant production, but also organic animal production is supported.

Conclusion

Market share of organic farming should be increased in Turkey. Because environmental pollution and health problems have increased. In addition, the decrease in biodiversity, barren soils, decrease in water resources and water pollution constitute a serious problem. Consumption of organic foods in Turkey's domestic market should also be expanded. Producers and consumers should be made aware of the environment and health. Organic farming supports will increase Turkey's competitiveness. Organic farmers and markets should be brought together. Cooperatives should be established in this area.

Abstract

Medlar (*Mespilus germanica* L.) is an old fruit species that is not present in production plantations and on larger areas in B&H and neighboring countries. It can mostly be found in backyards, as a sporadic fruit tree. Wild service tree (*Sorbus torminalis* (L.) Crantz) is a species of semi-shade, a regular companion of oak forests, with a wide ecological valence. Apart from belonging to the same family (*Rosaceae*), their fruits are both edible and medicinal, can be consumed only if *bletted* (softened by frost) and are characterized by a similar taste. The fruits of wild service tree were harvested on the mountain Manjača, while the fruits of medlar were collected from an old orchard in the suburbs of Banja Luka. Fruits were analyzed on the following: moisture, dry matter, total sugars, total acidity, mineral content, pectin, vitamin C, elements (Al, Ca, Cd, Cr, Cu, Fe, K, Mg, Mn, Mo, Na, P, Pb, Se, Zn), total phenols, flavonols, flavonoids, non-flavonoids and anthocyanins. Analyzes were carried out in four parallel repetitions and the results are expressed as mean value ± standard deviations. The obtained results showed that the fruits of the observed species have a rather uneven elemental composition, with the exception of Na and P. Checker tree fruits contain more vitamin C (15.80 mg/100g) than medlars (4.44 mg /100g). They are also superior in terms of total phenols, flavonoids and non-flavonoids (2416.49, 1299.33, 1117.16 μgGAE/g, respectively) compared to medlars (530.3, 36.14, 513.5 μgGAE/g, respectively). The same is the case with total flavonols (323.51 vs. 174.97 μgQE/g). Checkers contain an average of 301.24 μg/g of anthocyanins, which are not registered in medlars.

Key words: *medlar, wild service tree, nutrition value, element concentration, bioactive compounds.*

Introduction

Wild service tree or checker (chequer) tree (*Sorbus torminalis* Crantz) is widespread from Western Europe to southwestern Asia, with part of its range in North Africa. In our country, it most often occurs in the belt of oak forests, individually or in small groups, as a partial-shade species. The fruit is a typical syncarpous stone, which contains two seeds; the fruits are also called "checkers ("chequers"). They are round or ellipsoidal in shape, with significant variations in size and shape. Kárpáti (1960) distinguishes seven different fruit shapes: *typus, sphaerocarpa, pisifera, macrocarpa, microcarpa, dolichocarpa* and *pomoida.* While young, the fruit is reddish-yellow and when fully ripe dark brown, sprinkled with white dots. Fruit is inedible until over ripe, *i.e*. begin to blet, which usually happens after the first frost, when they can be eaten fresh, but are usually processed into compotes and jams. Earlier, in pre-hops times, when hops (*Humulus lupulus*) were not a primary component of beer, they were used in the production of beer, and flour was obtained from dried fruits. The fruits of the wild service tree also have a healing effect, which is eloquently mentioned by the scientific name of the taxon - *torminalis*, which means "good for colic". In folk medicine, the young bark and subcortex are used to treat diabetes. In addition to fruits, wood also has a recognizable use value. It is one of the hardest European types of wood with excellent aesthetic and technical characteristics, which is used to make musical instruments: flute, harpsichord, etc. Wild service tree is also important for forest ecosystems. Bees like to visit its flowers, fruits are a favorite food for birds, game and other forest animals, and the leaves are especially loved by deer and roe deer. From an utilitarian point of view, it is important to note that wild service tree bears fruit every two years or three times in four years (Barengo et al., 2001; Oršanić et al., 2009).

Medlar (*Mespulus germanica* L .; syn. *Crataegus germanica* (L.) Kunze) is the only species of the genus *Mespilus*. It appears as a shrub or low tree. The spontaneous area of medlar includes a part of Persia, Transcaucasia, Armenia, and in Europe, the Strandža mountain in Bulgaria. Its introversion in southern Europe is debatable, where it is probably subspontaneous, arriving from the cultures that were raised by ancient peoples (Jovanović, 1956). In our country it grows as a cultivated species, and can very rarely be found in warmer positions within the belt of oak forests. The fruit is brown, edible medlar, 2-3 cm long, with 2-5 seeds.

Medlar is a fruit that the ancient Assyrians and Babylonians used to enjoy. Pliny spoke of it as a source of excellent juice, and in "recent" history it is mentioned by both Cervantes and Chaucer. Even Shakespeare in the greatest love story, about Romeo and Juliet, found a place for – medlar; Act 2, Scene1 citation:

"Now will he sit under a medlar tree,
And wish his mistress were that kind of fruit
As maids call medlars, when they laugh alone.
O Romeo, that she were, O that she were
An open-arse and thou a poperin pear! "

Medlars are used to prepare various medicinal and edible preparations, such as: teas, liqueurs, compotes, jams. In folk medicine, medlar is used as a powerful anti-inflammatory agent that has a beneficial effect on the whole organism. It has been used for centuries for indigestion - suppresses intestinal and gastric inflammation, eliminates bloating. It is a powerful natural laxative. Due to its antiviral and antibacterial activity, it helps alleviate tonsillitis and airway inflammation (Phipps et al., 2003; Tucakov 1964, 1984).

Chemical composition of chequers and medlars have not been sufficiently investigated in our literature. In addition to the works of Mrkonjić (2017), Šebek et al. (2017) and Veličković et al. (2013), there are few other sources that deal with this issue in our language area. Knowing the chemical composition of these fruits is not an end in itself. It should contribute to the reaffirmation of the chequers and medlars, once highly desirable and valued in our country and in Europe, and now forgotten. By by gathering of chequers in the wilderness and medlars in the orchards, the rural and peri-urban population is given the opportunity to gain additional income, either by selling fresh fruits or through their processing into healthy organic products.

Material and method

Chequers were harvested on the mountain Manjača, while medlars were collected from an old orchard in the suburbs of Banja Luka, Bosnia and Herzegovina. The fruit harvest was done in the first week of October 2020, when chequers and medlars were at the stage of full physiological maturity. Fruits were picked from different parts of the crown with the telescopic scissors. Fruits that have undergone a ripening period were not used for analysis, whether they were left lying on the ground under a tree or stored in storage until over-ripening. There are two reasons for such approach. The first reason is the complexity and for now insufficient determination of the processes that take place during the ripening period, which makes comparisons and conclusions difficult (Rop et al., 2011; Altunaş et al., 2013). Another reason is that the eventual industrial processing of these fruits would be based exclusively on physiologically ripe fruits, and not on fruits in which the process of enzymatic browning has begun or already taking place, which generally results in loss of nutritional, functional and organoleptic qualities (Romero-Rodriguez et al., 2000; Rop et al., 2011).

Prior to the chemical analysis, the fruits are washed, cut into chops, chopped and homogenized in a stainless steel rotating knife homogenizer (Vasilišin et al., 2015). Certain components of the chemical composition were determined by standard AOAC methods (AOAC, 2016). For each component of the chemical composition three parallel analyzes were performed, and the results are expressed as mean values. Total anthocyanins were determined by the spectrophotometrically modified "single" pH method (Sun et al., 2002). The content of total phenols was determined by the modified Folin-Ciocalte method (Wolfe et al., 2003). As a standard compound, gallic acid was used and the results were expressed as equivalents of gallic acid (GAE), i.e. mg GAE/g. Total flavonoids were determined by Kumaran method (Kumaran & Karunakaran, 2007), and the total flavonols by Ordonez method (Ordonez et al., 2006). Quercetin was used as the standard compound, and the results were expressed as mg quercetin (Qc)/g.

Two methods have been used to measure the antioxidant activity of the fruits studied: ABTS (2,2-azinobis(3-ethyl-benzothiazoline-6-sulphonate) and DPPH (2,2-diphenyl-1-picrylhydrazyl). The DPPH test is one of the oldest and the most frequently used methods for the determination of the antioxidant activity of food extracts (Ratty et al., 1988). Antioxidant activity against the DPPH radical was determined by the Liyana-Pathiranana and Shahidi method (Liyana-Pathiranana & Shahidi, 2005), and for the ABTS radical the modified method of Re and associates was used (Re et al., 1999). As a standard compound, Trolox was used. The results were presented with the TEAC value (Trolox equivalent of antioxidant activity), i.e. as μg Trolox/g_{FW}. The results are expressed as the inhibitory concentration - IC_{50}. It is the concentration of extract (mg/ml) required to scavenge 50 % of DPPH.

The elemental composition of the investigated fruits (Na, K, Ca, Mg, P, Zn, Cu, Cr, Fe, Cd, Pb, Al, Se, Mn, Mo) was determined as follows. Fruit samples are burned in a mixture of concentrated acids (nitrogen and perchloric acid) in the digestion thermoblock according to the prescribed temperature regime. After digestion, the solutes were filtered in 50 mL dilution flask, diluted with deionized water, with conductivity of 0.056 μS/cm and stored for analysis of mineral substances. Each sample was prepared in duplicate. Optical Emission Spectrophotometer (ICP OES) was used to determine the mineral content of samples. The sample solutions were pumped by a peristaltic pump from tubes arranged on a Perkin Elmer auto-sampler model 510. Certificate reference standard solution, instrument calibration standard , with concentration of elements 100 mg/L was used for calibration of spectrophotometer. The concentrations of the elements for the calibration direction were different, determined according to preliminary measurements for the specified metals (Vučić et al., 2018). Linearity was performed by analysis of standard solutions. 20 standard solutions of five concentration levels depending on the analyse were determined. Limit of determination and quantification was performed by analysis of blanks.

Results and discussion

The results of the chemical analysis are shown in tables 1-4. Chequers contain 65.20 % of water and about 34.80% of dry matter, while medlars contain 78.79 % of water and 21.21 % of dry matter (Tab. 1). Medlars contain slightly more sugar (11.51 %), but also significantly less vitamin C (4.44 %), compared to chequers (7.38 % and 15.80 mg/100 g, respectively). However, compared to their wild relatives, fruit of the wild service tree is inferior in terms of vitamin C content. Thus, the whitebeam fruit (*Sorbus aria* Crantz) contains on average 37 mg of vitamin C/100 g and the rowan fruit (*Sorbus aucuparia* L.) 34 mg of vitamin C / 100 g (Vračarić et al., 1990). When it comes to total acidity and pectin content, the differences between chequers and medlars are negligible.

There is a significant difference in the content of total dry matter between the observed species. When we compare the content of total dry matter in our material with data from other areas, we notice a similar phenomenon. Thus, in the material from Straznica in the Czech Republic the content of dry matter in medlars is 29.88-37.15% (Rop et al., 2011), and in the material from Turkey 27.85% (Haciseferogullari et al., 2005), *i.e.* 28.20-33.68 (Altunaş et al., 2013).

Table 1: Chemical composition of fresh fruits of the wild service tree (chequers) and the medlar

	Water (%)	Total dry matter (%)	Total sugars (%)	Total acidity (%)	Pectin (%)	Vitamin C (mg/100 g)
Chequers	65.20	34.80	7.38	0.74	0.28	15.80
Medlars	78.79	21.21	11.51	0.60	0.27	4.44

Regarding the elemental composition, among the 15 analyzed elements, potassium is the most common in both types of fruits, followed by calcium and magnesium (Tab. 2). In checkers, Fe, Cd, Pb and Se were analyzed but not determined. In addition to the above, Cu and Mo have not yet been determined in medlars.

Table 2: Average element concentration (mg/kg_{DW}) in chequers and medlars

	Na	K	Ca	Mg	P	Zn	Cu	Cr	Al	Mn	Mo
Chequers	12.9	1892.2	213.97	115.8	80.6	11.0	0.7	0.10	3.11	0.42	0.009
Medlars	14.6	1096.7	1081.2	529.4	104.8	4.0	n.d.	0.21	1.68	1.18	n.d.

N.D. – analyzed but not detected

Chequers and medlars also contain chemical compounds from the category of phytochemicals, such as: phenols, flavonols, non-flavonoids and anthocyanins (Tab. 3). In all observed parameters, checkers are superior to medlars, especially when it comes to phenols and flavonoids, with the remark that anthocyanins are not even registered in medlars.

However, the content of phenols in our samples is almost 10 times lower than in the samples from the Belgrade Forest, Istanbul, Turkey (Gozde et al., 2015), where it is 20.44 mgGAE / g). Also our research confirmed the statement of the mentioned authors that water is the best solvent for extraction of phenols from chequers.

Table 3. Phytochemicals in chequers and medlars

	Phenols (µgGAE/g)	Flavonols (µgQcE/g)	Flavonoids (µgGAE/g)	Non-flavonoids (µgGAE/g)	Anthocyanins (µg/mg)
Chequers	2416.49	323.51	1299.33	1117.16	301.24
Medlars	520.3	174.97	36.14	513.5	N.D.

The antioxidant potential of the studied fruits species is shown in Table 4. Since lower IC_{50} values indicate greater free radical scavenging activity, the observed table shows that chequers have a significantly higher antioxidant capacity than medlars.
These results are in complete agreement with the data in Table 3 and the stated conclusion that chequers contain significantly more phenols and polyphenolic compounds, such as flavonoides, which are known to possess significant antioxidant activities (Rice-Evans et al., 1997; Rop et al., 2011; Gozde et al., 2015).

Table 4. Antioxidant activity of chequers and medlar fruits

Parameters	Chequers	Medlars
ABTS (IC_{50}) mg Trolox/ ml $_{F.W.}$	0.97 ± 0.15	5.58 ± 0.06
DPPH (IC_{50}) mg Trolox/ ml $_{F.W.}$	5.03± 0.57	46.39 ± 0.1

Notice: IC - inhibitory concentration required to scavenge 50 % of ABTS and DPPH

Conclusion

Ripe chequers and medlars are solid sources of minerals and trace elements. Checkers contain more vitamin C than medlars. They are also superior in terms of total phenols, flavonoids and non-flavonoids. Both species studied show enviable antioxidant potential, with checkers having a significantly higher antioxidant capacity than medlars.

ENVIRONMENT PROTECTION AND NATURAL RESOURCES MANAGEMENT

CSR STRATEGIES OF INVASIVE WEED FLORA IN VINEYARDS OF BOSNIA AND HERZEGOVINA

Abstract

Invasions of invasive species pose one of the greatest threats to biodiversity on a global scale. Because of that research on invasive species has recently been intensified, putting the focus mostly on studying invasive species and their habitats, determining impacts on indigenous species and communities, as well as options for controlling and countering proliferation. The problem of invasive species in Bosnia and Herzegovina is a relatively new area, considering that the List of Invasive Species was published only in 2019. The aim of this study was to list invasive species that occur as weed species in vineyards in Bosnia and Herzegovina and to expand the existing knowledge on CSR life strategies of invasive flora, combining the existing data from different sources as a whole, and determining the appropriate strategy for those species for which it is not known. At 73 vineyard locations, 27 invasive species were determined and their CSR life strategy was defined. Plant material necessary for the analysis was collected by field research in the area of vineyards in Bosnia and Herzegovina. The material is analysed and life strategies are defined on the basis of values of seven life traits (i.e. height, dry leaf mass, leaf dry matter content, onset and flowering period, lateral spread, specific leaf area). The most frequent type of strategy among the invasive flora of vineyards in Bosnia and Herzegovina is the CR strategy with 11 species and the C strategy with 9 species. Life strategy R is represented by 4 species and CSR with one species. With the increase of invasive alien species in vineyards, especially C and CR strategy plants, there is a high possibility of spreading these species to the surrounding ecosystems, natural and semi-natural vegetation, and thus seriously endangering biodiversity.

Keywords: *invasive species, CSR strategy, vineyards, Bosnia and Herzegovina.*

Introduction

Although there are numerous definitions of the Invasive Alien Species (IAS), all the definitions are based on the four major criteria: the origin of the species, its ability to reproduce in the wilderness, spatial dispersion and the influence onto the environment (Richardson et al., 2000). Invasive alien species endanger biological diversity. On the global scale they are the second largest threat to the biodiversity, immediately after direct destruction of the natural habitat (Council of Europe, 2007). There are more and more such species that have negative effects onto human health, for example *Ambrosia artemisifolia* L.

The problem of invasive species came into the focus of scientific research in the last several decades. As a part of a huge European project DAISIE (Delivering Alien Invasive Species Inventories for Europe) more than 11.000 alien species have been recorded. The researchers included in this project have a task to monitor and deliver invasive species inventories (Lambdon et al., 2008.).

Numerous species are continuously being introduced into new regions. Controlling invasive species and lowering their impact onto the native species and ecosystems represent nowadays one of the biggest challenges in the protection of nature in Europe and in the world. It is impossible to remove the invasive alien species completely from the habitat to which it spread, because it is not cost-effective. Therefore, it is of huge importance to discover the presence of the possible invasive alien species in the ecosystem at an early stage. Invasive alien species are as a rule connected to the anthropogenic habitats. Their impact is the largest onto the human-controlled habitats. Agricultural land, such as vineyards, are extremely weak habitats with highly expressed disturbances that are suitable for invasive species and their further introduction into natural habitats.

Despite legislative acts, enough attention has not been given to invasive species in Bosnia and Herzegovina. Namely, there are no laws that govern monitoring, control and prevention of the negative consequences of the invasive species. Before the register of the Invasive alien species was done (2019), there had only been some sporadic papers in Bosnia and Herzegovina mentioning invasive species. Šumatić (1990) writes about a massive presence of the species *Ambrosia artemisiifolia* in the compositions of the association *Panico-Galinsogetum Tx et Becker*, 1942 in the area of central part of northern Bosnia. The same author (1997) emphasises a special part of the association *Panico-Galinsogetum ambrosiosum artemisiifoliae* in the region of Derventa. Similar results have been noted by Mitrić (2004) in the orchards in the region from Gradačac to Prijedor. Šarić et al. (1992) describe as invasive species the following: *Sorghum halepense*, *Ambrosia artemisiifolia* and*Galeopsis tetrahit*.

Šarić et al. (2000) write about the spread of the following new weed species in Bosnia and Herzegovina: *Abutilon theophasti* Medik., *Xanthium strumarium* L. and *Datura stramonium* L. Šilić and Abadžić (2000) write about the spread of neophyte species in Bosnia and Herzegovina, such as the americanophytes. Some of them are dangerous and invasive weeds like *Ambrosia artemisiifolia* L., *Amorpha fruticosa* L., *Conyza canadensis* (L.) Cronq., *Erigeron annuus* (L.) Pers., *Galinsoga parviflora* Cav., *Tagetes minuta* L. Šumatić and Janjić (2006) have noted a considerable increase of adventive weed species in Bosnia and Herzegovina (Republic of Srpska) with regard to the earlier research from the from the 1960s.

The very first list of the invasive species with their distribution in the Federation of Bosnia and Herzegovina was done in 2019 in the collaboration of the Faculty of Science and Mathematics of the University of Sarajevo and the Federal Ministry of Environment and Tourism. The List comprises 81 plant species. An official List of the invasive species for the Republic of Srpska still does not exist. Therefore, the knowledge of the contents of the invasive weed flora and its changes because of the geographical and climate conditions, is highly useful in inventorying, monitoring and managing invasive weeds. Vrbničanin et al. (2004) recorded 97 alien invasive weed species in the flora of Serbia, with dominance of the species from the family Asteraceae. The Croatian List (Boršić et al., 2008) contains 64 invasive alien weed species while 73 invasive alien plant species have been recorded in Montenegro so far (Alien and invasive alien species in Montenegro , 2021).

Materials and methods

During a three-year research time span (2018, 2019 and 2020), 73 localities of the vineyards in Bosnia and Herzegovina were observed (Figure 1). Each locality latitude, longitude and altitude were found using a GPS. Keys and iconography, standard for this region, were used for the analysis, determination and identification of the plant taxa. . In addition to the plant register and their distribution, each identified taxon (species, subspecies or variety) was enriched with a belonging flora element, life form and CSR life strategy.

Figure 5. The localities of the researched vineyards

A wish to classify plant species into specific categories according to their life strategies for the sake of easier understanding such organisms, has existed in research for a long time now. One such system was suggested by Grime (1979) in his book *Plant strategies and vegetation processes*. Grime proposed a theory according to which all the external factors that limit the amount of present live or dead plant material in any habitat can be divided into two categories: stress and disturbance.

Grime made a division of the species into three basic categories on the basis of adjustability of the plants onto the factors: (1) C-competitors, (2) S-stress tolerators, and (3) R-ruderals. Under competition he means a tendency of the neighbouring plants to use the very same light quantum, ion of mineral nutrients, molecule of water and air volume.

- Competitive plants (C strategy) grow best in conditions of low stress and disturbance. They are competitive to the other species in the habitat because they are morphologically adjusted to use the resources best.
- Stress tolerant plants (S strategy) are adjusted to the conditions of high stress but low disturbances. They mostly grow in habitats with extreme conditions like extremely low pH soil, low amount of light, etc.
- Ruderal plants (R strategy) can survive disturbances, but not the constant stress. Therefore, they are one year colonizers of the habitats with disturbed conditions. The simultaneous presence of the high amount of stress and disturbances is not helpful for the plant life.

In addition to the three basic categories, 16 types were established through further analysis. They are suited to different combinations of stress and disturbance in the habitat.
On the basis of collected data, a CSR analysis was conducted for the invasive weed flora in the vineyards of Bosnia and Herzegovina. Data on CSR strategies were withdrawn from the Internet bases Flora Croatica Database (Nikolić, 2010), BiolFlor (Klotz et al., 2002) and from the intern Lookup base of programmes for the CSR strategies determination (Hunt et al., 2004). For the species for which the CSR strategy was different in only one of the three sources, the strategy from the overlapping two sources was adopted. In case that data about the CSR strategy were accessible in two sources, and they differed, the species were taken for further examination.

Results and discussion

Through the floristic research done in the vineyards of Bosnia and Herzegovina on chosen locations, 27 invasive weed species were noted. They were classified in 15 families (Table 1). According to the numerical presence of the species, the largest presence is noted in the following families: *Asteraceae* (10 weed species), *Amaranthaceae*, *Fabaceae* and *Poaceae* (with 2 invasive weed species each), *Asclepiadaceae*, *Euphorbiaceae*, *Malvaceae*, *Simaroubaceae*, *Solanaceae*, *Phytolaccaceae*, *Plantaginaceae*, *Portulacaceae*, *Rosaceae* and *Urticaceae* (with one weed species each).

Table 1. List of invasive weed species in the vineyards of Bosnia and Herzegovina

Species	***Family***	**Life form**	**Origin**	**CSR**
Abutilon therophrasti Medik	*Malvaceae*	T	Asia	CR
Ailanthus altissima (Mill.) Swingle	*Simaroubaceae*	F	Asia	C
Amaranthus albus L.	*Amaranthaceae*	T	North America	R
Amaranthus retroflexus L.	*Amaranthaceae*	T	North America	CR
Ambrosia artemisiifolia L	*Asteraceae*	T	North America	CR
Artemisia vulgaris subsp. verlotorm (Lamotte) Bonnier .	*Asteraceae*	H	America	C
Asclepias syriace L.	*Asclepiadace*	G	North America	C
Datura stramonium L.	*Solanaceae*	T	North America	CR
Conyza bonariensis (L.) Cronquist	*Asteraceae*	T	America	CR
Conyza canadensis (L.) Cronq.	*Asteraceae*	T	North America and Central America	CR
Cuscuta campestris Yunck.	*Cuscutaceae*	T	North America	/
Elusine indicata (L.) Geartn.	*Poaceae*	T	Africa	C
Erigeron annuus (L.) Pers.	*Asteraceae*	T	America	CR
Euphorbia prostrata Aiton	*Euphorbiaceae*	T	America	R
Galinsoga parviflora Cav.	*Asteraceae*	T	America	CR
Lathyrus tuberosum L.	*Fabaceae*	G	Asia	C
Medicago sativa L.	*Fabaceae*	H	Eastern Europe, Asia	C/CSR
Phytolacca americana L.	*Phytolaccaceae*	G	North America	C
Picris eschioides L.	*Asteraceae*	H	South Europe	CR
Portulacea oleracea L.	*Portulacaceae*	T	Asia	R
Rubus ceasiues L.	*Rosaceae*	P	Europe and Asia	C
Sorghum halepense (L.) Pers	*Poaceae*	H	Africa and south-western Asia	C

Tagetes minuta L.	*Asteraceae*	T	South America	/
Urtica dioica L.	*Urticaceae*	H	Europe and Asia	C
Veronica persica Poir.	*Plantaginaceae*	T	Asia	R
Xanthium strumarium L.	*Asteraceae*	T	North America	CR
Xanthium strumarium ssp. italicum (Moretti) D.	*Asteraceae*	T	North America	CR

All of the above listed invasive species are not present at the official list of the Invasive alien species in Bosnia and Herzegovina, but they are invasive in the neighbouring countries – Croatia, Serbia and Montenegro. Due to the vicinity and the similarity in the biogeographical regions these species are listed in this table.

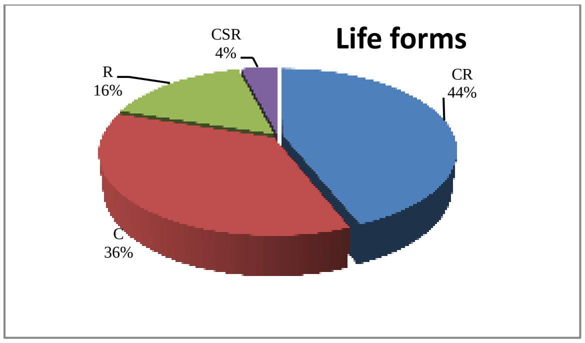

Figure 2. Life form of the invasive weed flora

Regarding life forms of the invasive weed species, life form Therophyte is dominant (17 weed species – 63 %) (Figure 2.). After Therophyte the next most numerous life form is *Hemicryptophyta* (5 weed species – 18 %), followed by *Geophyta* (three weed species – 11 %). They are followed by *Chamaephyta* and *Phanerphyta* with one (1) invasive weed species each
Regarding the origin, all the plants are introduced. The largest number of the plants was introduced from America (16 weed plants - 52 %), from Asia (9 weed plants – 29 %), four weed plants, whose native habitat was not in Bosnia and Herzegovina, arrived from other parts of Europe and two weed species from Africa.

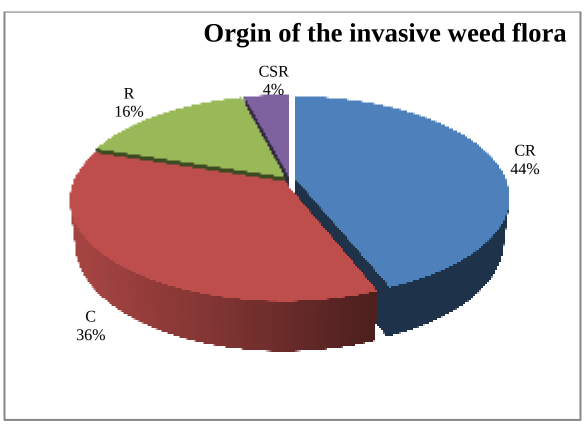

Figure 3. Origin of the invasive weed flora

The material was analysed on the basis of the collected invasive weed species and life strategies were established on the basis of 7 characteristics of life (height, mass of dried leaf, ratio of the dry matter of the leaf, the beginning and the duration of blooming, spatial spreading, specific leaf surface). The most frequent types of the strategy among the invasive flora in the vineyards of Bosnia and Herzegovina are CR strategy with 11 species and C strategy with 9 species. Life strategy R is present with 4 species and life strategy CSR with one species.

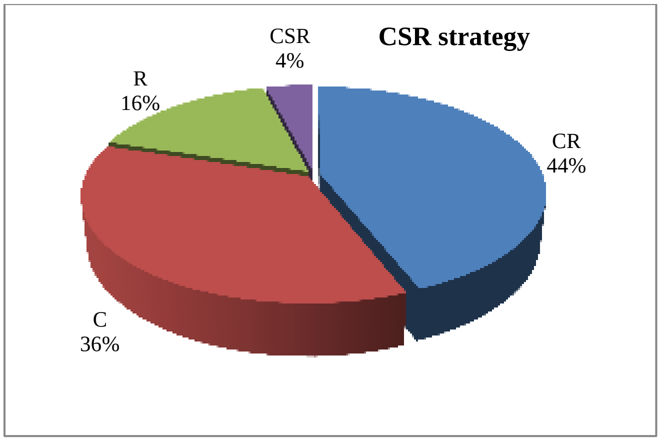

Figure 4. CRS strategy of the invasive weeds in the vineyards of Bosnia and Herzegovina

For some species CSR strategy was not done, because at the time of the fieldwork research some vegetative (*Cuscuta campestris* Yunck.) and generative (*Tagetes minuta* L.) parts were missing. As already said, CR and C strategies are dominant in this region, but also in the neighbouring countries, which is a matter of concern since these species have a negative impact on native species and diversity (Figure 4). The results of the research ask for further research of the CSR strategies of the invasive weed species that will contribute to better understanding of their spreading. Family *Asteraceae*, that has the largest number of invasive weeds, possesses some characteristics that can explain their superiority. *Asteraceae* are namely prone to the invasive behaviour due to their abundance of the life forms, due to dissemination adjustability and due to their huge numbers, which is the reason why they are highly present among the weeds. CSR system is based upon the influence of the environmental factors onto the flora so that the presence of a specific strategy can reveal data about the condition of the sheer ecosystem. To exemplify it, an increase of C type species in the habitat can be brought into connection with the anthropogenic habitat abandoning by the S type with an enlarged eutrophication, and by the R type with more frequent disturbances in the habitat (Hodgson et al., 1999).

Conclusion

The majority of the listed invasive families has a large number of herbaceous species with a short life cycle (Terophytes), summer development, good adjustability to the arable land. Also they are weed species that produce seeds in huge quantities *(Abutilon therophrasti* Medic., *Asclepias syriace* L., *Cuscuta campestris* Yunck., *Portulaceae oleraceae* L., et ct.).
According to the floristic research done at 73 locations in the vineyards of Bosnia and Herzegovina the most represented is the family *Asteraceae* with 10 weed species, whereas in the domain of life forms we have a dominance of the life form Therophyte with 17 weed species.

The largest number of invasive weeds comes from America. With the increase of invasive alien species in vineyards, especially C and CR strategy plants, there is a high possibility of spreading these species to the surrounding ecosystems, natural and semi-natural vegetation, and thus seriously endangering biodiversity.

Abstract

The goal of this research is to examine the spatial distribution of temporary and permanent wet zones in Bosnia and Herzegovina (B&H). In addition, the research refers to changes that occurred in the period 2012-2018 using the Copernicus Water and Wetness (WaW) and CORINE Land Cover (CLC) database. Regarding water resources, B&H is one of the richest European countries, with total amount to over 10 thousand m^3/per capita/per year. The article also shows the vertical distribution of temporary and permanent wet zones. The European digital elevation model (EU DEM) was used to divide the territory of B&H into three altitude zones: from 0-500 m, from 500-1000 m, and over 1000 m. As the country is at the contact of the Pannonian Plain in the north, the Dinaric Mountains in the central part and the Adriatic Sea in the south, the impact of large natural regions on wetness area distribution is examined.
The CLC database has been processed by extracting the wetland zones and calculating their spatial coverage and changes that happened during the period from 2000 to 2018. The research of WaW database shows that permanent wet areas occupy 0.1% and temporary wet areas occupy 2.5% of the B&H territory. According to CLC database wetlands cover 0.12% of the country's territory. So far, there has been no research on wetness zones based on the WaW high resolution layers database in B&H, which is the most significant contribution of this article.

Introduction

Soil moisture plays a pivotal role in vegetation dynamics, considering that soil water availability is a crucial limiting factor for plant photosynthesis (Proietti et al, 2019). Consequently, soil moisture maps provide an invaluable resource to quantify the effects of rainfall deficits on vegetated lands (Cammalleri et al, 2015). Soil moisture–atmosphere interactions are key elements of the regional climate system (Leutwayler et al, 2021). Wetlands are especially beneficial under extreme drought or flood conditions for their ability to retain water, reduce runoff, filter sediments, and provide water purification. The greatest impact to wetlands are from changes to hydrologic regimes (Hartig et al, 1997).
B&H is a country in the Western Balkans, with an area of 51209 km^2. The distribution of the total land area is as follows: 5% lowlands, 24% hills, 42% mountains, and 29% karst regions (TNC & SBUR of B&H, 2016). According to the last census from 2013, B&H has about 3.53 million inhabitants (ASB&H, 2016), or 69 per square kilometre. Annual precipitation varies from 800 mm in the north along the Sava River, to 2000 mm in the central and southeastern mountain regions (SNC B&H, 2013). The average annual rainfall in B&H is 1250 mm. Total renewable water resources per capita in B&H amount to 10592 m^3/per capita/per year (FAO,

2017). The total area of all water reservoirs and lakes cover 19921 ha (199.21 km^2) or 0.39% of the country's territory (Drašković & Gutalj, 2021). The river network density is 0.4 km / km^2.
The aim of the paper is to show the precise spatial distribution of temporary and permanent wet areas in B&H by altitude using the WaW and CLC databases. Wetness areas in B&H should be defined in the future as areas of high biodiversity, considering they provide important ecosystem services.

Materials and methods

The Copernicus Land Monitoring Service (CLMS) provides geographical information on land cover and its changes, land use, vegetation state, water cycle and earth surface energy variables to a broad range of users in Europe and across the world in the field of environmental terrestrial applications.
The main product of WaW database is a classified High-Resolution Layers (HRL), which contains defined classes of permanent water, temporary water, permanent wet, temporary wet, and dry areas, derived from water and wetness occurrences in the period 2012-2018. The Water Wetness Probability Index (WWPI) indicates the occurrence of water and/or wet areas throughout the entire observation period 2012-2018 for the 2018 product and is derived from frequencies of WATER, WET and DRY. The resulting product assembles the water and wet occurrence as an index on a scale between 0 (only dry observations) to 100 (only water observations) (see Figure 1). The HRL WWPI is provided in a pixel resolution of 10 m (CLMS, 2020).
WaW 2018 comprises the product in full spatial resolution of 10m x 10m (instead of the original 20m x 20m resolution of the WAW 2015 production). For the analysis of surface humidity, the WaW database from 2018 has been used, as an indicator of the spatial coverage of temporary and permanent wet areas in the period 2012-2018 (areas with 25% to 75% wet, including areas of changing soil moisture and intermittent wetlands).
Permanent water comprises e.g. rivers and lakes while temporary water include e.g. temporarily inundated areas. Among the wet zones, permanent wet areas comprises e.g. areas of permanently high soil moisture while temporary wet areas include e.g. areas of changing soil moisture (Langanke, 2016).
The CLC database contain wetlands information within the five main categories. The CLC database is available in both vector and raster format, while WaW is available only in raster format. The data are processed in GIS software and exported to Microsoft Excel, and then classified and calculated by individual types, areas and percentages.
The EU-Hydro database is available in the ESRI Geodatabase shapefile vector format. The river network is divided into two types: polygons (rivers wider than 50 m) and polylines (rivers narrower than 50 m). Digital elevation model (EU-DEMv1.1.) with a spatial resolution of 25 m has been used for distribution of wetness areas by altitude zones.

Results and Discussion

According to the WaW 2018 database, the areas under the category of permanent and temporary water occupy 33257 ha (0.64%) and 1464 ha (0.03%), which is a total of 0.67% of the territory of B&H (matches CLC 2018 data). Temporary wet areas cover 128680 ha (1286.8 km^2) or 2.5% and permanent wet cover 5222 ha (52.22 km^2) or 0.1% of the country's territory. CLC 2018 database shows that inland marshes cover 5242 ha and peatbogs 697 ha. So that, area of wetland cover 5939 ha (59.39 km^2).

Due to the increase in resolution from 20 m to 10 m and the reduction of the minimum cartographic unit from 1 ha in 2015 to 0.03 ha in 2018, these two databases are not completely comparable and the data may significantly differ by individual regions. According to WaW 2015 database temporary wet area cover 4.02% and permanent wet 0.1% of the B&H territory. From the same database permanent and temporary water cover respectively 0.44% and 0.13%, or 0.57% in total of country territory.

The largest temporary wet zones are karst fields at the west Bosnia region, and on the south at the region of Herzegovina. There are two main reasons: a large amount of precipitation (more than 1500 mm annually) and geological layers in which limestone rocks predominate that cannot accept all the water during rainy period. Another zone with large temporary wet areas is in the north-eastern part of the country, at regions of Posavina and Semberija. In this case, the reason for wetness is related to the relatively frequent outflow of large rivers and their tributaries from riverbeds and alluvial plains. Figure 1 shows wet occurrence by altitudes and in relation to geographical position of mayor rivers.

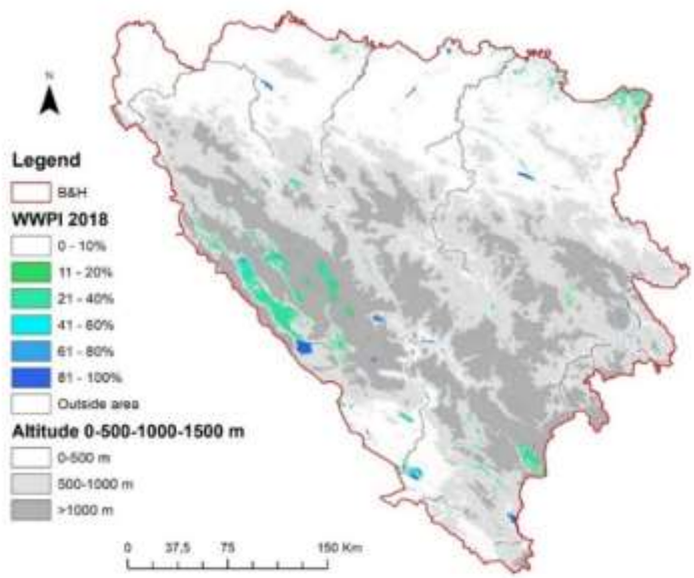

Figure 1. Wetness zones by percentage and altitude (Data source: WWPI 2018, EU-Hydro 2018 and EU-DEMv1.1)

Altitude and differences in vertical climate zonation certainly affect the appearance of temporary wet areas. Considering the altitude range from 0 to 2367 m, three altitude zones of 0-500 m (39.47% of the B&H territory), 500-1000 m (35.53%), and over 1000 m (25%) have been taken into account.

The WaW 2018 database shows that temporary wet area are not evenly distributed by altitude zones. They occur more within the zone of 500-1000 m (52.4%) than within the zone of 0-500 m (37.0%) and the zone over 1000 m (10.6%) (Table 1). This difference appear thanks to the karst fields in the west of the country whose altitude is between 500-1000 m. The only larger temporary wet area above 1000 m is at Kupreško karst field. The area in the north around the rivers Sava and Drina belongs to the zone from 0 to 500 m.

Table 1. Spatial distribution of temporary wet areas by altitude

Wetness zones	0-500 m		500-1000 m		>1000 m	
	P (km^2)	P (%)	P (km^2)	P (%)	P (km^2)	P (%)
Temporary wet	502.5	37.0	647.75	52.4	136.55	10.6
Permanent wet	27.16	52.1	24.56	47	0.5	0.9

*Data source: WaW 2018 and EU-DEMv1.1

When it comes to permanent wet area 52.1% is located within 0-500 m, 47% is within 1000-1500 m and 0.9% over 1000 m. Spatial distribution of permanent wet zones is similar to temporary wet zones, so lower wet zones are around Sava and Drina river, and higher are in the western part of the country.

Estimates show that B&H will be exposed to climate change impacts that could have consequences for its entire society. Studies of temperature change for the period 1961-2010 indicate that temperatures have increased in all areas of the country. A comparative seasonal analysis for 1981-2010 and 1961-1990 showed that the largest increases in average temperature during the summer months were observed in Herzegovina (Mostar 1.2°C). The largest decrease in annual precipitation was during the spring and summer seasons, in the region of Herzegovina (Mostar and Bileća, up to 20%) (SNC, 2013).

According to CLC Changes database, in period from 2000 to 2018 wetlands (4.1) reduced the area for 490 ha (4.9 km^2). Among them, inland marshes (4.1.1) were most endangered by other land cover types, primarily with water bodies (5.1.2) and non-irrigated arable land (2.1.1). Some areas with higher amount of precipitation caused expansion of water bodies over inland marshes, while part of wetlands has been converted to agricultural use. In future, some of remaining wetlands will be probably subject to agricultural drainage.

Runoff is identified as a key hydrological parameter affecting wetland function (Hartig et al., 1997). The average runoff coefficient in B&H is 0.57 (SNC B&H, 2013). Higher temperatures accompanied by lower precipitation will change the hydrologic regime enough to damage wetland functions in Herzegovina region. Other wet zones will be less affected. Wetland protection could assist to decrease vulnerability of climate change impacts.

Conclusions

According to WaW database in 2018 water cover 0.67% of territory of Bosnia and Herzegovina. Temporary and permanent wet area cover 2.5% and 0.1% respectively. The largest wetness zones are located in the western part of the country, at region of Livanjsko, Glamočko and Kupreško karst fields, and also Gatačko karst field at Herzegovina region. There are two main reasons for higher level of wetness. Firstly, area of karst fields receive over 1500 mm precipitations annually, and secondly, limestone geologic layers cannot accept all the water in humid period so water goes ascending and flooding the bottom of fields. Also, temporary wet zones appear along the alluvial plain, especially at Sava and Drina river basins in north-eastern part of the country.

The predicted climate changes in precipitation and air temperature will affect negatively on wetness areas in B&H. Aridity is expected to increase, because of reduced summer rainfall coupled with increased evaporation rates. The extent of future wetland losses will depend on land-use policies, socioeconomic conditions, and vulnerability to climate change.

Abstract

This paper has studied weed population of arable crops in Herzegovina region (Bosnia and Herzegovina). On 34 research localities, overall 51 species of vascular plants from total of 25 families were noted. The highest share had family *Asteraceae* (counting 11 species) and *Poaceae* (counting 5 species). The analysis of biological spectrum of association *Panico- Portulacetum oleraceae* Lozanovski 1962. Terophyte-hemicriptophyte character could be determined, with slightly higher share of terophytes, and smaller share of hemicriptophytes, resulting exclusively from mechanical measures of weed control. In areal spectrum of association *Panico-Portulacetum oleraceae* Lozanovski 1962 seven groups of flora elements were asserted, among which elements of wide-spread dominate. Thirty two (32) plant species related to the cosmopolite group of flora elements. The stands of the *association Panico-Portulacetum oleraceae* Lozanovski 1962 in arable crops of Herzegovina contain 51 weed species, which represents a certain floristic wealth in relation to the eponymous association described in other localities. Special emphasis has to be set on species common for all localities, which are the typical species of syntaxonomic units (association, alliance, order and class): *Portulaca oleracea* L., *Echinochloa crus-galli* (L.) Beauv., *Setaria glauca* (L.) Beauv., *Amaranthus retroflexus* L., *Chenopodium album* L. and *Solanum nigrum* L. The most common type of strategy in weed flora is R (28.00%), followed by plants of CR strategy (16.00%).

Keywords: *weed flora, CSR strategies, floral diversity.*

Introduction

Openness of perennial crops as well as the methods of cultivating the land are favourable to the 'entry' of a high number of ruderal species, particularly invasive, into floristic composition of weed communities, which results in 'ruderalisation' of weed communities, significant change of floristic composition, pushing of segetal weeds and inability to plan adequate controlling measures for a long period of time (Kovačević *et al.* 2014). The composition of flora is affected by agro-technical measures (method of land tilling, fertilizer spreading, herbicides use, grass sowing, mowing) and method of cultivation (cultivation form, inter-tillage and tillage in a row) (Barić *et al.* 2021)

The weeds are spread around the world (*ubikwists*), they have an exceptional ability of survival, they are able to crop up in various soils and under various climate conditions, growth and development phases quickly pass by, their seed is able to postpone the period of cropping up (dormancy); furthermore, they are able to keep live and sproutable seed for very many years under field conditions, they bear fruits several times a year, they produce seed of equal weight and form as well as the cultivated species, they increase in number generatively (by seed) and/or by vegetative organs, which are fragile and do not let to be pulled out (they break). The underground organs are rich with reserve nutritious organs so they easily resist stormy weather. They have especially developed methods of spreading to new areas. With their root and vegetative organs they deeply get through the soil. They are able to develop resistance to certain groups of herbicides and because of that, they compete for the space, nutrients, water and light with agricultural and other (desired) plant species, damaging them directly and indirectly. (Ministry of Foreign Trade and Economic Relations, 2021)

CSR classification (Hodgson et al. 1999) is a practical method for the categorization of plants according to Grime's theoretical triangular scheme of competitor, stress tolerator and ruderal plant strategies (CSR theory). The CSR classification method uses various functional traits quantified *in situ* (or measured from material collected *in situ*). (Pierce et al. 2013) Three principal strategies represent viable trait combinations arising under conditions of competition, abiotic limitation to growth or periodic biomass destruction, respectively. Specifically, C-selected 'competitors' are said to survive in relatively stable, productive habitats via investment of resources in continued vegetative growth and rapid attainment of large individual and organ size to aid resource pre-emption. S-selected 'stress tolerators' protect metabolic performance in variable and resource-poor environments by investing mainly in capacity to retain resources and repair cellular components in dense, persistent tissues. R-selection, or ruderalism, involves investment of a large proportion of resources not in the individual but in propagules from which the population can regenerate in the face of repeated lethal biomass destruction events, or disturbances. (Pierce et al.2017)

The goals of this paper are to research, describe and systematize the weed plants of arable crops the Herzegovina; to determine their position as compared to the affiliation to certain plant communities as well as plant forms. Moreover, the objective is to determine the CSR life strategy of weed plants by determining factors of competitiveness, stress tolerance and ruderal factors.

Material and methods

Floristic–phytocoenological researches of weed flora and vegetation of arable crops were conducted during three vegetation seasons (2018, 2019 and 2020), from spring to the late autumn.

The research encompassed 34 localities and by means of GPS the geographical latitude, geographical longitude and height above sea level have been very precisely determined (with an error of few meters) for all localities. Also, for every researched locality, where the phytocoenological photos were taken, the dates of taking photos were recorded as well as the municipalities, which certain locality belongs to.

Floristic–phytocoenological researches were carried out upon principles and methods of Swiss-French (Zürich-Montpellier) phytocoenology school Braun Blanquet (1965), and they encompassed analytical and synthetic phase of research.

Processing and determination of plant species were carried out by means of the following floristic works: Flora Europaea I-V (Tutin, ed., 1964-1980, 1993), Flora Bosne i Hercegovine – *Flora of Bosnia and Herzegovina* (Beck, 1903, 1906-1923), Flora SR Srbije I-IX – *Flora of Federal Republic of Serbia I-IX* (Josifović, ed., 1970-1977), Flora Hrvatske – *Flora of Croatia* (Domac, 1994), Ilustrovana korovska flora Jugoslavije – *Illustrated Weed Flora of Yugoslavia*

(Čanak et al., 1978), Ikonographie der Flora des Südöstlichen Mitteleuropa (Javorka et Csapody, 1979) and Flora Italiana (Fiori et Paoletti, 1921).
Nomenclature of plant species has been aligned according to the works: Flora Europaea (Tutin et al. 1964 –1980, 1993), then Flora Croatica Database (Nikolić, 2015), and only partly according to Pignatti (1982) and Trinajstić (1975 –1986).
Numerousness and superficial feature as well as integration in the analysed forest stands have been defined upon the principles and methods of Swiss-French phytocoenology school (1965 (Zürich-Montpellier), combined with the scale per Braun-Blanquet (1965).
Field testing, phytocoenological photos were taken at the areas of 100 m^2.
The phytocoenological photo represents a list of plant species in a certain forest stand, in process of which a combined assessment of numerousness and superficial feature has been obligatorily defined for every species, and often also the assessment of integration or social feature. The first and the second assessment are mutually divided by point. For every phytocoenological photo the general and ecological data on forest stand are recorded. All photos have been taken prior to the conduction of agro-technical measures (plowing, tilling with a rotary hole, inter-tillage, use of herbicides).
Syntaxonomic overview of vegetation is shown according to the following publications: Sintaksonomski pregled vegetacije Srbije - *Syntaxonomic overview of vegetation of Serbia* (Kojić et al., 1998) and Pflanzensoziologische Exkursionaflora für Deutschland und angrenzedne Gbiete (Oberdorfer, 2001).
Comparison of a large number of regularly developed species of some community defines the frequency of the presence of some plant species in a certain community. This analysis is the most successfully carried out based on the analytical phytocoenological table-sheet. A degree of the presence is shown in percentages showing in how many researched forest stands of some community certain plant species is present. The presence is expressed in Roman numerals I to V, i.e.:
I = species present in 1 - 20% of the photos,
II = species present in 21 - 40% of the photos,
III = species present in 41 - 60% of the photos,
IV = species present in 61 - 80% of the photos,
V = species present in 81 - 100% of the photos.
Grime CSR strategy of plants has been made. Grime has made exactly based on plants adaptiveness to the factors the classification into three basic categories: competitive (C), stress-tolerant (S) and ruderal (R) species. The competition assumes the tendency of neighbouring plants to use the same quantum of light, ion of mineral substances, molecule of water and volume of air.
The existing data on CSR strategies have been taken from the Internet databases Flora Croatica Database (Nikolić, 2010), BiolFlor (Klotz et al., 2002) and internal Lookup database of the programme for determining the CSR strategies (Hodgson et al., 1999).

Results and discussion

At the researched localities there are 51 plant species recorded with 25 families so the most numerous ones are the family *Asteraceae* with 11 species and *Poaceae* with 5 species.

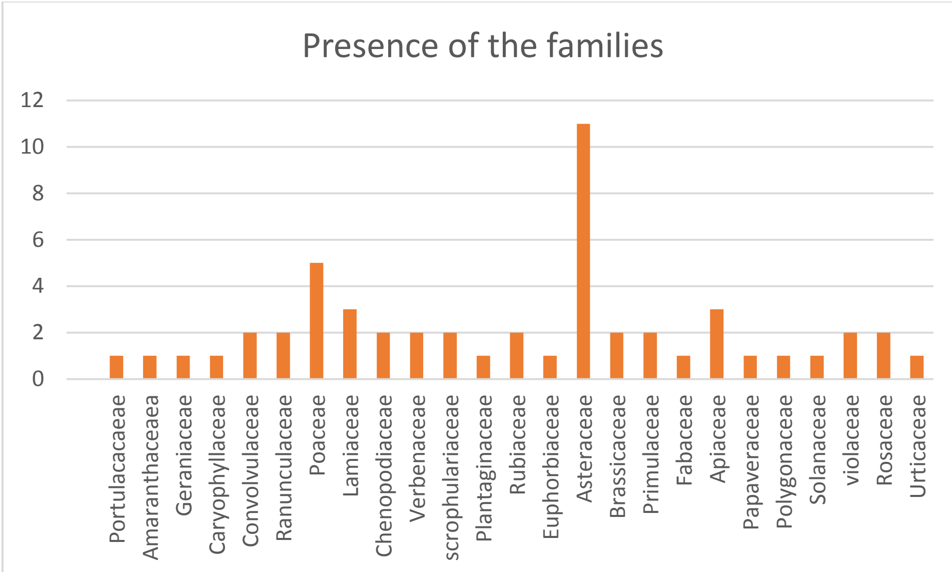

Figure 1. Presence of the families at the researched localities of arable crops

In the spectre of life forms, the life form of terophyte dominates (27 – 53%). After terophytes, the most numerous are the hemicryptophytes (19 species – 37 %) and geophytes (5 species – 10%).

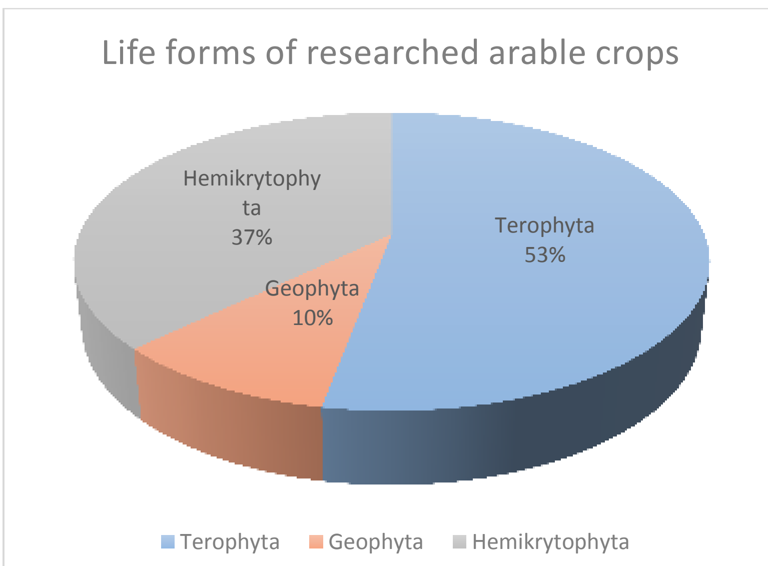

Figure 2. Overview of life forms of researched arable crops

In the areal spectre of the association *Panico-Portulacetum oleraceae* Lozanovski 1962 there are 7 groups of flora elements defined. A cosmopolitan group of flora elements dominates and 33 plant species (62%) belong to this group.

Forest stands of the association *Panico-Portulacetum oleraceae* Lozanovski 1962 in the arable crops of Herzegovina make 51 weed species, which represents a certain floristic richness in comparison to the association of the same name, described at other localities. Joint species at all localities are to be particularly pointed out which belong to the characteristic species of syntaxonomic units (association, alliance, order and class): *Portulaca oleracea* L., *Echinochloa crus-galli* (L.) Beauv., *Setaria glauca* (L.) Beauv., *Amaranthus retroflexus* L., *Chenopodium album* L. *and Solanum nigrum* L. Based on the collected weed flora, the material has been analysed so the life strategies have been defined on the basis of 7 life characteristics (height, weight of dry leaf, share of the leaf substance, starting point and period of flowering, side spreading, specific leaf surface). The most frequent type of the strategy among the weed arable crops is the R strategy with 15 species and CR strategy with 8 species.

Šinžar and Živanović (1993) studied the weed community of the vineyards in Banat (Vojvodina). Based on the results, the weed communities from the associations Panico – Portulacetum oleraceae in Banat are found to be danker habitat of the northern slopes of the peak mountains and they concord with 18 species in Bosnia and Herzegovina. Arable Crops of Strumica Valley (Lozanovski and Piperkovska, 1992) have shown significant differences in floristic composition and they are the result of more intensive anthropogenic impact, small floristic richness and sub-Mediterranean character of this area.

Conclusion

For the presence and extent of weed plants and constitution of weed communities, in addition to the abiotic factors, a significant share belongs also to the orographic factors. The majority of them acts indirectly by changing the others, in the first place the climate and edaphic factors. Out of the edaphic factors, for the cultivated plants and weeds as well as their followers, the biggest importance belongs to the height above sea level and exposition. If the agro-technical measures are more intensive, the weed community is kept more on the level of weed communities of wide-row plough-field arable crops with the dominating terophytes and weaker presence of geophytes and hemicryptophytes. Weed suppression with agro-technical measures substantially raises the price of production and it has a relatively short effect so therefore the use of herbicides has enabled that the weeds could be efficiently supressed for a long period of time with the increase of cost-effectiveness of the production.

Abstract

Melliferous plants are key to the ecosystem pollination service. The melliferous plants are under strong anthropogenic pressure in the conditions of intensive agriculture and modern climate changes in southern Europe. The study is aimed at identifying and spatial distribution of honey plants species in traditional agricultural areas of northern Bulgaria: following the example of Vratsa district, Krivodol municipality. The study covers the period 2019-2021. Special attention is paid to the semi-natural and natural fragments in the landscape - headlands, hay meadows and pastures. The study presents the results of field observations conducted by the Braun-Blanquet method in 120 phytocenological descriptions of representative areas in the plain-hilly terrain. 14 habitat types according to the EUNIS classification have been identified and the projective cover and the number of honey-bearing species in habitats have been assessed, and the species with over 10% projective cover have been extracted and described. In the course of the research, landfills with invasive melliferous plants were visited and described. There is destruction of hay meadows and pastures and their conversion into arable land, which leads to loss of melliferous plants and habitats.

Key words: *melliferous plants, habitats, Northern Bulgaria, agricultural landscapes.*

Introduction

Melliferous vegetation (pollen- and nectar-rich plants) is an important component of modern biodiversity (IPBES, 2016). It contributes significantly to maintaining pollinator activity and limiting the degradation of natural and semi-natural habitats subjected to the combined impacts of urbanization, intensive agriculture and climate change (Perennes, 2021). Melliferous vegetation is an essential prerequisite for the spatial distribution and abundance of pollinating insects and plays a determining role in the spatial organisation of agriculture, productivity and sustainability in cultivated plants and the effectiveness of good agricultural practices (Regulation (EU) 2017/2393). Understanding the role of Melliferous vegetation in the structure of natural and cultivated habitats is essential for developing spatial patterns of pollination of cultivated and wild plants, clarifying the vulnerability of native pollinators (primarily bees) and developing adaptive land management practices.
The ecosystem service of pollination provided by honey bees is crucial for the normal functioning of different ecosystems: natural, semi-natural and agrarian. After the key ecological prerequisites for pollination processes to take place is the presence of honey bee vegetation in the

structure of landscapes. Contemporary challenges in land management pose as acute the issue of maintaining beekeeping traditions in areas dominated by agricultural activity as a guarantee of their sustainability.

The EU Pollinators Initiative (2018) identifies land-use change, intensive agriculture and pesticide use, pollution, invasive alien species, disease and climate change as major threats to the distribution of melliferous plants and associated pollinators.

The balance of honey bee vegetation and pollinators is perennially in the focus of the scientific community, managers and decision makers (IPBES, 2016). It is widely acknowledged that declines in pollinators and pollination lead to losses in biodiversity (over 85% of wild flowering plants depend on pollination) and serious problems in crop yields - annual food production from agriculture worth nearly $577 billion is formed with the direct involvement of pollinators (IPBES, 2016). Melliferous vegetation, as a major input for pollinator dispersal, is a key factor for ecosystems and humanity in terms of biodiversity, agriculture, climate change adaptation, and all other pollination-related ecosystem services. Pollinator conservation must be included in ecosystem and habitat restoration processes and to promote their long-term sustainability (Christmann, S., 2019).

The aim of the present study is to determine the distribution and diversity of melliferous plants in different habitat types in part of Northern Bulgaria. The region is known for its traditional agricultural landscapes for the Bulgarian geographical conditions – wide area arable lands, hay meadows and pastures, fragmented forest vegetation. An important sub-task of the study is the identification of current anthropogenic pressures on the territory that negatively affect the distribution of melliferous vegetation - structural changes in landscapes, land use change, invasive species, etc., and hinder the provision of pollination services.

Material and methods

As a result of a preliminary geographical analysis, the municipality of Krivodol, Vratsa region was selected as the pilot area (Fig. 1). The total area of the territory included in the study amounts to 25 km^2. The spatial extent and shape of the territories selected for field analyses was tailored to the biological and physiological capacities of the honey bee for activity relative to the location of the hive (Tsankov, 2015). Field surveys were conducted between 2019 and 2021, and phytocenological descriptions were collected in different ecosystem types. The descriptions were made in July, when the maximum in vegetation development occurs, following the methodological approach of Brown-Blanke (Westhoff & van der Maarel, 1973). 120 phytocenological descriptions were carried out.

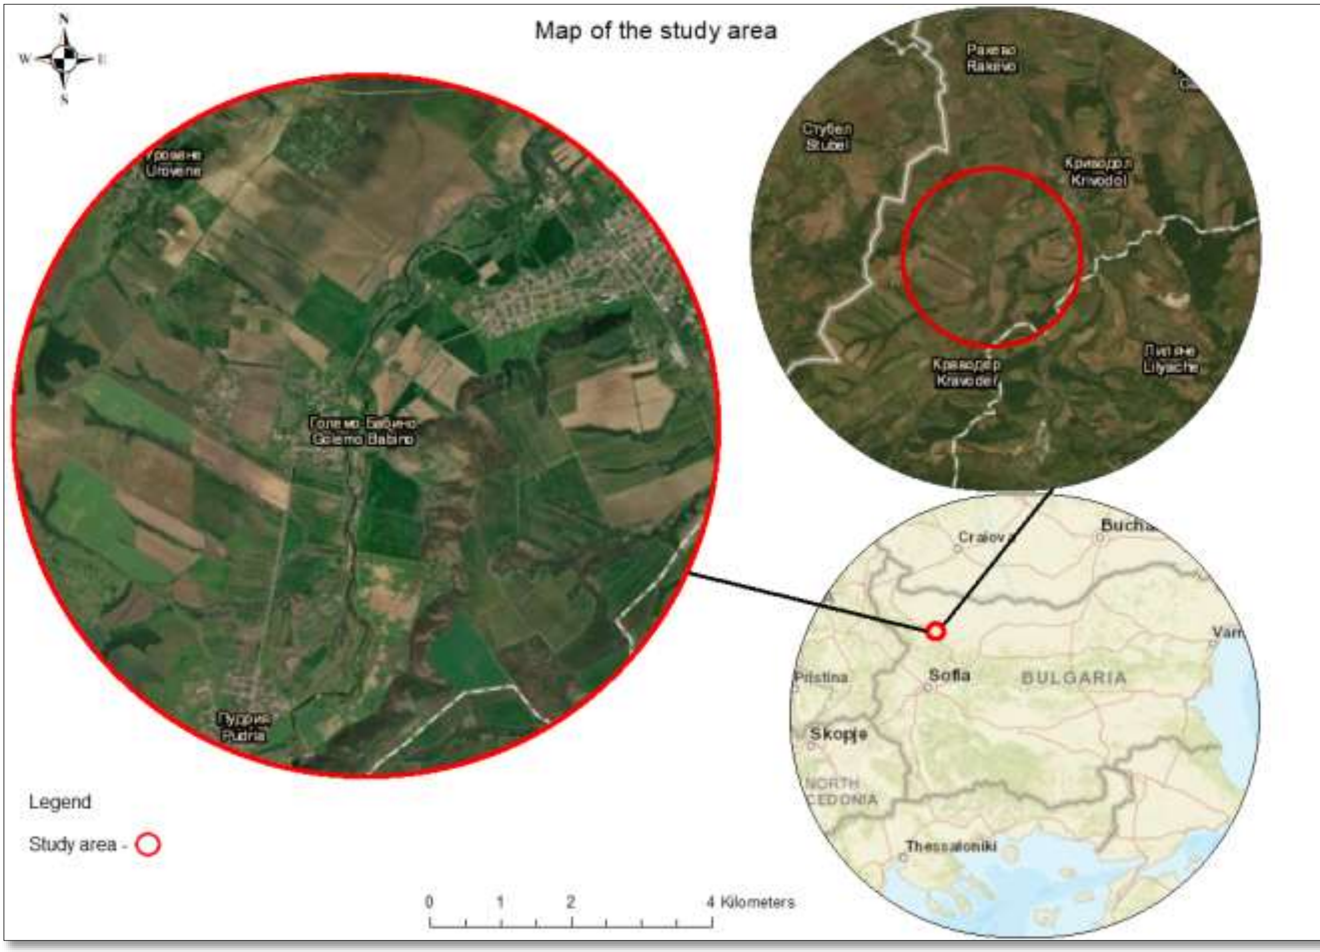

Fig. №1 Study area

Field studies include the abundance and diversity of melliferous plants species in natural habitats, collecting samples and specimens. Sample plots were laid out in homogeneous and representative plots of the plant communities, following the methodology of Chytry & Otypkova (2003), namely for herbaceous vegetation - $16m^2$; for shrub vegetation - $64m^2$, for forest vegetation - $225m^2$. All vascular plant species were noted within the boundary of each sample plot. Using a previously prepared honey plant list from which were extracted all honey plant species an their abundance and cover within the phytocenological descriptions boundaries were estimated using the Braun-Blanquet scale (Braun-Blanquet, 1965). For each phytocenological description, the following types of data on environmental conditions were collected: elevation, exposure, soil power, and grazing intensity.

Results and discussion

As a result of the surveys conducted and the subsequent analysis of the honey plant richness, 14 natural habitat types have been identified, corresponding to the EUNIS classification. The assessment of their composition, structure and ecological characteristics is based on 120 phytocenological descriptions.

Ruderal and herbaceous phytocenoses are the most widespread, followed by forest and shrub phytocenoses. In the last 15-20 years, as a result of the reduction in grassland use, the cover of shrub vegetation is also increasing. The remaining vegetation types are of limited distribution - hygro- and hydrophilous phytocenoses.

Forest vegetation

Euro-Siberian steppe *Quercus* woods (G1.7A1): Abiotic characteristic and distribution: this vegetation type is characterized by remnant forests that have been highly modified due to prolonged anthropogenic impact. They occupy limited areas in the land of the villages of Golemo Babino, Pudria and Urovone, with altitudes ranging from 200 to 220 m above the sea level. The soils are medium to relatively deep, and shallow in places where there is outcrop of bedrock. Composition and structure: Within this vegetation category, there is a distinct tree, shrub, grass and moss floor in the vertical structure. The overall projective vegetation cover is 100%, with tree floor cover ranging from 80-100%. Shrub and herbaceous floor cover are 60-70% and 70-85%, respectively. A total of 30 species of melliferous have been identified in the species composition of the habitat phytocenoses, forming a cover of 90-100%. The species with >10% cover are *Quercus cerris*, *Q. pubescens*, *Q. frainetto*, *Crataegus monogyna*, *Acer campestre*, *A. tataricum*, *Fraxinus ornus*, *Buglossoides purpuruleaceae*, *Ligustrum vulgare*, *Hedera helix* and *Glechoma hederacea*.

Riverine willow woodland (G1.11): Abiotic characteristics and distribution: This habitats has a limited distribution in this area. It forms banded polygons along the river channel. The soils are alluvial, well moistened. Composition and structure: The overall projective vegetation cover is 100%. Coverage of the shrub and herbaceous floors are 30-80% and 80-85%, respectively. In the species composition of the phytocenoses of the habitat, a total of 22 species of melliferous plants have been identified, forming a cover of 95-100%. The species with >10% cover are *Salix fragilis, Acer campestre, Cornus sanguinea, Clematis vitalba, Aegopodium podagraria, Crataegus monogyna, Hedera helix, Prunus avium, Rubus caesius, Ulmus glabra, U. minor*.

Robinia plantations (G1.C3): Abiotic characteristic and distribution: This vegetation has a fragmented distribution in the study area, with strips around arable land and artificial plantations along villages Golemo Babino, Urovene and Krivodol. *Robinia pseudoacacia* has secondary widespread as the species occurs in a variety of ecological conditions, including highly disturbed areas. Composition and structure: In the species composition, 11 species of melliferous plants are found, which form a cover of 95-100%. The species with >10% cover are *Robinia pseudoacacia, Crataegus monogyna, Prunus cerasifera.*

Shrub vegetation

Moesian oriental hornbeam thickets (F3. 2431): Abiotic characteristic and distribution: The vegetation has a fragmented distribution in the study area in the around of the villages of Golemo Babino, Urovene and the town of Krivodol. The soils are shallow to medium in depth. Composition and structure: this vegetation occurs on eroded terrains or on the site of highly degraded forest phytocenoses. After the processes of deforestation and erosion, *Carpinus orientalis* has spread significantly and formed its modern cover. In the species composition, 18 species of melliferous plants are found, which form a cover of about 50%. The species with > 10% cover are *Cornus mas, Fraxinus ornus*.

Medio-European rich-soil thickets (F3.11): Abiotic characteristic and distribution: this vegetation has a fragmented distribution in the study area in the margins of arable land, grassland, etc. The soils are of medium depth. Composition and structure: Coverage of the shrubs are 90-100%. The herbaceous floor is well developed, but in 80% of the cases it is strongly influenced by the density of the shrubs. There are 29 species of melliferous plants in the species composition, forming a cover of about 80-100%. The species with > 10% cover are *Acer campestre, Buglossoides purpuruleacea, Clematis vitalba, Cornus sanguinea, Crataegus monogyna, Prunus spinosa, Rubus caesius.*

Grass vegetation

Moesio-Carpathian steppes (E1.222): Abiotic characteristic and distribution: this vegetation is widespread in the study area, comprising predominantly grassland. Soils are medium to shallow in depth. Composition and structure: It is a herbaceous vegetation with a semi-enclosed horizontal structure (90-100%). Characterised by a rich species composition. The species composition includes 65 species of melliferous plants which form a cover of about 10-100%. The species with > 10% cover are *Agrimonia eupatoria, Dorycnium herbaceum, Galium verum, Medicago falcata, Origanum vulgare, Plantago lanceolate, Potentilla argentea, Xeranthemum cylindraceum, Trifolium repens.*

Permanent mesotrophic pastures and aftermath-grazed meadows (E2.1): Abiotic characteristic and distribution: This vegetation has a local distribution on the leveled areas in the area of the village of Pudria and the town of Krivodol. The soils are powerful. There is a pasture use regime. Composition and structure: These phytocenoses have a closed horizontal structure with a projective cover of 90-100%. The species composition is poor and is composed of species resistant to trampling. In the species composition, 18 species of melliferous plants have been identified, forming a cover of about 30-80%. The species with > 10% cover are *Trifolium repens, Mentha spicata, Xeranthemum cylindraceum.*

Low and medium altitude hay meadows (E2.2): Abiotic characteristic and distribution: This vegetation has a local distribution on the flattened terrain and waterlogged land in the village of Kravoder. The soils are powerful. Composition and structure: These phytocenoses have a closed horizontal structure with a projective cover of 100%. In the species composition 7 species of honey plants are found which form a cover of about 3%. There are no species of these with a cover > 10%.

Continental humid meadows (E3.46): Abiotic characteristic and distribution: This vegetation has a local distribution between the villages of Golemo Babino and Pudria. The soils are powerful, waterlogged periodically during the year. Composition and structure: In the species composition, 9 species of melliferous plants are found, which form a cover of about 65-95%. The species with > 10% cover are *Epilobium hirsutum, Lythrum salicaria*.

Water-fringing reedbeds and tall helophytes other than canes (C3.2): Abiotic characteristic and distribution: This vegetation has a local distribution on floodplains and waterlogged habitats in the area of the villages of Golemo Babino, Pudria, Urovone and the town of Krivodol. Soils are waterlogged and some localities are permanently submerged in water. Composition and structure: This vegetation has a closed horizontal structure with a projective cover of 100%. In the species composition, 11 species of melliferous plants were found to form very little or no cover. The only exception is a description with 100% projective coverage. Only *Galega officinalis* is a species with > 10% cover.

Fox sedge tussocks (D5.219): Abiotic characteristic and distribution: this vegetation has a local distribution on the land of the village of Pudria. The soils are waterlogged. Composition and structure: This vegetation has a closed horizontal structure with a projective cover of 100%. In the species composition 2 species of honey plants are found, which form a cover of about 3,2%. There are no species with > 10% cover.

Iris beds (C3.24B): Abiotic characteristic and distribution. This vegetation is native to the area of Krivodol. It occupies an area of several square meters. The habitat is waterlogged, with a water depth of 20-25 cm. Composition and structure. In the species composition, 1 species of melliferous plant (*Lythrum salicaria*) is identified, which has a cover of about 0.5%. There are no species with > 10% cover.

Anthropogenic herb stands (E5.1): Abiotic characteristic and distribution: This vegetation combines ruderal and weedy vegetation that is widespread in the study area (crops, landfills, roadsides, orchards, hedgerows, etc.). This unit is very difficult as a polygon site because of the small areas it occupies and the fact that some of the phytocenoses develop within the range of other habitats of the EUNIS classification, such as cropland. Composition and structure: This vegetation has a semi-open to closed horizontal structure with a projected cover of 80-100%. Species with greater abundance and cover are highly heterogeneous. In the species composition, 76 species of melliferous plants have been identified, forming a cover of 5-100%. The species with > 10% cover are *Verbascum densiflorum, Trifolium arvense, Stachys annua, Sambucus ebulus, Salvia verticillata, Rumex acetosa, Rubus caesius, Potentilla supina, Portulaca oleracea, Polygonum aviculare, Plantago major, Persicaria lapathifolia, Malva sylvestris, Daucus carota, Cichorium intybus, Chamomilla recutita, Carduus acanthoides.*

Intensively-farmed crops interspersed with strips of natural and/or semi-natural vegetation (X07): Located within the entire study area. They are formed on the sites of natural forest, grass and shrub vegetation that was widespread in the past and destroyed by man. Arable farmland is included in this unit. Communities of mapping unit E5.1 develop adjacent to or at certain times of the year on areas of arable land.

The pooled data show that the abundance and cover of honey plants varies substantially across the identified natural habitats. In terms of the minimum projected cover of honey plants, the data are similar. For mean and maximum values, the variation is significant. The highest values are found at E3.46, G1.11, F3.11, G1.C3 and G1.7A1, which is due to the dominance of species in the phytocenoses that are melliferous plants. On the other hand, the lowest values were at X.07, E.2.2 and D5.219.

In terms of environmental factors, there are disturbances to the natural vegetation in the area that pose a potential risk to beekeeping. Most of the semi-natural forest vegetation has been destroyed as a result of agricultural development over the last century. The few remaining areas of forest vegetation are of very limited extent, mainly on steep valley slopes. Their fragmentation and degradation impair the provision of full ecosystem services. The forest habitats support a rich diversity of honey bee plants, some of which (*Quercus cerris*, *Q. pubescens*, *Q. frainetto, Robinia pseudoacacia*) have over 75% projective cover and provide abundant natural grazing for bees. Much of the moisture-loving woody vegetation (*Salix fragilis, Populus nigra*) along the bed of the Botunia River has been destroyed in recent years and no measures have been taken to restore it. This has led to changes in the river bed and also to several spring floods of the land around the river.

The problem facing beekeeping is the destruction and "degradation" of grasslands and pastures. In the past, these habitats were widespread due to livestock farming by the local population.

They are the habitats of many numbers and types of melliferous plants that are important for bees in periods without major grazing by agricultural crops. Destroying them and converting them to arable land reduces the richness and diversity of food sources for bees. In places, the destruction of these grasslands leads to flooding, landslides, compaction of the topsoil and accelerated soil erosion. The destruction of weed vegetation in the ecotone zones around the fields is often observed when agricultural areas are treated. Another adverse effect on the diversity of melliferous plant species, and especially on bee activity, is the narrowing and destruction of hayfields as a result of ploughing. Hedgerows are the 'corridors' along which honey bees move (nectar corridors).

Conclusion

In the selected pilot area of traditional agricultural landscapes in northern Bulgaria, as a result of the research conducted, 14 habitat types have been identified (EUNIS). This is the first time such a study has been carried out in this territory. The highest concentration of melliferous plants (64-74 species) was found in habitats E1.222 and E5.1. There is a limited presence of honey bees (2-3 species) in the structure of E.2.2. and D5.219. The areal cover of melliferous plants varies widely: differences in minimum projected cover of 61 species range from 0.1-1%. The highest values for the mean projective cover are reported for habitats G1.11 and E3.46 and it is 21.5%, while the lowest values are reported for habitat D5.219 (- 1.07%. There is a strong fragmentation of semi-natural habitats and the destruction of hedgerows (nectar corridors) and ecotone zones near arable areas, which is a major threat to the presence of melliferous vegetation in the structure of landscapes.
The study will be used as a basis for extending the scope of the study to melliferous vegetation and the ecosystem services associated with it.

Abstract

Despite the political efforts, France is among the main consuming countries of pesticides in the world and the first at European level with a consumption of more than 85,900 tons/year (BNV-D[1], 2019). The preservation of natural resources through the management of diffuse pollution related to pesticide use is considered as a major challenge in France and based on the identification of the highest risk areas. Our work aims to map the phytosanitary practices impact on human health and on natural resources, based on indicators of phytosanitary pressure (TFI: Treatment Frequency Index) and risk (IRSA: Indicator of Risk on the Applicator's Health, and IRTE: Indicator of Toxicity Risk on the Environment). These indicators are calculated with the EToPhy[2] software. This approach allows to present the spatial distribution of risk and phytosanitary pressure in the south-west of France (Gimone watershed). This mapping process is based on the scores of phytosanitary pressure and risk assigned to each plot, calculated from the applied dose of pesticides and their toxicity degree.

The spatialization of the health and environmental impact of farmers' phytosanitary practices enable us to identify the plots that represent the highest risk and their location to natural resources such as streams. The result could be used to improve the management of agricultural phytosanitary practices, taking into account the proximity of treated plots to different natural resources.

Keywords: *Risk, phytosanitary practices, spatialization, indicators, natural resources.*

Introduction

In the early 1960s, a period known as the "Green Revolution", agricultural production methods shifted towards the intensification of cropping systems with the aim of ensuring food security. Following this agricultural revolution, the use of pesticides was increased in France and all over the world (Guichard *et al.*, 2017; Sharma *et al.*, 2019). Thus, the types of plant protection products and the methods of application have diversified.

Indeed, the excessive use of phytosanitary products in agriculture has generated the contamination of surface and groundwater which constitutes the resources intended for human consumption. This pollution leads several problems of public health and on the environment such

as the quality of water resources and agricultural products (Aouadi *et al.,* 2018). Monitoring and reducing the diffuse phytosanitary pollution have become major issues for water resources, human health and the balance of natural ecosystems.
Several research studies have been carried out to analyze the health and environmental impact of pesticide use and the contribution of agricultural practices to the diffuse pollution (Mghirbi *et al.*, 2015; Mghirbi *et al.*, 2018; Kanj 2018; Grimene *et al.*, 2021).
Our research is oriented towards the same perspective of risk assessment related to agricultural phytosanitary practices based on indicators of phytosanitary pressure (TFI: Treatment Frequency Index) and risk (IRSA: Indicator of Risk on the Applicator's Health and IRTE: Indicator of toxicity Risk on the Environment). These indicators make it possible to illustrate the spatial distribution of the phytosanitary pressure and the toxicity risk related to pesticide use at plots level on Gimone watershed in the south-west France.

Materials and methods

The adopted approach in this work consists of a spatial risk assessment of agricultural phytosanitary practices through the Indicator of Risk on the Applicator's Health (IRSA) and the Environment (IRTE), calculated by EToPhy. The EToPhy tool makes it possible to refine the analysis of the health and environmental impact of pesticide use through the disaggregation of the IRSA and IRTE into 2 sub-indicators of risk to human health (IRSA acute, IRSA chronic) and 3 environmental sub-indicators relating to the three environmental compartments: water, soil and air (IRTE aquatic, IRTE terrestrial invertebrate, IRTE bird) (Mghirbi *et al.,* 2015; Mghirbi, 2016). These indicators are then integrated into a GIS in order to design spatial distribution maps of the health and environmental impact of agricultural phytosanitary practices. These maps will allow to identify the plots with high risk to human health and to the environment in the Gimone watershed, which extended over the two departments of Gers and Tarn-et-Garonne, located in the south-west of France (Figure 1).

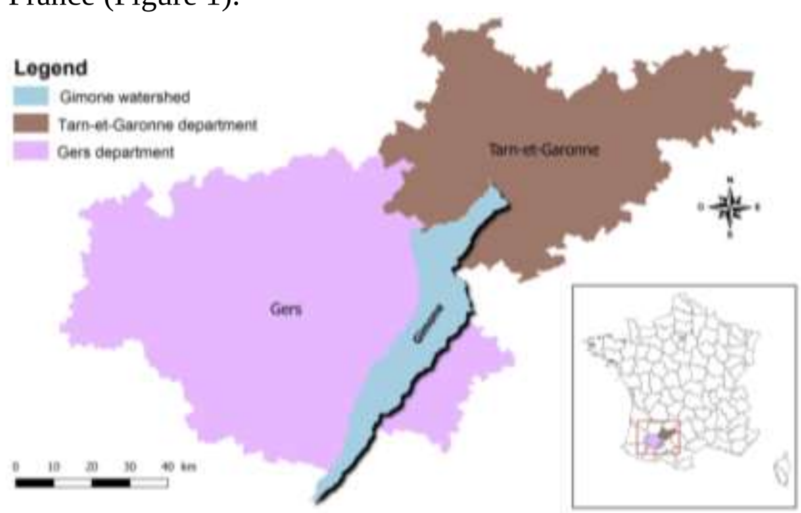

Figure 1. Study area location: the Gimone watershed in south-west France (sources: IGN GEOFLA 2017, Carthage Database 2013).

The territory of the Gimone watershed is largely occupied by agriculture, about 57,400 ha of the UAA[3] (i.e. around 70% of its surface area). The land use is almost homogeneous with a predominance of agricultural areas dedicated to annual crops (wheat, sunflowers, soybeans, corn). Cereal crops dominated by soft wheat and durum wheat represent the main crops, followed by sunflower and soybeans.

Given the dominance of agriculture at the watershed level, it turns out that agricultural practices, including the phytosanitary products applied by farmers have an impact on the water quality. The Gimone watershed is considered to be a territory with high agricultural pressure and low potential for resilience to diffuse pollution given its physical characteristics which play a negative role in the pollutant transfer.

Our study is based on two types of data:

- A geographic database: represents the parcels data from the study area and which contains all the geo-referenced parcels from the geographic data sources (Graphical Parcels Register RPG).
- A phytosanitary practices database: represents all phytosanitary treatments (pesticide applications) on the surveyed plots and all parameters related to the application of the plant protection products (farm identifier, plot identifier, plot area, treated area, TFI, approved dose, applied dose, IRSA and its sub-indicators, IRTE and its sub-indicators).

The phytosanitary practices database will used to calculate risk indicators for the different surveyed plots. The IRSA is a scoring indicator which assesses the acute and chronic toxicity of plant protection products taking into account the physico-chemical and toxicological properties of the active ingredients. The IRTE assesses the toxicity risk of phytosanitary products on non-target living organisms in each environmental compartments (water, air, soil) based on the eco-toxicological and physico-chemical characteristics of the active ingredients. In order to carry out this analysis of agricultural phytosanitary practices, a sample of 161 farms (3,340 plots) was selected on the Gimone watershed, illustrated in the following table.

Table 1. Distribution of crops according to the plots surveyed in the Gers and Tarn-et-Garonne departments

Results and discussion

Analysis of the agricultural phytosanitary practices

The analysis of agricultural phytosanitary practices enabled us to draw up graphs which illustrate the risk variability between the different crops (Figure 2) and also to compare the risk between the different production methods, conventional/integrated and organic (Figure 3).
The graph below shows an overall analysis of the risk and pressure indicators between some crops from four crop categories (field crops, arboriculture, market gardening and viticulture) in order to compare the health and environmental impact of phytosanitary practices according to the products applied by farmers. The results of the analysis show a remarkable difference between the risks related to different crop categories. The tree crops (arboriculture) presented the highest treatment frequency and risk, especially on human health. The risk is higher in the plots of apple trees with a treatment frequency more than 26.

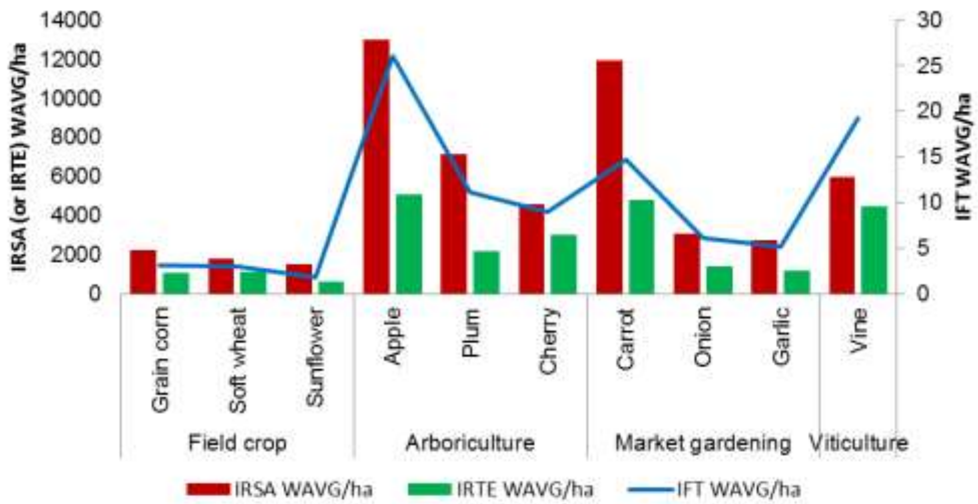

Figure 2. Variability of indicators according to crop categories from conventional/integrated production (values expressed as weighted average per hectare)

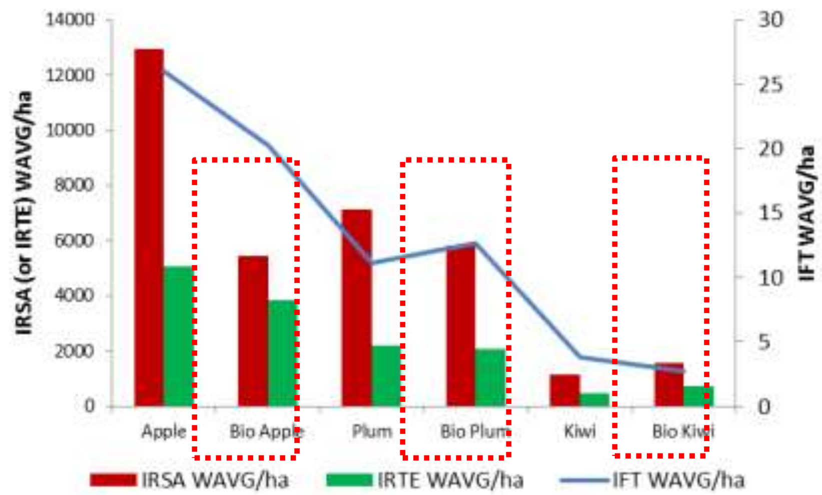

Figure 3. Variability of indicators according to the production mode (conventional/integrated and organic) between tree crops (values expressed as weighted average per hectare)

According to the production mode, the average TFI/ha in organic farming is lower than in conventional/integrated. This indicate that the treatment frequency of organic crops remain always lower than that of conventional production. The risk is lower in organic plots, but it is not negligible either.

The use of risk sub-indicators to human health and the environment makes it possible to refine the analysis of the toxicity degree of plant protection products in order to improve the management of plant protection practices and the pesticide choice. The graphs 4 and 5 show a comparison of the toxicity part between different crop categories.

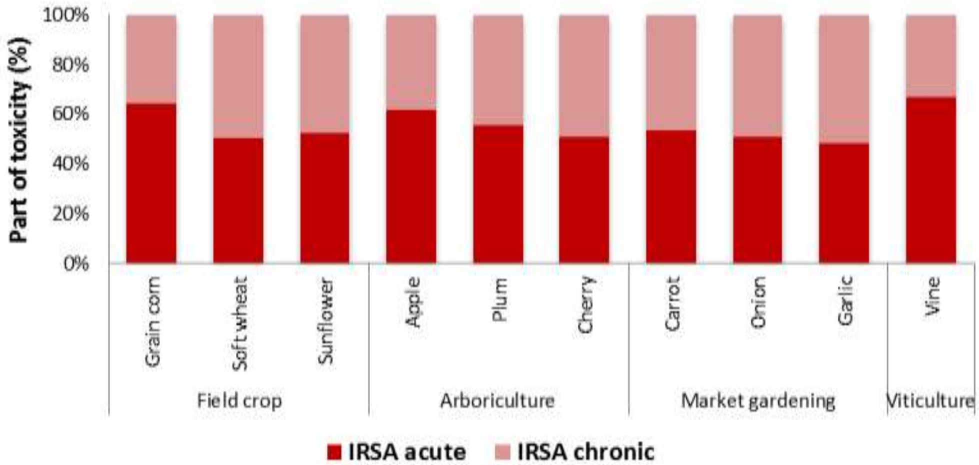

Figure 4. Comparison of acute and chronic toxicity part of plant protection practices between crops

Regardless of the crop, the acute toxicity risk of phytosanitary practices is greater than 50%. The majority of the products used on the surveyed plots have more acute health risk (irritation risk and risk via inhalation, dermal or oral route) than chronic (RMC risk, neurotoxicity and endocrine-disrupting effect).

The environmental risk sub-indicators presented in figure 5 show the toxicity part of phytosanitary practices for each environmental compartment: soil, air and water (IRTE terrestrial invertebrate, IRTE bird and IRTE aquatic) according to crops.

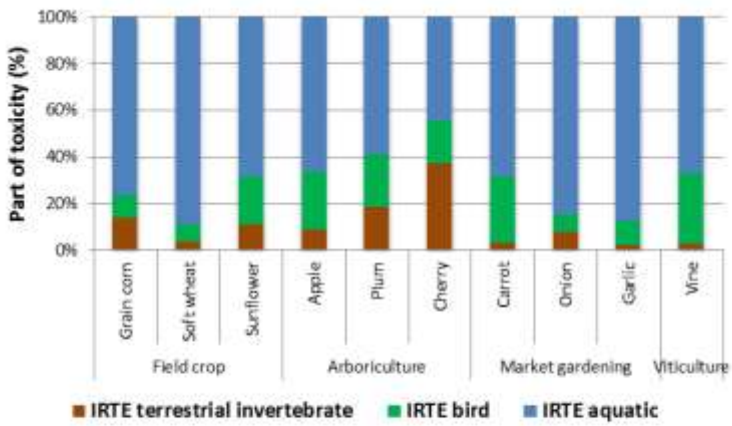

Figure 5. Comparison of the toxicity part of plant protection practices for each environmental compartment between crops

The proportion of the toxicity risk to the aquatic environment is over 70% for field crops, market gardening and in viticulture, which leads us to study in more detail the risk of phytosanitary diffuse pollution on the aquatic environment.

Risk mapping of agricultural phytosanitary practices

Risk mapping is carried out at plot scale which associated to a crop. Each crop has an average toxicity risk value/ha. The risk indicators are represented according to 3 classes from low to high, from green to red, respectively (Figure 6). The spatial analyse of the toxicity risk of phytosanitary practices on human health reveals that the medium to high health risk patches cover 40% of the total UAA of the catchment area (Figure 6A). This analysis clearly shows us the issue of health security for farmers and their neighbourhood through the identification of areas with high risk on human health. The risk of aquatic toxicity varies between medium and high scores and represents around 30% of the total UAA of the Gimone area. The issue associated with this medium-high toxicity risk is the proximity of the treated plots to the streams or rivers, which makes it possible a direct transfer of pollutants towards the aquatic environment (Figure 6B). This spatial analyse leads us to act on phytosanitary practices through the improvement of the active ingredients/products choice by farmers depending on the proximity of plots to the natural environment, in order to replace the phytosanitary products with a high toxicity risk to the aquatic environment with less harmful one.

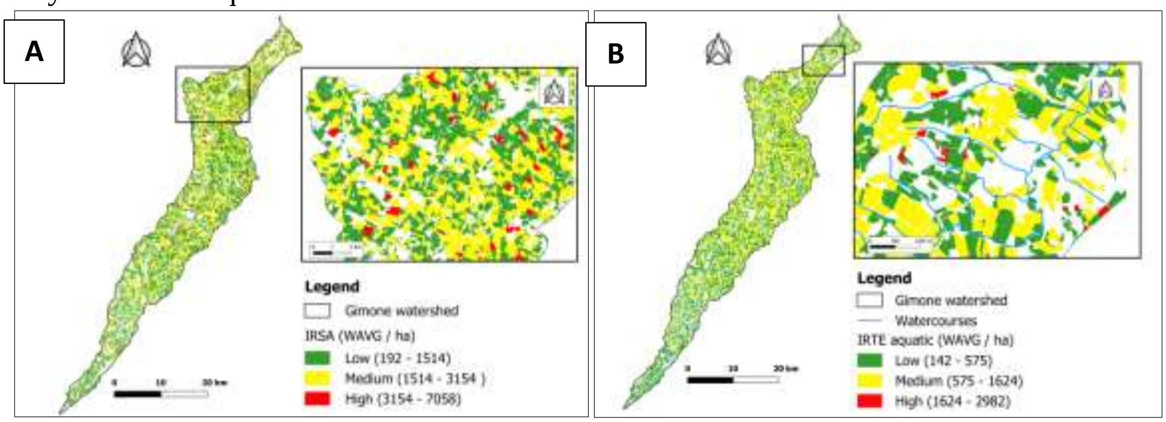

Figure 6. Map of human health risk related to agricultural phytosanitary practices on the plots of the Gimone watershed (A); Map of aquatic toxicity risk related to agricultural phytosanitary practices on the plots of the Gimone watershed (B) (Sources: Carthage DB, RPG 2017)

Conclusion

The evaluation of phytosanitary practices is based on the complementarity between TFI, IRSA, IRTE and the risk sub-indicators used to determine the toxicity degree of plant protection products on human health and on the 3 environmental compartments: soil, air and water.

An improved management of phytosanitary practices can be implemented through the right choice of products depending on the proximity of plots to natural environment and using decision support tools to analyse the health and environmental impact of pesticide use.

An increasing orientation of several famers towards the organic production mode cannot ensure a reduction in the toxicity risk associated to phytosanitary practices because the organic farming is not safe to human health and to the environment.Spatial analysis of the health and environmental impact of agricultural phytosanitary practices using GIS is considered as a decision support tool to improve the management of the pesticide use at plots and farms level. Furthermore, this spatial analysis provides to the natural resources managers a reflection support tool to improve the management of the diffuse phytosanitary pollution through the identification of areas with high risk on non-target living organisms in the different environmental compartments (water, air and soil). These tools make it possible to set up agri-environmental measures and action plans at different scales from plot to the watershed. These measures aim to reduce the toxicity risk of agricultural phytosanitary practices on human health and on the environment.

Acknowledgment

This work was carried out as part of the research project SPAGER_Phy (Spatialization and Management of Phytosanitary Risks) funded by the Occitanie region to conduct a doctoral thesis. We gratefully acknowledge the financial support provided by the LAMES laboratory of CIHEAM-IAMM. This work was done in collaboration with the Qualisol cooperative, in which it participated by organizing investigations with farmers and providing databases of agricultural practices. EToPhy was developed by CIHEAM-IAMM and the R&D Company Ecoclimasol as part of the collaborative research project GesPPEIR "*Gestion eau, Phytosanitaires, Prévisions et Indicateurs de Risques*" funded by the ERDF and the Occitanie region, France (2016-2021).

Abstract

EToPhy is a web application/platform which aims to assess and control the impacts related to the phytosanitary products used in agriculture on the environment and on human health. The EToPhy web platform is presented as a dashboard to determine the phytosanitary footprint of agricultural phytosanitary practices based on indicators of phytosanitary pressure (TFI: Treatment Frequency Index), and of risk (IRSA: Indicator of Risk on the Applicator's Health, IRTE: Indicator of Toxicity Risk on the Environment). These risk indicators break down into acute and chronic IRSA and IRTE sub-indicators for terrestrial invertebrates, birds, and aquatic organisms. This tool provides two web applications to improve the management of pesticide use related risk to the applicator's health and to the environment for professionals involved in the management of plant protection products (PPPs):
- EToPhy *Simulateur* aims to assess the toxicity degree of PPPs and to find alternatives that are less harmful according to the crop and pest to be treated.
- EToPhy *Analyses* makes it possible to analyze the health and environmental impact of farmer phytosanitary practices at different scales (product, field, crop and farm).
The phytosanitary pressure and risk indicators have enabled us to analyze the impact of plant protection practices and to compare the cropping systems of conventional, integrated and organic agriculture.

Keywords: *EToPhy web platform, human health, environment, indicators, plant protection products.*

Introduction

The use of pesticides in agriculture has been steadily increasing in recent years in France and around the world, despite efforts by political and public decision-makers to implement sustainable strategies and measures for reducing the use of plant protection products (Auberto *et al.*, 2005; Guichard *et al.*, 2017; Sharma *et al.*, 2019). Several studies have shown the health and environmental impact of plant protection practices and the effect of frequent exposure to pesticides on public health and the environment (Alavanja, 2009; Hallenbeck & Cunningham-Burns, 2012; Baldi *et al.*, 2013; Mahmood *et al.*, 2016). As a result, the management of diffuse

pollution related to the use of plant protection products has become a concern for the different stakeholders involved in pesticide management (policy makers, land and natural resource managers, agricultural technicians/advisors and farmers).
These different stakeholders have expressed their need for decision support tools to improve the management of risks due to plant protection products used in agriculture to human health and the environment. Several tools have been developed based on technological and/or technical solutions in order to control the risks of phytosanitary diffuse pollution at different spatial scales, from the plot to the watershed or agricultural region (Bockstaller & Girardin, 2003; Bockstaller *et al.*, 2008; Houdart *et al.*, 2009; Ossard *et al.*, 2009; Ayadi *et al.*, 2014; Mghirbi *et al.*, 2015, 2017, 2018; Lammoglia *et al.*, 2017; Kanj, 2018; Juan *et al.*, 2018). The development of the EToPhy[4] tool by the CIHEAM-IAMM research team, as part of the TRam research project (Ayadi, 2013, Le Grusse *et al.*, 2014, Mghirbi, 2016), adds to the list of research work carried out to meet the expectations of the different stakeholders by improving the management of phytosanitary practices and reducing their sanitary and environmental impact.
EToPhy was initially developed as desktop software for use in teaching and research. This format was not operational enough for professionals involved in pesticide management, hence the idea of developing a simple and practical web version as a collaboration between the CIHEAM-IAMM and the R&D company Ecoclimasol within the GesPPEIR collaborative research project.

Materials and methods

Design of the EToPhy web platform

A first step towards the identification of potential user needs was carried out through repeated workshops with technicians from agricultural cooperatives, and farmers from the south-west of France, as part of the GesPPEIR project. The objective of this participatory approach was to build a web platform according to the needs of professionals involved in the management of phytosanitary practices. This platform consists in evaluating and controlling the risks linked to the use of pesticides to human health and the environment at the level of plots and farms.
Indeed, the EToPhy web platform is a dashboard for determining the phytosanitary footprint of pesticides and agricultural phytosanitary practices based on pressure indicators such as the TFI (Treatment Frequency Index, an official French indicator used within the Ecophyto plan which characterises the intensity of pesticide use) and risk indicators such as the IRSA (*Indicateur de Risque sur la Santé de l'Applicateur*: Indicator of Risk on the Applicator's Health) and the IRTE (*Indicateur de Risque de Toxicité sur l'Environnement*: Indicator of Toxicity Risk on the Environment). Moreover, the EToPhy tool makes it possible to refine the analysis of the health and environmental impact of pesticides through the disaggregation of the IRSA and IRTE into 2 sub-indicators of risk to human health (IRSA acute, IRSA chronic) and 3 environmental sub-indicators relating to the three environmental compartments: water, soil and air (IRTE aquatic, IRTE terrestrial invertebrate, IRTE bird) (Mghirbi *et al.*, 2015; Mghirbi, 2016).
The IRSA and IRTE indicators were mainly developed based on the work of researchers from Quebec (Samuel *et al.*, 2012) and Norway (Spikkerud, 2000; Spikkerud *et al.*, 2004), as well as the work of European focus groups (Boesten *et al.*, 1997; Linder *et al.*, 2001; Klein *et al.*, 2003). These risk indicators differ from those used in Quebec in that they are adapted to European

[4] **EToPhy software (2020)**, APP deposit n°: IDDN.FR.001.090003.000. S.P.2020.000.31500.

standards, and take into account European approvals and regulations (Balderacchi & Trevisan, 2010).
IRSA is a generic scoring indicator that can be modified according to the application context. It assesses the acute and chronic toxicity of plant protection products by considering the physicochemical and toxicological properties of the active ingredients. It also expresses the potential risk associated with the use of the product by taking into account the exposure related to the type of formulation (Samuel *et al.*, 2012; Ayadi, 2013; Mghirbi, 2016).
IRTE is a scoring indicator, determined by the sum of six variables that evaluate eco-toxicological impacts on non-target living organisms (terrestrial invertebrates: earthworms and honeybees; herbivorous birds: Virginia quail, and granivorous birds: mallard; aquatic organisms: fish, daphnia, algae and aquatic plants) and physico-chemical behaviours in the receiving environment (mobility, persistence in soil and bioaccumulation). It assigns a weight to these variables (a score from 0 to 8 representing the level of toxicity), and then integrates them into the calculation, based on a toxicity/exposure ratio (Samuel *et al.*, 2012; Ayadi, 2013; Mghirbi *et al.*, 2015; Mghirbi, 2016).
These scoring indicators (IRSA and IRTE) are generic and can be modulated according to phytosanitary practices (commercial preparation, physicochemical and eco-toxicological characteristics), spatial scale (place of application: open field, greenhouse, garden, etc.), as well as according to the conditions of the physical environment and/or receiving environment (crop interception factor, drift, runoff and drainage potential) (Samuel *et al.*, 2012; Ayadi, 2013).
The calculation of these indicators is based on the use of 2 databases (updated several times a year): (i) one on the commercial characteristics and uses of registered plant protection products, Basagri[5] (provided by the company Lexagri), (ii) and one on the physico-chemical, toxicological and eco-toxicological properties of active ingredients, Footprint[6](Lewis et al., 2016). The databases were structured on the Ecoclimasol servers to automatically manage the regular updates of the two databases, as well as their possible changes in format. It was also necessary to structure the pairings between the Basagri parameters and those of Footprint (PPDB) to calculate the indicators.

Functionalities of the EToPhy web platform

Two applications have been developed on the "EToPhy web[7]" platform (also entitled "Dephyto"): EToPhy *Simulateur* and EToPhy *Analyses* (Figure 1). EToPhy *Simulateur* aims to assess the toxicity of plant protection products and active ingredients marketed (from the Basagri and Footprint databases) and to find alternatives that are less harmful to human health and the environment depending on the crop and the target/pest to be treated.
EToPhy *Analyses* makes it possible to analyze the sanitary and environmental impact of farmer phytosanitary practices at different levels (product, plot, crop and farm) in order to reduce the risk linked to the use of pesticides to human health and non-target organisms in the 3 environmental compartments: water, air and soil. This application works by means of 2 services used successively. First, the user should locate these plots on a map via the GEOLOC service. Then, the phytosanitary interventions of each plot must be stored in a record book via the LOGBOOK service. The database associated with this service is able to store information from

[5] https://www.lexagri.com/service_basagri.php
[6] http://sitem.herts.ac.uk/aeru/ppdb/
[7] https://www.etophy.fr

different databases, such as Basagri (database of commercial products used in EToPhy *Simulateur*), but also databases usually used by farmers and agricultural cooperatives in France (e.g. the Télépac[8] database for CAP declarations). Once all the information is filled in, EToPhy *Analyses* makes it possible to compare phytosanitary practices between plots, crops and farms. This operation makes it easier for users to identify the product(s) that have too high impact on health and the environment, in order to substitute them by using the risk comparator of plant protection products on EToPhy *Simulateur*. In addition to these EToPhy *Analyses* functions, the user can refine his/her choice of plant protection products according to environmental issues, and to the characteristics of the natural environment through the geolocation of plots via the GEOLOC service. Several other comparison queries provide users with a relatively rich field of analysis of phytosanitary practices according to agricultural campaigns, production methods (conventional, integrated or organic) and specificities of pesticide choices between synthetic and bio-control products.

Results and discussion

EToPhy *Simulateur*

The EToPhy *Simulateur* web application takes the form of a search engine. It calculates the IRSA and IRTE risk indicators linked to the use of a plant protection product based on a search by product name (Figure 2), by active ingredient name, or for a specific target on a given crop. It provides regulatory information on the product uses (Figure 2) and details of the risks to the environment such as the eco-toxicological impact on non-target organisms (earthworms, bees, birds, aquatic plants, fish, etc.), as well as to human health, such as chronic and acute toxicity (Figures 3 and 4). Finally, it allows the comparison of the toxicity of different products and helps the user to choose products that are less toxic to human health and to the 3 environmental compartments: soil, air and water (Figure 5).

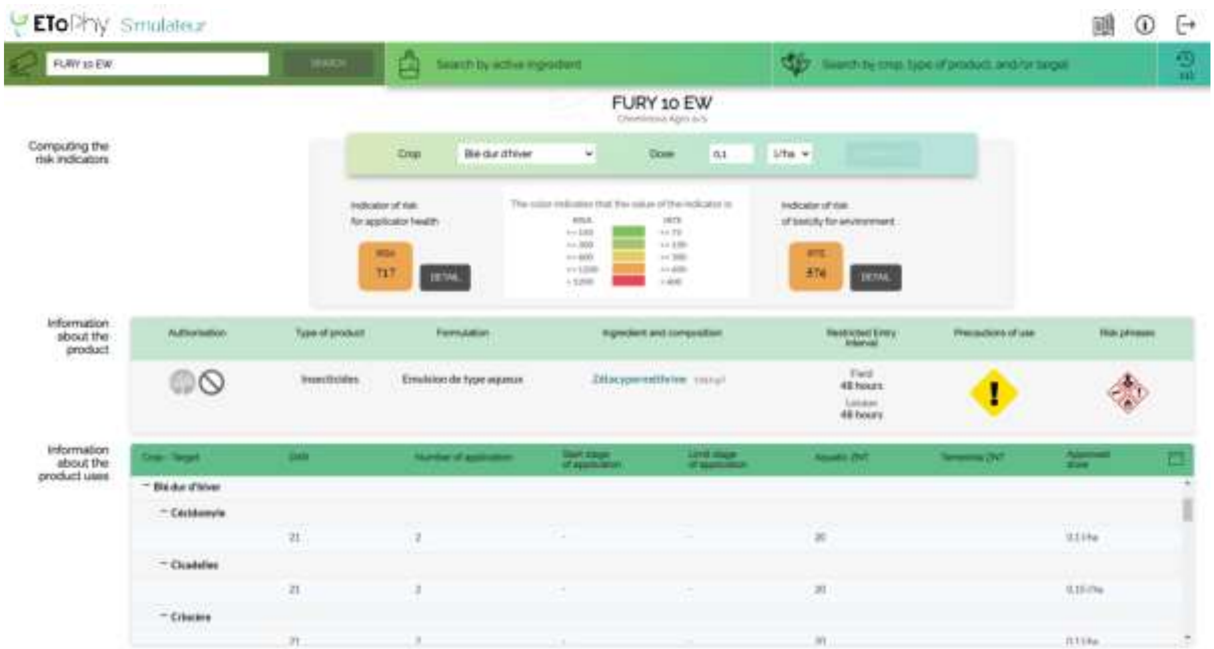

Figure 2. EToPhy Simulateur screenshot – Visualisation of the applicator health risk indicator (IRSA) and environmental toxicity risk indicator (IRTE) for the Fury 10 EW product with a 0.1 l/ha dose, and regulatory information on these uses.

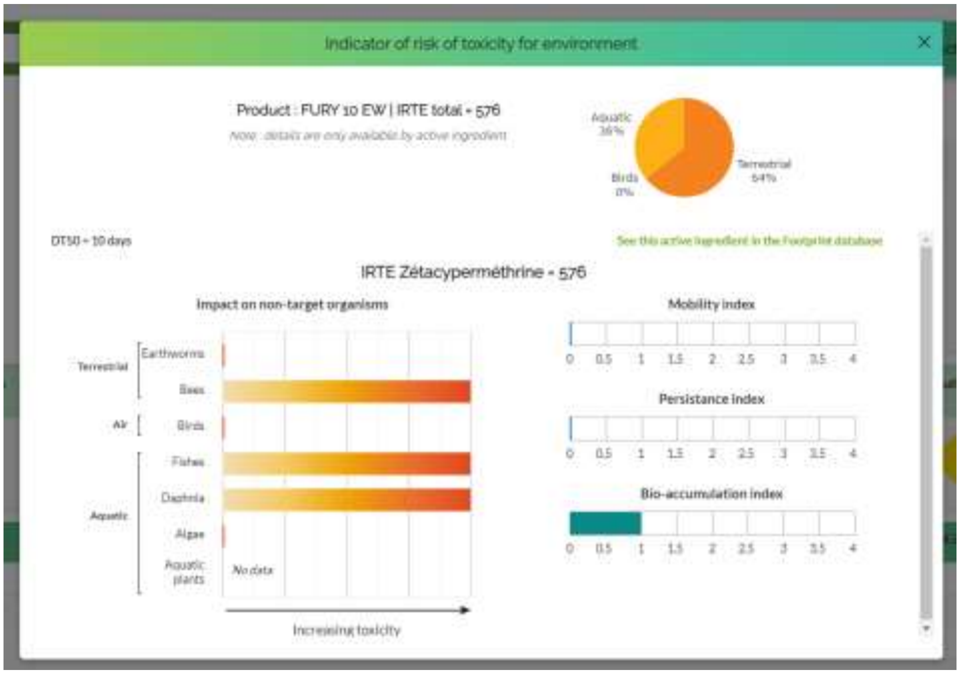

Figure 4. EToPhy Simulateur screenshot showing the details of the environmental toxicity risk indicator (IRTE) for Fury 10 EW with a 0.1 l/ha dose.

Figure 5. EToPhy Simulateur screenshot showing the comparative table of the toxicity risk of different phytosanitary products for a given crop-target (Wine grape vine - Powdery mildew).

EToPhy *Analyses*

EToPhy *Analyses* calculates the phytosanitary footprint of each phytosanitary intervention applied on the plot in question and recorded in LOGBOOK (Figure 6). The phytosanitary footprint is expressed via the IRSA and IRTE risk indicators (and the sub-indicators), and the TFI. EToPhy *Analyses* consists of a tool for selecting farms, crop years, plots and crops, for which the user wishes to visualise the results of the risk indicators and the TFI (Figure 7). Based on this selection, graphs offer a comparison of TFI, IRSA and IRTE indicators between the applied products (synthetic or bio-control), between plots or crops, between seasons and between farms, while taking into account the production mode (conventional, integrated or organic). Figure 7 shows an example of the contribution to the phytosanitary footprint (indicators in values/ha and in %) of the different products applied on a farm (conventional/integrated production for durum wheat, winter oilseed rape and maize plots). The user can then evaluate the environmental performance according to the levels of analysis (product, plot, crop), identify practices to be improved, as well as simulate crop treatment practices that are less toxic to human health and the environment.

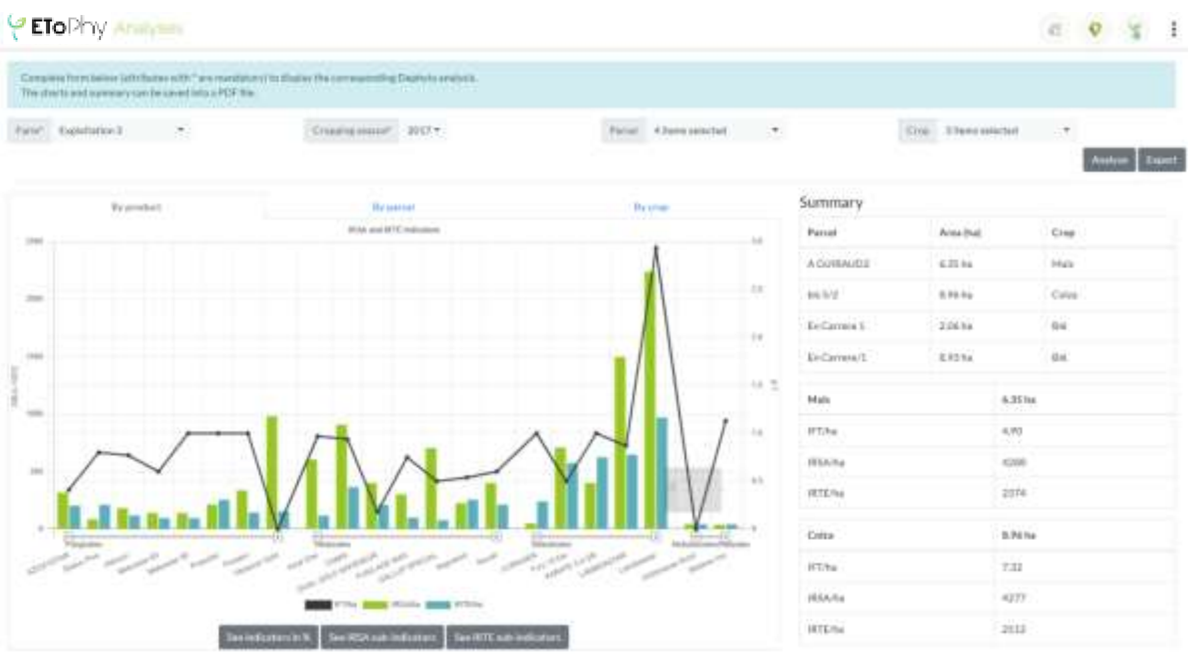

Figure 7. Screenshot of the EToPhy *Analyses* service - Contribution to the phytosanitary footprint (indicators in values/ha and in %) of the different products used on a farm with durum wheat, rape and maize plots.

Conclusion

The development of the EToPhy web platform, as a decision support and risk analysis tool for pesticide use, is part of the precision agriculture and smart agriculture concepts to improve the management of agricultural phytosanitary practices. The deployment of big data technology makes it possible to manage the significant number of parameters (characteristics of commercial products and active ingredients), in order to simplify user access to information from databases. The pressure and risk indicators calculated on the platform represent a decision support dashboard for the better integrated management of the health and environmental impact of plant protection products applied on plots. The functionalities of the EToPhy web platform (EToPhy *Analyses* and EToPhy *Simulateur*) play a dual role in the monitoring and the control of the diffuse phytosanitary pollution, depending on the spatial scale of phytosanitary practice management: at a local level (plot/farm) and at a territorial level (catchment area, agricultural region).

ASSESSING THE POTENTIAL USE OF GFS-ANL MODEL WEATHER DATA IN FIELD-SCALE PRECISION AGRICULTURE IMPLEMENTATION

Abstract

Implementation of precision irrigation (PI) approaches requires accurate meteorological data to estimate the evaporative demand of the atmosphere and thus the potential crop water needs. Consequently, extensive networks of meteorological stations are needed if such practices are to be integrated within farmers management practices. However, the establishment of such networks are costly. Free meteorological forecast models (e.g., global forecast model, GFS) can be used as an alternative free source of data. These models, except from a weather prediction for the next days, offer databases with historic meteorological data based on re-analysis (e.g., GFS-ANL). Nevertheless, their spatial resolution of 0.25×0.25 degrees (~ 28×28 km), is quite large and questions the reliability of the obtained data. In this framework, data from three weather stations located within the water district of Thessaly in central Greece and the corresponding GFS-ANL time series were collected. The parameters that were obtained were air temperature, wind speed, relative humidity and precipitation. Successively, a statistical analysis was performed to evaluate the model capability to simulate satisfactorily the measured weather data. The results indicated that the GFS-ANL model could simulate the air temperature quite fair (R^2 ~0.97; RMSE < 1.77 °C), but that was not the case for the rest or the parameters.

Keywords: *irrigation, precision agriculture, weather model, reference evapotranspiration.*

Introduction

All the precision irrigation approaches, except maybe only those that are using almost-real-time field soil moisture measurements, exploit meteorological data to estimate the reference evapotranspiration (ET_0), a process that describes the way that the water is transferred from earth to the atmosphere via evaporation from the soil surface (or other surfaces e.g., plant leaves) and through transpiration by plants (Allen et al., 1998; Tsakmakis et al., 2017).

While there is a substantial number of formulas proposed for the estimation of ET_0, like Blaney-Criddle, Penman, Priestley-Taylor, Turk and Hargreaves (Liu et al., 2017), the most popular and reliable formula for ET_0 estimation is FAO-56 Penman-Monteith, a modified version of the formulas originally proposed by Penman and Monteith (Allen et al., 1998). The latter is utilizing the meteorological parameters of maximum temperature, mean temperature, minimum temperature, maximum relative humidity, mean relative humidity, minimum relative humidity, mean wind speed and mean solar shortwave radiation (Rs) or net radiation to estimate ET_0.

Moreover, precipitation height, even though it's not required for the ET_0 estimations, constitutes a vital meteorological parameter in the overall PI programming and implementation, as it can postpone irrigation events and change the initial scheduling. It is obvious that field specific measurements of the above-mentioned parameters would guarantee accurate and precise

estimations but that's not always the case. Specifically, in the region of Thessaly, in central Greece, the network of meteorological stations is not dense and in most of the cases the fields are about 20-30 km from the closest station. Moreover, the data acquisition from the existing stations is laborious and difficult, as at the moment there is not available a national unified Application Programming Interface (API) that will provide easy and fast access to the metrological stations network.
As an alternative solution, data from free meteorological forecast models maybe can be used (e.g., global forecast model, GFS). These models, except from a weather prediction for the next days, offer databases with historic meteorological data based on re-analysis (e.g., GFS-ANL). The drawback of these databases is that they refer to a global grid with a cell spatial resolution of 0.25×0.25 degrees (~ 28×28 km). Thus, the question arising is; are these large-scale data suitable for the implantation of a PI field-scale approach? To answer this question an analysis was performed between data obtained from a meteorological station located within the region of Thessaly and the corresponding historic data-series from GFS-ANL model.

Material and Methods

The data used for this analysis were obtained from three meteorological stations that are installed nearby the villages Achilion, (Lat: 39.548138°, Long: 22.685881°, Alt:48 m), Chalki (Lat: 39.57083°, Long: 22.54333°, Alt:75 m) and Agia (Lat: 39.71615°, Long: 22.76201°, Alt:167 m). All three villages are located within the water district of Thessaly (EL08), in central Greece. The meteorological stations in the villages of Achilion and Agia were able to measure air temperature, relative humidity, wind speed and direction, solar shortwave radiation (Rs) and precipitation height, while the station in Chalki village recorded air temperature, wind speed and precipitation. The stations were installed and have been in operation for different time periods (e.g., station in Achilion was installed on 2020, in Chalki from 2017 etc.). For the purpose of this study the time period between March to August 2020 was selected, as during this time (a) all the three stations were in operation and (b) it corresponds to the summer arable crops cultivation period.
The GFS-ANL data for the same period was downloaded from the archives of National Oceanic and Atmospheric Administration center (NOAA). Specifically, the retrieved data was referred to the model run of 00:00 and the predictions of 00:00, 06:00, 12:00 and 18:00. The grid cell that corresponded to the study area had latitude and longitude equal to 39.50° and 22.75°, respectively. Retrieved meteorological parameters were air temperature, relative humidity, wind speed and precipitation height. Successively, the retrieved 6-hours temporal analysis data were resampled to daily values. It should be mentioned that substantial gaps were observed in NOAA archived data and thus the retrieved time series were not complete. Subsequently, the meteorological stations' time series were filtered to match the available NOAA archived dates.
Once the data was correctly prepared, a statistical analysis was performed to evaluate the simulation capability of the GFS-ANL model. The statistical parameters that were used to assess the potential differences between the field-stations measured data and the GFS-ANL historic time series were (a) the coefficient of determination (R^2) as a measure of the goodness-of-fit between the measured and the modeled data and (b) Root Mean Square Error as an index of the residual error among the field-measurements and the large-scale modeled data (RMSE; Eq. 1)

$$RMSE = \left[\frac{\sum_{i=1}^{n}(Si-Oi)}{n}\right]^{0.5} \quad (1)$$

Results and Discussion

The fluctuations of the meteorological stations measured and the GFS-ANL modeled air temperature, relative humidity, wind speed and precipitation height are illustrated in Figure 1. At first glance the measured and modeled air temperature data seems to follow the same pattern for all the three stations (Figure 1a, 1b, 1c). This trend is confirmed by statistical indices, with R^2 exhibiting values equal to 0.92, 0.97 and 0.97 in the cases of Achilion, Chalki and Agia meteorological stations, respectively (Table 1). Moreover, the RMSE was found to be 2.39 °C in the case of Achilion station, but less than 1.58 °C in the cases of Chalki and Agia stations. When the data from the three stations were aggregated, the R^2 and RMSE were found to be 0.97 and 1.77 °C, respectively, indicating a quite satisfactory match between the modeled and measured time series. The corresponding aggregated data scatter plot (Figure 2a), showed that the residual difference between the two series is almost evenly distributed around the 1:1 line, with just a few cases where the GFS-ANL model overestimated substantially the air temperature values. Similar results have been reported by previous studies (Sinha and Chandrasekar, 2010; Fairman et al., 2011).

In the case of wind speed, the obtained results were not satisfactory. The pattern between the measured and modeled data was found to vary considerably among the stations (Figure 1d, 1e, 1f). Specifically, in Agia, the GFS-ANL model was found to overestimate the wind speed consistently, whilst in the locations of Achilion and Chalki the measured and modeled wind speed data were arbitrarily blended during spring, but GFS-ANL tent to underestimate wind speed values during the summer (June to August). These trends were described by the statistical analysis quite well, with R^2 be equal to 0.36 in Agia, where model constantly overestimated the wind speed values, and 0.10 and 0.03 in the cases of Achilion and Chalki, respectively (Table 1). Additionally, the RMSE was fluctuating between 0.66 and 1.09 m/s, among the stations, confirming the significant variations among the measured and modeled values. As a result of the poor model performance observed in the individual stations, the aggregated wind speed data implied a poor model capability to provide robust wind speed datasets, with R^2 and RMSE values equal to 0.03 and 0.85 m/s, respectively. The corresponding aggregated data scatter plot (Figure 2b), illustrates clearly the inconsistency between the measured and modeled values, unveiling a subtle model trend to overestimate wind speed.

Looking closely to the precipitation measured and modeled time series, its' clearly illustrated that during 2020 cultivation period there were just three events where more than 3 mm of water fell, on April 4, June 16 and August 8 (Figure 1g, 1h, 1i). It is worth to mention that in the unique case that the GFS-ANL model reported an event with more than 6 mm of water (April 4th), the very same day all the three stations recorded a precipitation event with more than 6 mm. However, that's not the case for the other two events. On June 16, the precipitation event reported by GFS-ANL was recorded by Achilion and Chalki weather stations, but not by the weather station in Agia. More strikingly, on August 8, while all the weather stations recorded a precipitation event with more than 10 mm, the GFS-ANL model does not show rain at all. Moreover, various minor precipitation events (less than 3 mm of water) that were recorded by Achilion weather station, were not reported by GFS-ANL model or recorded by the other two stations. As a result, the R^2 in the case of Achilion was found to be 0.03 (Table 1), while for the other two stations was remarkably higher, equal to 0.69 and 0.53 for Chalki and Agia weather stations, respectively. Accordingly, the RMSE for Achilion was 2.42 mm, whilst for the other two stations was calculated less than 1.79 mm. When all the stations data was aggregated the overall model, performance was found to be poor (R^2 0.12; RMSE 2.04 mm), but this is mainly attributed to the discrepancies between GFS-ANL and Achilion station time series. Lastly, the aggregated data scatter plot (Figure 2c), implied that the model tends to underestimate the precipitation height.

Figures 1j and 1k, illustrated that GFS-ANL consistently underestimated the relative humidity values, both in Achilion and Agia stations. The magnitude of underestimation found to be similar in both cases (RMSE ~ 17.80 %). Accordingly, the correlation between the modeled and measured data was poor for both stations, with R^2 showing values lower than 0.4. When the data of both stations was aggregated the R^2 improved slightly (0.42) but the RMSE remained the same (17.80%). The overestimation trend that was illustrated in Figures 1j and 1k, is reconfirmed buy the aggregated data scatter plot (Figure 2d), where the overwhelming majority of the scatter dots are observed to be located left of 1:1 line (y axis).

Conclusions

Even though the analysis performed in this study concerns only three meteorological stations and a short time period, its main findings are considered to be indicative of the GFS-ANL model capability to simulate with accuracy and precision the meteorological conditions that prevail in field scale. The results showed that while the air temperature data can be used with pretty fair accuracy for PI scheduling, the relative humidity, wind speed and precipitation data could not be used for such a purpose. In the cases of precipitation and wind speed, the unique differences observed among the modeled and measured data for each station, may imply that the variations of land relief could have a crucial impact in the actual precipitation and wind speed values and thus could not be simulated satisfactorily by a model with a 28x28 grid cell spatial analysis. As for the relative humidity, the constant GFS-ANL underestimation indicates that a statistical correction, based on long time series of measures and observed data, may improve the model capacity to simulate the former. This conclusion highlights the need of the establishment of an extensive meteorological station web, capable to provide the PI algorithms and models with reliable data and thus increasing their robustness and reliability.

Abstract

Since the appearance of humans on the earth, various wastes started being produced, such as human or animal solid or liquid excreta and liquid or solid wastes produced by man's domestic, agricultural, and industrial activities. Today, vast quantities of wastewater and biosolids are being produced the world over, and they are either disposed of in the surface water systems or accumulate in the soil, causing environmental problems. Both the wastewater and biosolids contain valuable constituents such as water, plant nutrients, organic matter (OM), and energy. Safe reuse of treated wastewater and sludge in agriculture could reduce the inorganic fertilizers usage, decreasing unexploited rejected wastewater and sludge, contributing sustainably to the environment. However, the decision-making for safe and rational reuse of wastewater and sludge is a complex task. A computer-aided Decision Support System (DSS) contribution seems to offer an attractive solution for safe reuse and effective management of the effluents mentioned above. The present work describes such a DSS developed by the HOU Laboratory of Sustainable Waste Management Technologies. To demonstrate the DSS function based on the reuse of wastewater and biosolids, two examples are given of reuse of treated municipal wastewater (TMW) and biosolids, one with low nutrient content and a second with high nutrient content. From the DSS reports, it is concluded that by using wastewater and biosolids with higher nutrient concentrations, considerable gains, up to 100% of nutrients are achieved.

Keywords: *wastewater, sludge, biosolids, safe reuse, decision support system.*

Introduction

Since the appearance of human beings on the earth, various wastes started being produced and spread in the environment, such as human or animal solid or liquid excreta originating from the physiological activities of the organism, as well as liquid or solid wastes produced by the domestic, agricultural, and industrial activities of man.

Of course, these wastes in ancient times, were in balance with the environment as they were generated in lower quantities and they generally were natural, nontoxic byproducts as those of the present time. They were basically friendly to the environment. The increase of the human population during the course of history, led inevitably to the disturbance of this balance, and consequently the various environmental problems started appearing gradually and steadily. Thus, for example the production of the wastewater worldwide has reached 5.6×10^9 m^3, of which is reused for the irrigation of crops, only a small fraction, corresponding to <1% of the total natural irrigation water (Jiménez & Asano, 2008; Puma & Cook, 2010). This marginal water is mainly used in arid to semiarid regions. For example in Jordan 38% (Alfarra et al., 2011), in California 46% (Sato et al., 2013) and 85% in Israel (Goldstein et al., 2014). Similarly, large quantities of

biosolids are being produced annually in the world. Thus, only in the European Union (EU) 10.275.697 t of biosolids have been produced (Zorpas, 2017).
Both the wastewater and biosolids contain valuable constituents such as water, plant nutrients, organic matter (OM), and energy. Especially, the biosolids are carriers of both high levels of OM and plant nutrients; the average range of N P K composition for anaerobically digested sludge being: N 4.2 - 4.8%, P 2.7 - 3.0%, K 0.3 - 0.4%, and N 4.8%, P 2.7%, and K 0.4% for aerobically treated sludge (Sommers, 1977), and OM 22.6 – 28.4%, Zn 219.0 – 313.1 mg/kg, Cu 11.4 – 109.4 mg/kg, Fe 184.8 – 427.5 mg/kg, Mn 10.5 – 208.5 mg/kg (Dimitrelos, 2015).
In the meantime, the human population is increasing in such rates that according to estimations of the United Nations (UN) it is expected that it will increase by 2.1 billion people till the 2030, especially in the developing countries and consequently there will be an increase of the wastewater and biosolid production. This situation is indeed alarming and the authorities are hardly trying to find ways to dispose these outputs in a safe and productive way.
The decision-making for safe and rational reuse of wastewater and sludge is a complex task. Among the recent developments that have been accomplished in relation to the exploitation of wastewater and biosolids, is the contribution of a computer-aided system, which seems to open new innovative paths for effectively and efficiently facing the severe problem of safe reuse. The research team of the School of Science and Technology of the Hellenic Open University developed a DSS, which could be used as a very useful tool in approaching the safe reuse of wastewater and biosolids in Agriculture (Koukoulakis et al, 2019). This paper aims to demonstrate the DSS's ability for reusing wastewater and biosolids based on examples with real-world data inputs.

Material and Methods

The current version of the DSS used in this work is built as a web application with PHP, MySQL and JavaScript. The DSS calculates the optimum nutrient dose for the crop, based on the nutrient inputs contained in soil in the form of residual nutrients, in wastewater, and in biosolids and the nutrient losses due to leaching, denitrification, fixation and removal via crop harvesting. It is also able to evaluate the quantity of inorganic fertilizer-carrier corresponding to the optimum nutrient dose, and the quantity to be applied during the different crop growth stages (early growth, flowering, fruit set etc) and it guides the user about the proper time (Fall, Winter, Spring), and the method of application of the fertilizer.
The DSS calculates the the value of the soil pollution index and can give quantitative information about the level of soil pollution with heavy metals. It can also determine the quality of the wastewater being used, and it may exclude it from reuse if its concentrations in heavy metals are higher than the international standards.
The knowledge base of the DSS contains rules with recommended maximum heavy metal concentrations in wastewater. The system estimates Elemental Pollution Index before and after wastewater and biosolids application and it can detect highly acidic soils and calculates the optimum rate of liming material needed for the desired pH. Its knowledge base also contains a large set of rules to calculate optimum nutrient dose and to provide fertilization advices for every supported crop.
To demonstrate the DSS function based on the reuse of wastewater and biosolids, two examples are given of reuse of treated municipal wastewater (TMW) and biosolids, one with low nutrient content and a second with high nutrient content. The examples utilize analytical input data from

the same potato crop. Also, the same soil data are used in both cases, and an equal volume of wastewater (3500 m^3/ha) and biosolids weight (10000 kg/ha) was applied, respectively. The DSS evaluates input data and suggests optimal nutrient doses in every scenario.

Results and Discussion

The following two examples are given of reuse, first with low nutrient content of treated municipal wastewater (TMWW) and biosolids and second with high content, respectively.
Example 1: Application to potato crop of 3500 m^3/ha wastewater of low plant nutrients and soil heavy metal content, respectively. Also of 10000 kg/ha biosolids, similarly of low nutrient and heavy metal content. The physical – chemical and elemental content of the soil are reported in Table 2 and
Table 3. The wastewater and biosolids data are reported in
Table 4. The level of the heavy metal soil pollution is evaluated by the pollution indexes in Table 5. Optimum nutrient doses are calculated by the DSS suggested for application to potato crop, as well as the attained nutrient dose gains are reported in Table 6.
Example 2: Application to the potato crop of equal TMWW volume and biosolid weight to the above quantities per ha of wastewater and biosolids respectively but of higher content in plant nutrient (
Table 4). The analytical data of soil is unchanged because the same soil is used. The evaluation of the heavy metal soil pollution level is given in Table 5. The nutrient doses and gains suggested by the DSS are given in Table 6.

Table 5. Evaluation of soil pollution level

Soil pollution index	Value of pollution index before irrigation with treated wastewater	Value of pollution index after irrigation with treated wastewater	Evaluation of pollution level
EPI Example 1	0.1698	0.1956	No pollution
EPI Example 2	0.1698	0.2022	No pollution

Table 6. Nutrient doses calculated by the DSS suggested for application to potato crops for the two examples respectively

Nutrient	**Example 1 Nutrient dose$_1$ (kg/ha)**	**Example 2 Nutrient dose$_2$ (kg/ha)**	**Suggested nutrient dose gain [1] (kg/ha)**	**Percent of suggested nutrient dose gain (%)**
N	101.28	91.06	10.22	10
P_2O_5	22.64	0.00	22.64	100
K_2O	93.02	0.00	93.02	100
MgO	0.00	0.00	-	-
Fe	1.12	0.31	0.81	72
Zn	1.43	0.00	1.43	100
Mn	9.80	9.38	0.42	4
Cu	1.79	1.59	0.20	11
B	1.34	0.00	1.34	100

[1] Suggested nutrient dose gain = Nutrient dose$_1$ – nutrient dose$_2$

In both examples, the DSS calculated low soil pollution index after irrigation with treated wastewater and decided that the wastewater was safe for reuse (Table 4).
In Example 1, the DSS calculated extra nutrient doses for N, P_2O_5, K_2O, Fe, Zn, Mn, Cu and B. This is due to application of low plant nutrients content wastewater and biosolids (Table 5).

In Example 2 with the application of higher plant nutrients content wastewater and biosolids, the DSS calculated lower extra nutrient doses for N, Fe, Mn and Cu (Table 5). For the rest of the nutrients the DSS calculated that the applied wastewater and biosolids nutrients content is sufficient and suggested that no extra fertilization required (Table 5).
Based on the data of table 5, it is clear that by using wastewater and biosolids with higher nutrient concentrations, considerable gains, up to 100% of nutrients are achieved.

Conclusions

The DSS can evaluate soil pollution levels and alert the user for possible implications such as for example increase of soil heavy metal accumulation level, and appearance of toxicity phenomena in the growing plants. The examples mentioned above also demonstrate that using the DSS could lead to significant nutrient gains of up to 100%, leading to less inorganic fertilizers consumption and therefore contributing to the farmer's economy. The use of the DSS could effectively alleviate the problems related to the reuse until a cost-effective removal of toxic heavy metals will be able to transform the TMWW and biosolids in agriculture and generally in the ecosystem as safe as possible, protecting the human life and the environmental quality.

Abstract

Agricultural management practices on fertilizer nitrogen are vital to soil sustainability and crop productivity, as well as to reducing global greenhouse gases and environmental pollution. An increasing number of models have been adapted for specific purposes and scales of application which may lead to better understanding of crop response under different environmental conditions and management practices in agriculture. One of the greatest challenges is the capability of models to simulate adequately crop growth and soil nitrogen dynamics under different management practices. Among the crop simulation models that have been developed over the last decades, CropSyst model was selected for the present study. CropSyst (Cropping Systems Simulation Model) is a multi-year multi-crop simulation model developed to study the effect of cropping systems management on productivity and environment and has been widely used to simulate the growth of several crops with generally good results in many parts of the world. The objective of this study was the evaluation of CropSyst model's ability to simulate the soil inorganic nitrogen and cotton production in two locations in Greece, Larissa (central Greece) and Orestiada (northern Greece). The simulated results were compared with the measurements of soil inorganic N and crop yield of the two experimental fields throughout the growing season. It is concluded that the amount of soil inorganic nitrogen as well as the cotton yield were generally simulated well for both locations, indicating an overall satisfactory model performance. Hence, CropSyst model can be an important tool in agricultural research to assess the environmental impact and agronomic benefit of fertilizer N applications to irrigated areas.

Keywords: *CropSyst Crop Growth Simulation Model, Soil nitrogen simulation, Cotton yield.*

Introduction

During the last few decades, cropping systems modeling for simulating crop growth and development has been evolving along with the progress of computer technology aiming to provide tools for understanding and analyzing the main processes characterizing the agroecosystems behavior (Todorovic *et al.*, 2009). The evolution of the modeling efforts is influenced by the changing goals, target users and policies over the years ranging from models with a scientific insight at plant scale to those focused on practical applications and management practices impacts (Sinclair and Seligman, 2000). Those models result from the mathematical representation of the processes that explain the crop-soil interaction driven by weather and management (van Ittersum and Donatelli, 2003) and thus, they are suitable for testing hypotheses, for the evaluation of the impacts of alternative management practices (Acutis *et al.*, 2000) and climate scenarios (Confalonieri *et al.*, 2006).

Nitrogen (N) is a critical resource for the development of the best management practices in agriculture and cannot be analyzed independently of weather, soil characteristics, hydrology, crop characteristics, management practices and other factors of the complex soil-plant-atmosphere system (Stöckle *et al.*, 1994). Cropping systems models are powerful tools for investigating the processes related to N movements and transformation in soils and they can be used to provide information as regards the ability of given management practices to increase productivity while minimizing the environmental impact (Stöckle *et al.*, 1994) for increasing the agroecosystem efficiency.

CropSyst (Stöckle *et al.* 2003) is a multi-year, multi-crop simulation model developed to evaluate the effects of soil, weather and management on crop growth and environmental impact. The model is particularly suitable for the simulation of complex cropping systems and can be used for simulating a succession of different crops. Furthermore, several tillage, irrigation and N fertilization options are implemented in this model and a reduced number of inputs are needed with respect to other approaches (Confalonieri and Bocchi, 2005). CropSyst has been tested for simulating crop yields and N balances for different cropping systems and appears promising as a tool to analyze management practices for N. For this study, CropSyst model was used to simulate the soil inorganic N and cotton production in two experimental fields in central and northern Greece.

Materials and methods

In the current study, for the simulation of cotton yield and soil inorganic N in both locations in Greece, CropSyst model was used. CropSyst simulates the soil water budget, soil-plant N budget, crop growth and development, residues production and decomposition, soil erosion by water, and salinity as influenced by weather, soil features, crop characteristics and cropping system management options (Stöckle *et al.*, 2003). The inorganic N budget in CropSyst model includes separate budgets for nitrate and ammonium and the processes used are N transformations (net ammonification, nitrification, and denitrification), ammonium sorption, symbiotic N fixation, crop N demand and crop N uptake (Stöckle *et al*., 2003).

Nitrogen transformations follow the approach presented by Stöckle and Campbell (1989) using first-order kinetics. The amount of organic N mineralized is calculated by the equation:

$$\mathrm{MIN} = \mathrm{MIN_{pot}}\left(\mathrm{MIN} - \mathrm{MF} \times e^{(-\mathrm{MRATE} \times \Delta t)}\right) \quad (1)$$

where MIN (kg N ha^{-1}) is the amount of organic matter N mineralized into ammonium in time t, MIN_{pot} (kg N ha^{-1}) is the potential amount of organic matter N available for mineralization, MF is a soil moisture function and MRATE (day^{-1}) is the mineralization rate constant depending on soil temperature.

The daily amount of nitrified ammonium is estimated by:

$$\mathrm{NIT} = \mathrm{NH_4}\left(1 - e^{(-\mathrm{NRATE} \times \Delta t)}\right) \times \mathrm{MF} \quad (2)$$

where NIT (kg NH_4-N ha^{-1}) is the amount of ammonium N transformed into nitrate in time t, NH_4 (kg NH_4-N ha^{-1}) is the amount of ammonium N available for nitrification, NRATE (day^{-1}) is the nitrification rate constant and MF is the soil moisture function.

The daily amount of denitrification is calculated as follows:

$$DEN = NO_3\left(1 - e^{(-DRATE \times \Delta t)}\right) \quad (3)$$

where DEN (kg NO_3-N ha^{-1}) is the amount of nitrate N transformed into gaseous N in time t, NO_3 (kg NO_3-N ha^{-1}) is the amount of nitrate available for denitrification, DRATE (day^{-1}) is the denitrification rate constant dependent on the denitrification rate value at 15°C.

Crop yield is calculated as the total biomass at physiological maturity (B_{PM}) multiplied by the unstressed harvest index (HI).

$$Y = B_{PM} \times HI \quad (4)$$

$$HI = \frac{\text{Harvestable Yield}}{\text{Above Ground Biomass}} \quad (5)$$

where Y (kg ha^{-1}) is the crop yield and B_{PM} (kg ha^{-1}) is the total biomass accumulated at physiological maturity. The harvest index can be adjusted at the calibration phase to account for sensitivity to water and nitrogen stress during flowering and/or grain filling.

Two cotton producing fields were selected to evaluate the CropSyst model's ability to simulate crop yield and soil inorganic N through the crop growing season. The first field was located in Larissa, central Greece, whereas the second field in Orestiada, northern Greece (Figure 1a). Climate parameters of the two areas are also presented in Figure 1b. Soil quality properties of the two fields are presented in Table 1. The field in Larissa was classified as clayey soil throughout its soil profile, whereas the field in Orestiada as a clay loam.

60-90 cm	26.0	37.2	36.8	7.6	0.7	38.6	0.31	1.5	155.8

Cotton production and soil inorganic N fluctuations in Larissa were simulated for the 2019 growing season. Cotton seeding was on the 4th of May 2019 and harvest on the 16th of October 2019. The total amount of fertilizer N applied was 149.7 kg ha^{-1} (Table 2). The total amount of precipitation and irrigation water applied during the growing season was 575 mm. Soil samples were collected on May 20, July 1, August 20 and September 23, 2019, at three sampling depths (0-30, 30-60 and 60-90 cm).

Cotton production and soil inorganic N fluctuations in Orestiada were simulated for the 2020 growing season. Cotton seeding was on the 30th of April 2020 and harvest on the 16th and 23rd of October 2020. The total amount of fertilizer N applied was 201.0 kg ha^{-1} (Table 2). The total amount of precipitation and irrigation water applied during the growing season was 445 mm. Soil samples were collected on May 18, July 21 and October 23, 2020, at three sampling depths (0-30, 30-60 and 60-90 cm).

In both cases, the collected soil samples were air-dried, ground, sieved (2 mm) and analyzed for NH_4-N and NO_3-N by extraction with KCl (2M) and spectrophotometric determination. Soil inorganic N was calculated as the sum of NH_4-N and NO_3-N. Cotton seed fresh yield was determined at harvest.

Results and discussion

Cotton yield was well simulated in both locations by the CropSyst model (Figure 2). In both cases, cotton yield simulated values were slightly underestimated (by less than 1%), compared to the observed ones.

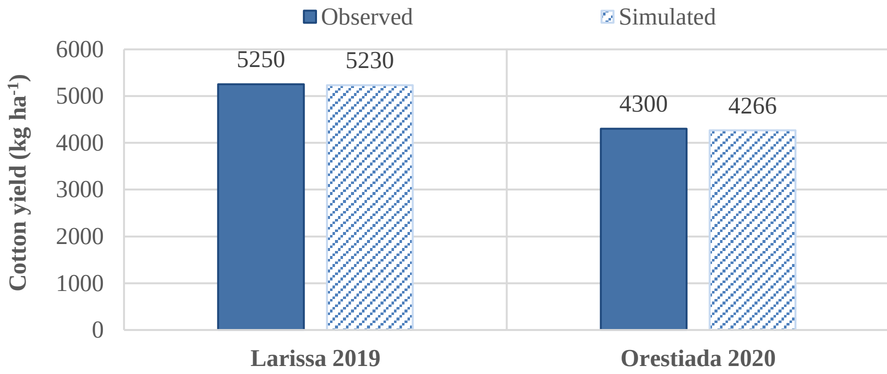

Figure 2. Cotton yield in Larissa, 2019 (left) and Orestiada, 2020 (right); observed and simulated values by the CropSyst model.

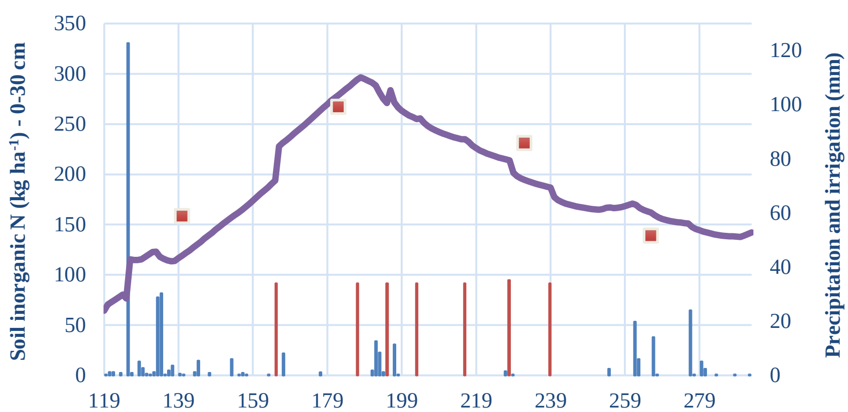
As far as the soil inorganic N fluctuations through the soil profile during the crop growing season in Larissa 2019, it can be seen in Figure 3 that the model simulated well the soil inorganic N within the top 30 cm depths. In lower depths (30-90 cm), however, model simulation overestimated, in comparison to the measured value, soil inorganic N towards the end of the growing season indicating higher potential for N losses over time.

Model simulation of soil inorganic N fluctuations through the soil profile during the cotton growing season in Orestiada 2020 (Figure 4) showed a tendency to overestimate the soil inorganic N content within the topsoil (0-30 cm) during the period of high cotton N requirements. Since crop yield was well simulated by the model, this finding may probably be attributed to an underestimation of N losses (predominantly through ammonia volatilization and/or nitrate leaching) during this period, especially taking into consideration that the amount of fertilizer N applied was rather high (201 kg N ha^{-1}), well above cotton N requirements.



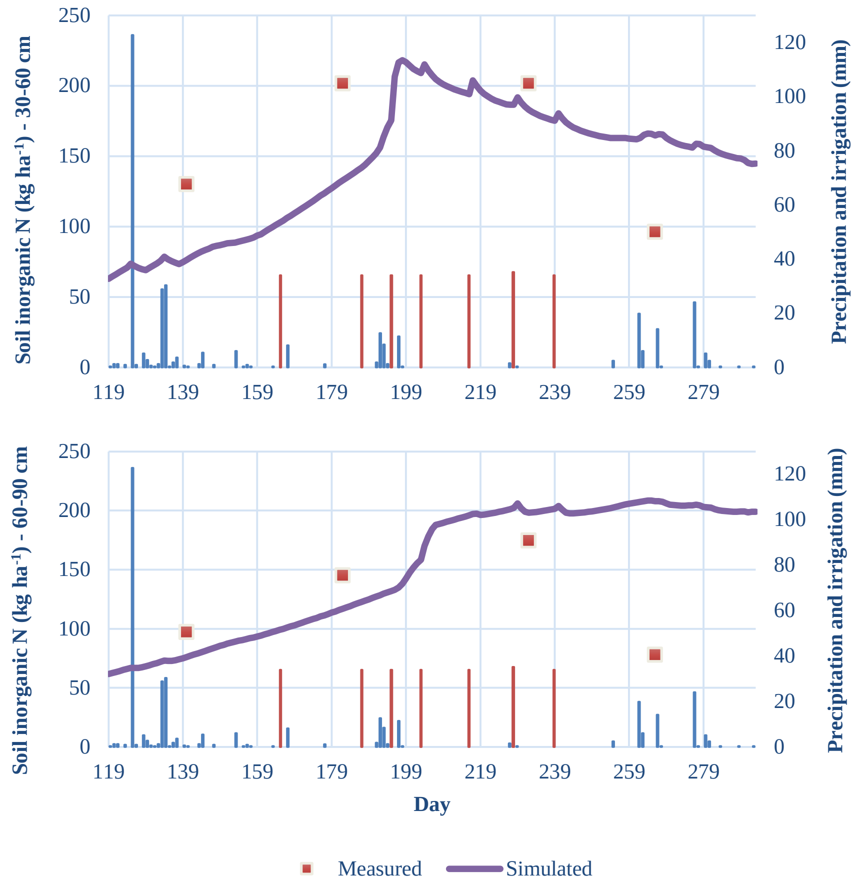


Figure 3. Soil inorganic N (sum of NH_4-N and NO_3-N) within the 0-30 cm depths (top), 30-60 cm depths (middle) and 60-90 cm depths (bottom), during cotton growing season in Larissa, 2019; measured and simulated values by the CropSyst model. The blue bars show precipitation, whereas the red bars irrigation water applied.

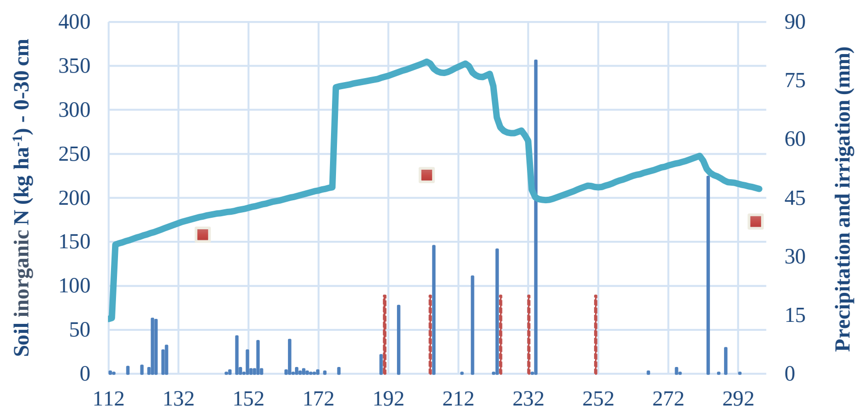

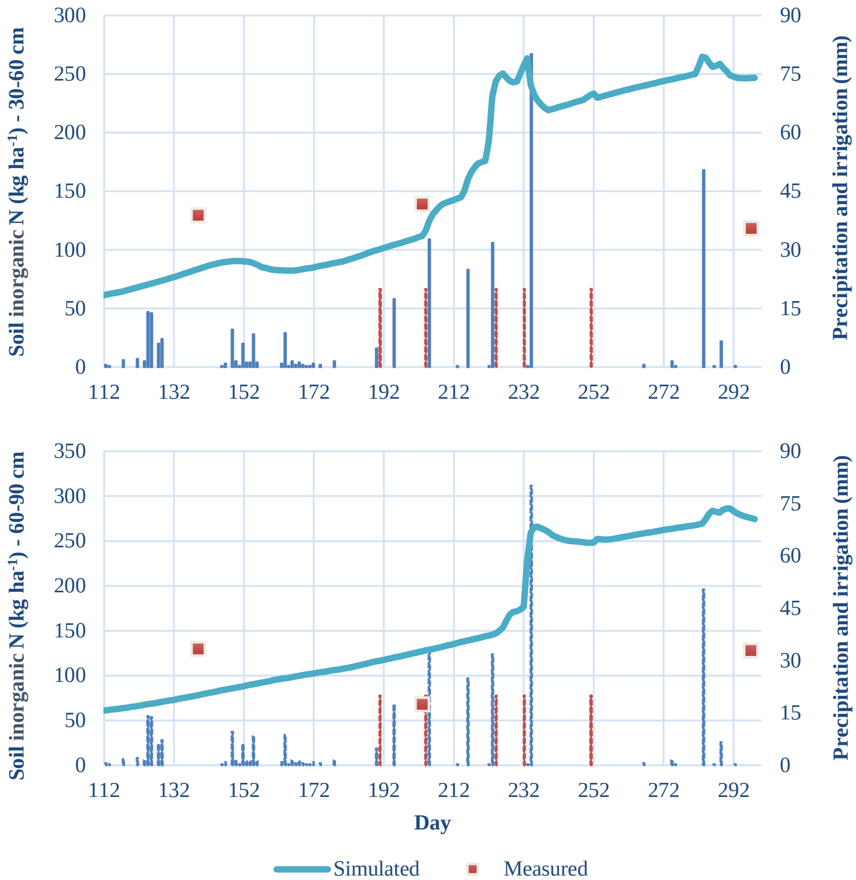

Figure 4. Soil inorganic N (sum of NH_4-N and NO_3-N) within the 0-30 cm depths (top), 30-60 cm depths (middle) and 60-90 cm depths (bottom), during cotton growing season in Orestiada, 2020; measured and simulated values by the CropSyst model. The blue bars show precipitation, whereas the red bars irrigation water applied.

As in the case of Larissa, also in Orestiada in lower depths (30-90 cm) soil inorganic N simulation showed higher values, than the measured ones, towards the end of the growing season indicating higher potential for N losses over time. The mismatch between measured and simulated soil inorganic N values towards the end of the growing season within the 30-90 cm depths may not necessarily mean that the model overestimated the total amount of N losses as some of these losses may have occurred earlier in the growing season (e.g. in the form of ammonia volatilization). Also, it is possible the simulated higher N losses potential to be partially attributed to the model simulation of the N mineralization due to soil incorporation of cotton residues after harvest.

In general, although differences between measured and simulated values were observed in some cases, the distribution of soil inorganic N during the crop growing season was simulated satisfactorily by CropSyst model in both locations.

Conclusion

In this study CropSyst model was used to simulate cotton yield and soil inorganic nitrogen under high nitrogen inputs in two locations in central and northern Greece. Cotton yield was well simulated in both locations. Soil inorganic N distribution during the crop growing season was generally satisfactorily simulated in both locations. Thus, CropSyst model can be considered as an important tool to assess the environmental impact and agronomic benefit of fertilizer N applications to irrigated areas under Mediterranean conditions.

VULNERABILITY ASSESSMENT OF SOIL SALINIZATION BY IRRIGATION WITH SALINE WATER: APPLICATION IN THE COASTAL AREA OF RHODOPE, NE GREECE

Abstract

The water scarcity has led to a significant decline of water table in many coastal aquifers of the Mediterranean basin. This has also led to salinization of groundwater reserves due to seawater intrusion, which will eventually affect the irrigated agricultural land due to salt accumulation by irrigation with saline waters. To cope with this problem, MEDSAL Project (www.medsal.net) aims to evaluate the vulnerability of soil to salinization by irrigation with saline waters through its intrinsic ability to leach salts via water percolation below the root zone with the aid of precipitation. The specific approach is based on the existing formula LOSW-P, which evaluates the precipitation water losses by percolation below the root-zone of 30 cm from a theoretical reference crop surface considering soil physical properties, topography and mean long-term climate conditions. The application of LOSW-P was performed for the Rhodope pilot area of MEDSAL project, as well as all for the total of irrigated lands in Greece. The results showed that ~80% of irrigated lands (including Rhodope) present LOSW-P values <100 mm·year^{-1} (only through precipitation), which are relatively low considering that these regions require irrigation rates >600 mm·year^{-1}. At least for the case of Greece, the proposed methodology of the MEDSAL project indicated that the use of water with relatively higher salinity may not be a solution to most irrigated lands (including Rhodope coastal area) and further solutions shall be evaluated.

Keywords: *soil vulnerability to salinization, MEDSAL project, Greece.*

Introduction

The water scarcity, mainly caused by droughts and overexploitation of the available groundwater recourses used for irrigation and domestic use has led to a significant decline of water table in many coastal aquifers of the Mediterranean basin. This phenomenon is anticipated to be further impacted by the foreseen climate change in the forthcoming years (Stigter *et al*., 2014; Martín-Arias *et al*., 2020). As a result of the water scarcity in coastal areas, the salinization of groundwater reserves due to seawater intrusion and/or other potential factors (e.g. trapped saline lenses, evaporitic formations, hydrothermal brines, etc) will eventually affect the soil resources of the irrigated agricultural land due to salt accumulation by irrigation. The use of brackish/saline water for irrigation creates consequent threats for agricultural soils due to the increase of their salinity-sodicity, which could eventually be a step towards a consequent desertification of Mediterranean agricultural lands (Okur & Örçen, 2020).

In the context of MEDSAL Project (www.medsal.net), which aims to provide holistic approaches for securing the availability and quality of groundwater reserves in the Mediterranean coastal areas, the additional component of soil quality is also highly regarded, since the afore described pressures and the imminent climate change has already led in some cases and will eventually lead to further use of brackish/saline water resources for irrigation. To efficiently cope with the adverse effects of this phenomenon, a suite of methodological steps and actions should be carefully developed structuring proactive management approaches, which could prevent and/or minimize the impact of soil salinity. The first step of such approaches, which is the subject of this work, is to propose a method for evaluating the intrinsic ability of agricultural land to leach salts via water percolation below the root zone with the aid of precipitation. This approach is based on the assumption that the less water is percolated below the root zone due to precipitation, the less salt is leached below the root zone and therefore the more vulnerable is the soil to salt accumulation due to irrigation with brackish/saline waters. The specific approach is based on the existing formula LOSW-P (Aschonitis *et al.*, 2012), which was developed to assess the intrinsic vulnerability of agricultural land to water losses by percolation below the root-zone of 30 cm of a theoretical reference crop (Penman-Monteith concept) considering soil physical properties, topography and mean long-term climate conditions.

Material and methods

The proposed LOSW-P methodology considers a uniform surface of actively dense cover with clipped perennial grass, whose rates of evapotranspiration under non-water stress conditions are equivalent to the reference crop evapotranspiration of American Society of Civil Engineers (ASCE)-standardized/Food Agriculture Organization of the United Nations (FAO)-56 concept (Allen *et al.*, 2005). The use of grass as a reference surface is used to remove the effect of different land uses. The LOSW-P index was calibrated based on the inputs and outputs of simulation scenarios performed by the Groundwater Loading Effects of Agricultural Management Systems (GLEAMS) model (Knisel and Davis, 2000). The simulations covered: (i) Different soils with respective hydraulic characteristics of the four hydrological soil types A, B, C and D of USDA–NRCS (2007); (ii) Different topography by using different slopes of grass surfaces using the curve number vs. the slope of the grass surface relationship of Getter *et al.* (2007); (iii) Different climate conditions from Greece, Italy and USA; (iv) Irrigation or non-irrigation conditions. Irrigation was applied automatically by the GLEAMS model when the soil moisture was falling to 20% of available soil moisture (ASM) in order to return it to 100% ASM corresponding to field capacity conditions. All scenarios were performed for the first 30 cm of the soil profile, which included the largest percentage of the rootzone. The results were used to develop and calibrate LOSW-P index, which describe annual water losses by percolation below the 30 cm according to the following equation (Aschonitis *et al.*, 2012):

$$LOSW\text{-}P = \begin{Bmatrix} 0.0941\sqrt{K_s} - \ 0.761\sqrt{SL} + 0.4185\sqrt{P} \\ - \ 0.0487\sqrt{ET_o} + 0.0903\sqrt{IR} \end{Bmatrix}^2 \tag{1}$$

where *LOSW-P* is the annual water losses by percolation under the 30 cm of a reference grass (mm $year^{-1}$), K_s is saturated hydraulic conductivity (mm day^{-1}), *SL* is soil surface slope (%), *P* is annual precipitation (mm $year^{-1}$), ET_o is the annual reference evapotranspiration (mm $year^{-1}$) and *IR* is the annual irrigation to cover the deficit of reference evapotranspiration (mm $year^{-1}$). It has to be noted that when the formula inside the brackets of Eq.1 leads to negative values, the value of *LOSW-P* is set equal to 0. The above equation can be used either for $IR = 0$ or $IR \neq 0$. For the latter case, the annual irrigation *IR* for covering the deficit of annual reference evapotranspiration is calculated as follows (Aschonitis *et al*., 2013):

$$IR = \sum_{1}^{12} IR_i \text{ , where } IR_i = ET_{o,i} - P_i \text{ when } ET_{o,i} > P_i \text{ else } IR_i = 0 \qquad (2)$$

where *IR* is the annual irrigation required for covering the deficit of annual reference evapotranspiration (mm year^{-1}), IR_i is the monthly irrigation for covering the deficit of reference evapotranspiration of the month i (mm month^{-1}), $ET_{o,i}$ is the monthly reference evapotranspiration (mm month^{-1}) (estimated in this study by FAO-56 method), P_i is the monthly precipitation and i is the month. The use of larger *IR* values from the values of Eq.2 for over-irrigation analysis using Eq.1 is not indicated. In this study Eq.1 was applied for *IR*=0 in order to assess the amount of precipitation water (clean water) that percolates below the root zone and is responsible for salt leaching.

The ET_o is estimated using the ASCE-standardized method (former FAO-56) for short reference crop by the following function (Allen *et al*., 2005):

$$ET_o = \frac{0.408\Delta(R_n - G) + \dfrac{\gamma u_2(e_s - e_a)C_n}{(T + 273.16)}}{\Delta + \gamma(1 + C_d u_2)} \qquad (3)$$

where ET_o is the reference crop evapotranspiration (mm d^{-1}), R_n is net radiation at the crop surface (MJ m^{-2} d^{-1}), u_2 is mean daily wind speed at 2 m height (m s^{-1}), T is the mean daily air temperature (°C), G is soil heat flux density at the soil surface (MJ m^{-2} d^{-1}), e_s is the mean daily vapor pressure (kPa), e_a is the mean daily actual vapor pressure (kPa), Δ is the slope of the saturation vapor pressure–temperature curve (kPa °C^{-1}), γ is the psychrometric constant (kPa °C^{-1}) and C_n and C_d are constants of 900 and 0.34, respectively.

The LOSW-P for the annual water losses by percolation under the 30 cm of a reference grass was estimated using the following four databases:

- The database of Hijmans *et al.* (2005) provides gridded data of mean monthly precipitation P and mean monthly temperature T for the period 1950–2000 (WorldClim version 1.2) at 30 arc-sec (~1×1 km) spatial resolution. Their mean annual values are given in Fig.1a,b, respectively.
- The database of Aschonitis *et al.* (2017) (10.1594/PANGAEA.868808) provides gridded data of mean monthly reference evapotranspiration ET_o (Eq.3) of the period 1950–2000 at 30 arc-sec (~1×1 km) spatial resolution (Fig.1c) (this database is built using temperatures from the WorldClim version 1.2 database). Using the ET_o and precipitation, the irrigation map of the reference crop *IR* is built according to Eq.2 (Fig.1d).
- The surface slope (Fig.1e) was obtained by the digital elevation model of GTOPO30 (pixel analysis of 30 arc-sec, ~1×1 km) as it is given by the USGS (United States Geological Survey).
- The European Soil Database provided by the European Commission Joint Research Centre (Hiederer *et al*., 2013) provides soil data (% sand, % silt, % clay, % gravel, % organic carbon) with spatial analysis (~1×1 km). These data are used to estimate the saturated hy-draulic conductivity Ks according to the respective pedotransfer function (PTF) of Saxton and Rawls (2006), taking into account the gravel and organic matter effect (Fig.1f).
- The Corine Land Cover 2018 (https://land.copernicus.eu/pan-european/corine-land-cover/clc2018) was used to derive irrigated lands.

The application of LOSW-P formula was performed for the Rhodope pilot area of MEDSAL project, as well as all for the total of irrigated lands in Greece for performing comparisons at national scale.

Results and discussion

The *LOSW-P* ranged between 21-241 mm·year^{-1} (mean annual water losses by percolation only by precipitation) with an average value of 82 mm·year^{-1} at country level, based on all irrigated lands of Greece. The respective values of *LOSW-P* for the coastal region of Rhodope ranged between 31-91 mm·year^{-1} with an average value of 81 mm·year^{-1}, which approximates the average value of *LOSW-P* at a country level. The respective irrigation requirements for covering the reference crop evapotranspiration after removing precipitation ranged between 320-1122 mm·year^{-1} at country level and 645-676 mm·year^{-1} for Rhodope region (Fig.2).

Figure 1. Mean annual values of (a) precipitation, (b) temperature, (c) reference evapotranspiration according to ASCE-standardized for short reference crops, (d) irrigation required for covering the deficit of annual reference evapotranspiration for the period 1950–2000, (e) surface slope and (f) saturated hydraulic conductivity in Greece.

The results of the study showed that ~80% of irrigated lands of Greece (including Rhodope) present *LOSW-P* values <100 mm·year^{-1} (Fig.2), which are relatively low considering that these regions require irrigation rates >600 mm·year^{-1} (Fig.1d). This indicates that the use of high salinity waters at amounts larger than 500 mm·year^{-1} would increase the soil salinity due to the inadequate salt leaching by precipitation water. The problem of inadequate salt leaching is expected to be more intense in soils with higher percentages of clay and lower values of saturated hydraulic conductivity. For these regions, the LOSW-P maps should also be combined with current soil salinity maps and water salinity monitoring of available water sources for irrigation (groundwater and reclaimed wastewater) in order to build integrated water resources management for combatting soil desertification by the salt accumulation by irrigation.

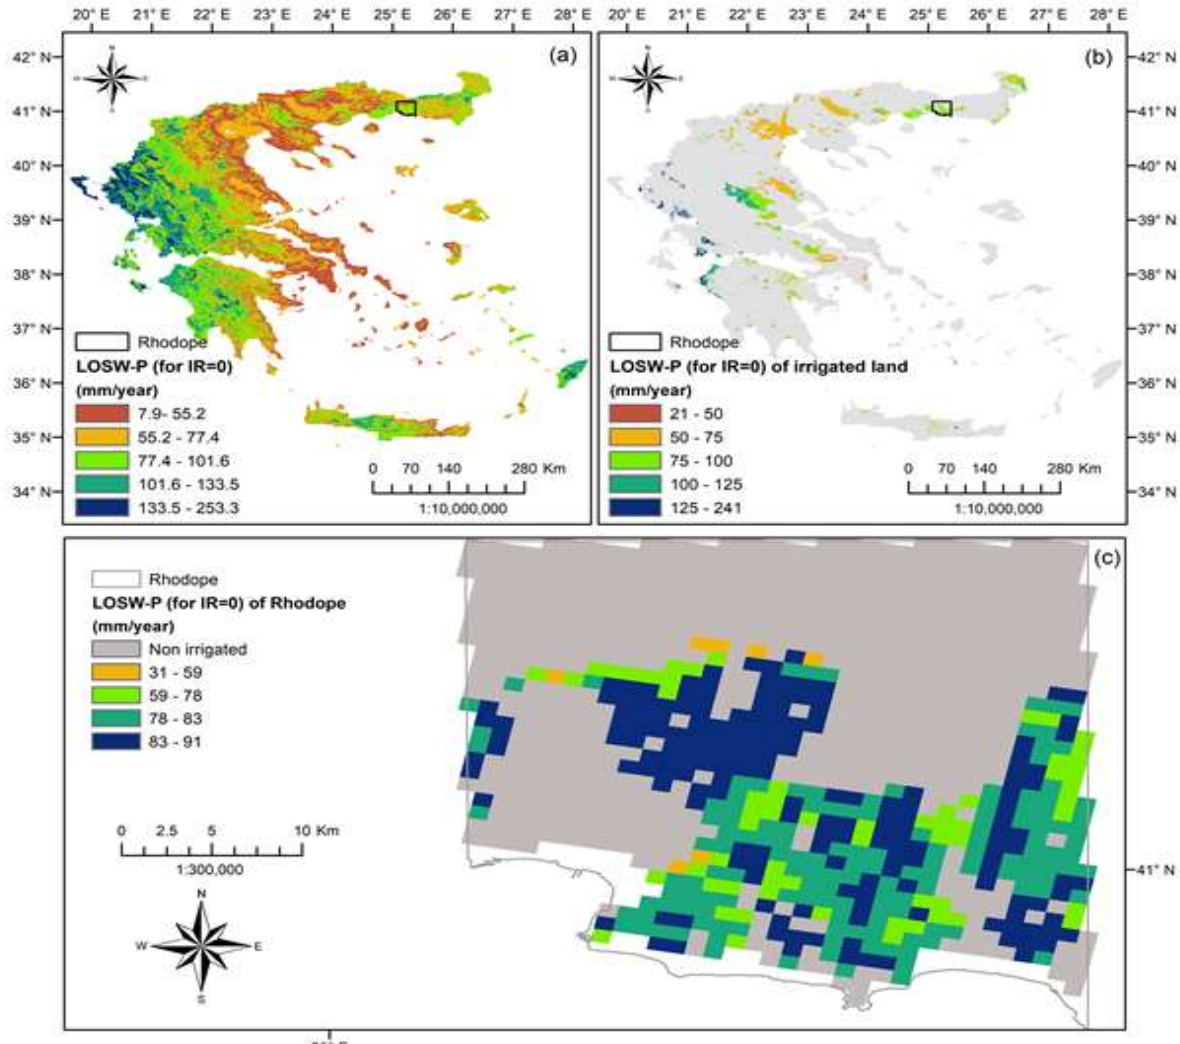

Figure 2. Mean annual values of (a) *LOSW-P* (for *IR*=0) for the whole Greece, (b) *LOSW-P* (for *IR*=0) for all the irrigated lands of Greece, (c) *LOSW-P* (for *IR*=0) for all the irrigated lands of Rhodope.

Conclusions

In this study, the *LOSW-P* methodology was proposed in the context of MEDSAL project for evaluating the intrinsic ability of agricultural land to leach salts via water percolation below the root zone with the aid of precipitation. At least for the case of Greece, the proposed methodology indicated that the use of water with relatively higher salinity may not be a solution to most irrigated lands (including Rhodope coastal area) due to the low *LOSW-P* values and further solutions shall be evaluated.

Abstract

Estimating biomass or crop yield can improve farm management and optimize precision agriculture applications. Satellite data provides good information from the farms. In this regard, this research was aimed at finding a fast method with acceptable accuracy in order to predict the yield of winter wheat by using NDVI and LAI indices on the five farms located in Neyshabur, Khorasan Razavi province. The MODIS images of the TERRA satellite were conducted during the years 2012-2013 to 2014-2015. The results showed that there was a high correlation between NDVI and LAI indices (88 to 99%) over the years. The correlation between the observed performances with the LAI index varied between 2012-2013 and 2014-2015 so that in some years there was a strong correlation and in some years, a weak correlation. The correlation coefficient between observed wheat yield and NDVI index was 85.63, 15, and 48% in 2012-2013, 2013-2014 and 2014-2015 respectively. Results showed that vegetation indices changed in different fields and at different times during the growing season, so that the trend of changes in the indexes increased with approaching June and then decreased with approaching the wheat harvest time. Based on the results of this study, the sum of squared errors (RMSE) for the 10 calibrated farms was calculated to be 1.38 ton/ha, and the total squared errors (RMSE) was validated for 5 farms equal to 1.45 ton/ha. Based our results, wheat yield can be well predicted using regression between vegetation indices in flowering and filling stage and yield using regression analysis.

Key words: *Yield estimation, Remote sensing, Leaf area index, Normalized difference vegetation Index,*

Introduction

Crop growth and yield information are critical for the government in guiding and readjusting the macro planting system and improving agricultural operation and management (Guo, 2007). The Global population continues to rise and will reach between 7.4 and 10.6 billion people by the year 2050 (United Nations, 2003). With the growing population and rising per-capita consumption, the demand for cereals and grains is expected to increase 1.3% per year (Duvick and Cassman, 1999). Wheat is one of the most important staple crops and is widely grown throughout the world, mainly in Asia, Europe, and America (Sui et al., 2018). Remote sensing data, owing to their non-contact, timely, and repetitive coverage at a regional scale, provides the opportunity for crop-production estimation and growth monitoring prior to harvest (Thorp et al., 2012). Normalized Difference Vegetation Index (NDVI) is the most extensively used parameter to statistically correlate to crop growth and yield for spring and winter wheat, corn, rice, sorghum and soybeans across the world, such as the USA, Brazil, Argentina, Greece, Morocco, Zimbabwe, China, Mongolia, India, Poland and other countries (Groten, 1993; Gumma et al., 2014; Kogan et al., 2012; Maselli et al., 1993; Rasmussen, 1992; J.H. Zhang et al., 2014). NDVI is the most used for the yield estimation. Compared with the leaf area index (LAI) and the fraction of photosynthetically active radiation (FPAR), the NDVI is more relevant to the potato yield (ITA, 2002) and (Jiao et al., 2014) built a regression model between the regional yield and the accumulated MODIS NDVI at the booting–heading stage of winter wheat, and the wheat yield was well estimated with the relative error of 5%. (Becker-Reshef et al., 2010). LAI is a key biophysical variable influencing land surface processes such as photosynthesis, transpiration, and energy balance and is a required input for various ecological models (Bonan, 1993). Either direct or indirect methods have been used to estimate in situ LAI. Assessment of crop leaf area index (LAI) in agricultural landscapes is of importance for addressing various agricultural issues such as: crop growth monitoring, vegetation stress, crop forecasting, yield predictions and management practices. Indeed, LAI is a canopy biophysical variable that plays a major role in vegetation physiological processes.

Huang et al. (Conway, and Toenniessen, 1999) assimilated the LAI derived from Landsat thematic map (TM) and MODIS data into the world food studies (WOFOST) crop growth model for predicting the regional-scale winter wheat yield of China's Hebei Province, and the improved predicting accuracy with the root mean square error (RMSE) of 151.92 kg/ha was obtained. (Sui et al., 2018). Therefore, the current research aims to evaluate the potential of MODIS-derived measures of greenness and leaf area index (LAI), and information related to the actual yield of wheat to estimate wheat production and yield in the region of Neyshabour as a case study.

Material and methods

Cereal production and yield at a national scale from 2012–2015 were obtained from the Ministry of Agriculture Jahad (https://www.maj.ir/Index.aspx). Wheat yields were measured as tons per hectare of land harvested regionally and in different farms, and the total harvest is calculated accordingly. The Study area located between 58°13'N to 59º3′N Latitude and 35º4′E to 36º39′E Longitude. The maximum and minimum elevation of the basin is 1520 m and 1213 m above MSL, respectively. The weather data were collected at the weather station by the Iran Meteorological Administration and made available on the Islamic republic of Iran Meteorological Organization (http://irimo.ir). They included: temperature, rainfall, relative humidity, and wind speed. The performance of the 5 farms was measured (Table 1).

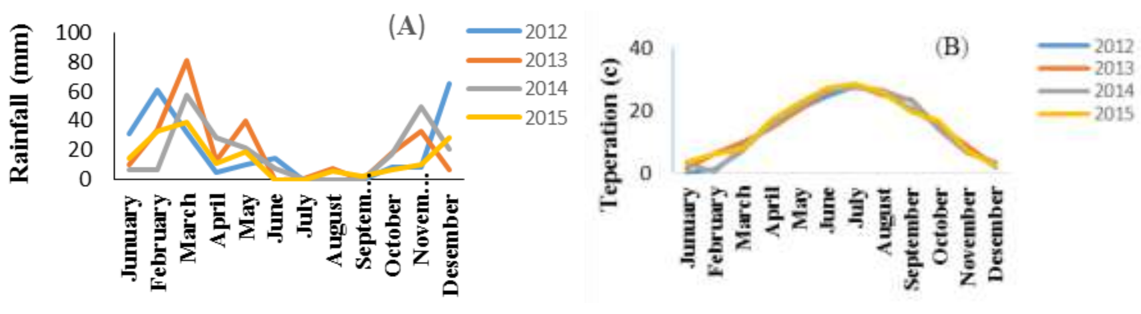

Fig 1. 365 days mean rainfall (A) temperatures (B) for the Neyshabur study site, for the wheat crop cycles December to 30 November) of 2012 (blue), 2013 (brick red), 2014 (Gray), 2015 (Red).

Table 1. Wheat yield in 5 farms during 2012-2013 till 2014-2015 crop years.

Farms number	Owners	Yields (Tons/ hectare)			Area cultivation (hectares)
		2012-2013	2013-2014	2014 -2015	
1	Site 1	3.7	6	4	50
2	Site 2	3	3.5	4	70
3	Site 3	5.7	5.3	5.7	13
4	Site 4	4	4.5	5	50
5	Site 5	4	4.5	5	50

Results and discussion

The results showed that LAI index had a correlation coefficient of 73% with yield in 2012-2013 crop year (Fig. 2-A). The correlation between the LAI index and yield in the crop year of 2013-2014 and 2014-2015 was 8.03 and 26.73.7%, respectively (Fig. 2-B, and 2-C). Sarvad et al. (2014), reported a positive and significant correlation between leaf area index and grain yield and biological yield. In general, it can be stated that the correlation between the LAI index and the observed performance was variable, which may be due to farm management quality such as fertilizer management, irrigation or weed management and weather condition in different years.

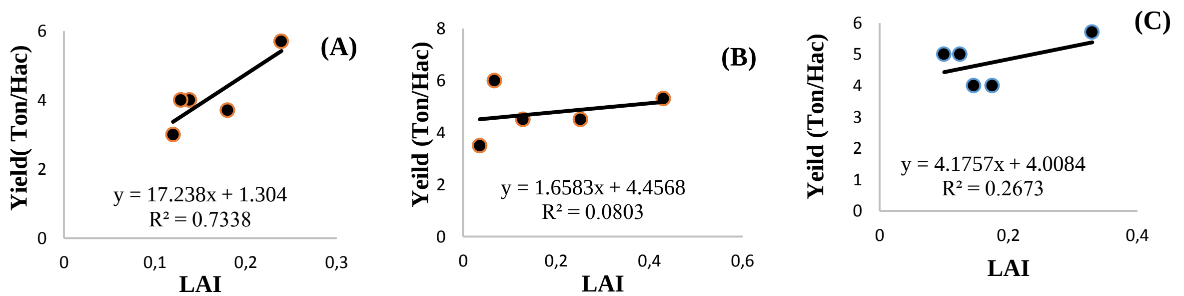

Fig. 2. The regression between the LAI and yield in three crop years, (A) 2012-2013, (B) 2013-2014, (C) 2014-2015.

The correlation between NDVI and yield in the growing season 2012-2013 showed that in this time, the correlation was 85.63% (Fig. 3-A). Although, in the other years, the correlation was not high. For example: in crop year 2013-2014 between NDVI and yield was negative (-15%), While in the growing season of 2014-2015 the index showed a correlation of 48% with yield (Figures 3-B and 3-C). The images used in the flowering stage of wheat had a high correlation between spectral indices and wheat biomass.

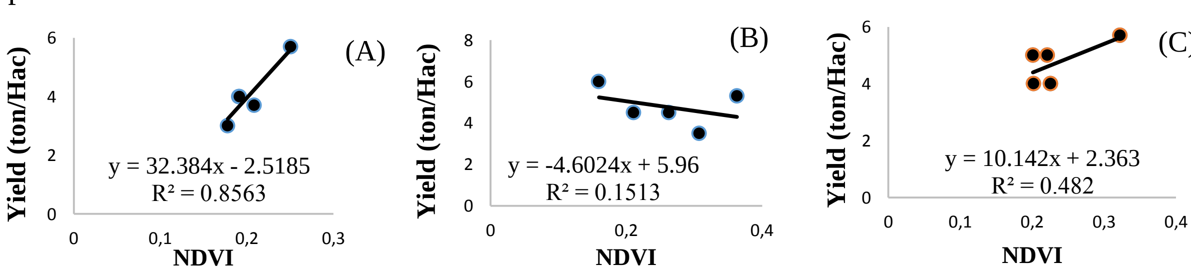

Fig. 3. The regression between the NDVI and yield (A). 2012-2013. (B) 2013-2014. (C) 2014-2015.

The study of regression between vegetation index indicates that a strong linear relationship was been established between LAI and NDVI in May to July. By examining the regression relations between vegetation indexes within 2012 to 2015 years, it can be argued that these indicators have a good relationship with each other. For example: In 2012-2013, the correlation between these two indicators was between 88 to 92 percent. As well as, in 2013-2014, the range of correlations was between 92 till 99 percent which reflects the high correlation between these two indicators. However, in 2014-2015, the high correlation between the indicators was between 98 to 99 percent. In general, the trend of changes in vegetation indices shows that, as the flower season of winter wheat approaches, the vegetative index has increased and as we approach the harvesting season, the trend is decreasing (Fig. 4).

Zhao et al (2011) revealed that renormalized difference water index (RDWI) and MODIS near-infrared reflectance had the highest correlation with yield at grain-filling stages. Thus, considering that June is the season of flowering and filling of wheat in Neyshabur region, the high correlation between LAI and NDVI obtained at this stage not far from expectation.

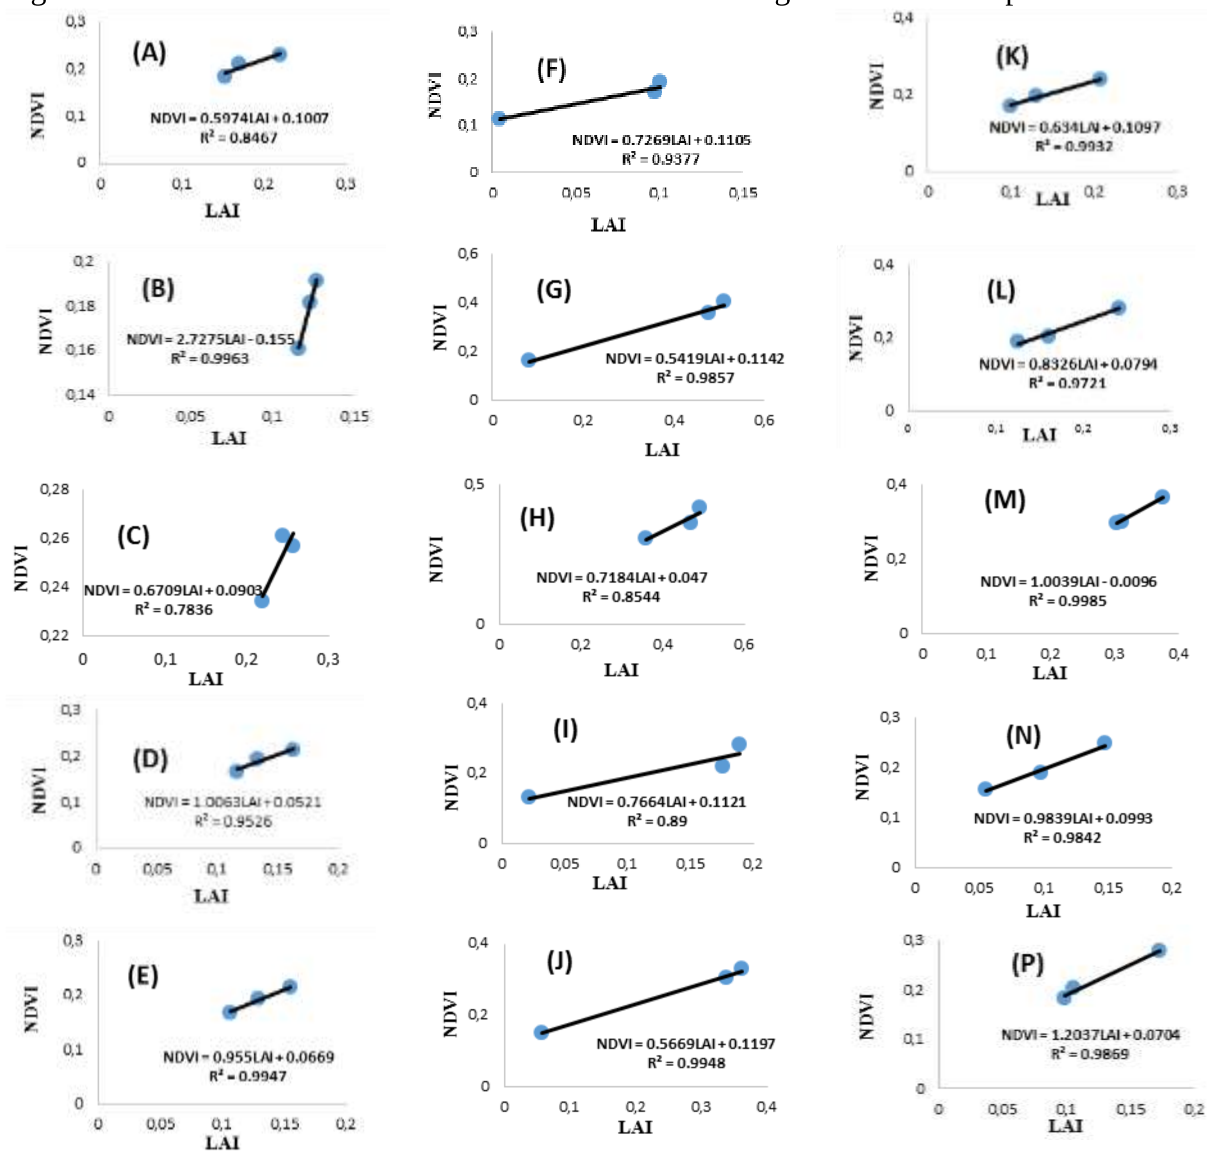

Fig 4. The regression between LAI and NDVI in three years, A to E charts 2012-2013 crop year, F to J charts 2013-2014 crop year and K to P charts 2014-2015.

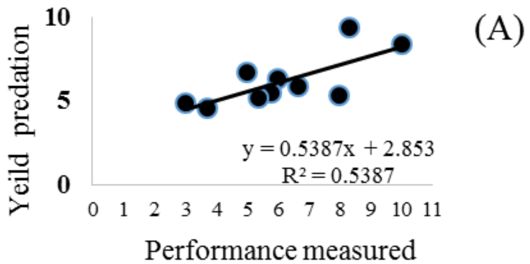
The regression relationship between the predicted values and the observed actual yield of wheat was also linear and acceptable. The results obtained using of predicted wheat yield data were acceptable with 53% accuracy. In this study, in order to determine the error coefficient, a correlation was established between actual performance and predicted performance. Finally, it was found that the calibrated farms with square root error of 1.38 tons per hectare and 5 validated farms with square root error of 1.45 tons per hectare can be a very good model for predicting wheat yield with the help of the above indicators and satellite images (Fig. 5).



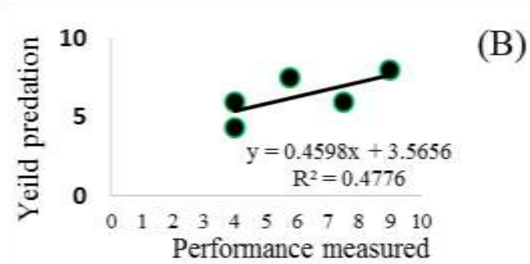


Fig. 5. (A) Ten calibration figure farms, (B) Five Validation figure farms.

Conclusion

Using remote sensing data can eliminate various barriers for managers to make decisions, with the technology being able to estimate wheat yield significantly. Our results showed that wheat yield was varied between years and fields duo to farm management quality and weather condition in different years. The correlation between LAI index and NDVI with wheat yield was varied from year to year. The maximum correlation between growth indices was found at the flowering and filling stages of winter wheat. Based our results, wheat yield can be well predicted using regression between vegetation indices in flowering and filling stage and yield using regression analysis.

Abstract

In recent years, climate change has greatly affected rainfall and air temperature levels leading to a reduction of water resources in Southern Europe. Agriculture has been hit hard by the fall in water supply and a negative impact on irrigated crops has been observed. The treated wastewater (TWW) reuse for agricultural irrigation can represent a solution for farmers, allowing to reduce the consumption of freshwater (FW) and the need of mineral fertilisers. In the rural environment, constructed wetland systems are the most promising nature-based solutions to obtain TWW. This paper reports a two-year study on the wastewater treatment performance of a pilot-scale horizontal subsurface flow system in Sicily (Italy) and the effect of two sources of irrigation water (FW and TWW) on tomato plants and soil characteristics. The system had a total surface area of 100 m^2 and was planted with giant reed and umbrella sedge. An experimental field of tomato was set up close to the system. Results highlighted a high pollutant removal efficiency (RE) of the system. In particular, RE levels of *Escherichia coli* was found to be higher than 85% on average. The production and qualitative parameters of tomato fruits were significantly affected by the different irrigation treatments. The total yield of fruits was higher than 70 t ha^{-1} in the TWW-irrigated plots. Microbial contamination was high in fruits which were in contact with bare soil. The source of irrigation water did not vary the chemical composition of the soil. Our findings confirm that TWW provides an additional water source and nutrients where the supply of FW is limited.

Keywords: *Constructed wetland*; *Treated wastewater reuse; Tomato; Savings.*

Introduction

In the Mediterranean region, agricultural production has been lately affected by climate change. Higher air temperatures, less distribution of rainfall events and more frequent periods of drought have caused a significant reduction of crop yields in many areas of Southern Europe. In this scenario, the reuse of treated wastewater (TWW) for irrigation purpose represents a useful practice for sustainable water management due to various agronomic reasons. It increases the water resource in the agricultural sector, saving higher quality water for human consumption and lower quality water for irrigation (Leto *et al*., 2013). It meets growing water demand and reduces discharge of wastewater (WW) in soil and water bodies (Pedrero *et al*., 2010; Licata *et al*., 2019). It represents a source of mineral and organic nutrients and its application can increase crop yields and reduce the use of chemical fertilisers (La Bella *et al*., 2016). However, despite these benefits, the use of TWW irrigation could affect the chemical soil characteristics and increase the level of pathogens in plant and soil (Rusan *et al*., 2007; Castro *et al*., 2011). As a consequence, efficient WW treatment is needed in order to safeguard the environment and, at the same time, provide benefits for agriculture. In some Italian regions, conventional treatment systems are outdated and do not always meet legislative requirements as they do not perform all treatments needed to ensure high water quality (Licata *et al*., 2017). In this situation, constructed wetlands (CWs) can play a key role in the treatment and reuse of various types of WW due to their characteristics. CWs represent an example of a nature-based solution and can be integrated into wastewater treatment plants, as tertiary-treatment technology, to complete the purification process of WW. A number of studies demonstrate the potential of CWs in the agricultural sector and make in evidence the application of CWs for obtaining TWW. In particular, various authors have examined the effects of TWW on horticultural crops, evaluating how TWW affects plant and soil characteristics both in the short and long-term (Cirelli *et al*., 2012; Gatta *et al*., 2018). Among open field crops, tomato represents the most investigated crop for the Mediterranean area as a major dietary component in many countries. Tomato is, in fact, a key element in the human diet due to its high nutritional and health properties. In recent years, research on this species has focused on the effects of TWW irrigation on yield and quality highlighting the increase in marketable yields (MY) and fall in health and hygiene standards in the fruits (Al-Lahman *et al*., 2003; Gatta *et al*., 2015). The aim of this paper was to assess the WW treatment performance of a pilot-scale horizontal subsurface flow system (HSSFs) CW in Sicily (Italy) and the effect of freshwater (FW) and TWW on tomato plants and soil characteristics in the short-term.

Materials and methods

Tests were carried out in two years from 2016-2017 in the area of the HSSFs CW in Raffadali, located in Western Sicily (Italy - 37°24'N – 1°05'E, 446 m a.s.l.). The CW was used to treat urban WW produced from the municipal treatment plant. The CW had a total area of 100 m^2 and included two parallel units which were separately planted with giant reed (*Arundo donax* L.) and umbrella sedge (*Cyperus alternifolius* L.). The main functional and technical characteristics were described by Leto *et al*. (2013) in a previous study.

WW samples were taken monthly at the inlet and outlet pipes from April to September of each year. Total suspended solids (TSS), biochemical oxygen demand (BOD_5), chemical oxygen demand (COD), total nitrogen (TN) and total phosphorus (TP) levels were determined in accordance with Italian water analytical methods. Total coliforms (TC), faecal coliforms (FC), faecal streptococci (FS) and *Escherichia coli* (EC) levels were determined in accordance with APHA standard methods for water testing. For each planted-unit, pollutant removal efficiency (RE) was based on pollutant concentration and calculated by guidelines of the International Water Association.

An experimental field of tomato was set up close to the HSSFs CW. A cultivar was transplanted in the third 10-day-period of April 2016 and 2017, using a plant density of 2.2 plants m^{-2}. The single plot size was 50 m^2. A split-plot design for a two-factor experiment was adopted with three replications. Irrigation was applied from April to June twice a week for 1 h and from July to September twice a week for 3 h. Irrigated-plots received 80 kg N ha^{-1}, 130 kg P_2O_5 ha^{-1} and 120 kg K_2O ha^{-1} through fertigation. Total yield (TY) of fruits was calculated Fruit diameter (D), fruit colour (Co), fruit soluble solids content (SSC) and titratable acidity (TA) of tomato juice were determined on a sample of 20 marketable fruits from each plot. Dry matter (DM) content was also calculated by drying the fruits in a ventilated oven at 70 °C. Fruits in 300 g samples were harvested a week before irrigation from each plot to determine the levels of FC, FS and EC in both fruit skin and flesh.

Regarding soil, samples were taken at a depth of 0-30 cm from each plot and analysed for pH, electrical conductivity, total organic carbon (TOC), total Kjeldahl nitrogen (TKN), total calcium carbonate ($CaCO_3$), phosphorus (P), potassium (K) and sodium (Na) content.
Statistical analyses were performed using the package MINITAB 17 for Windows. For WW composition, all the representative values were shown using mean ± standard deviation calculations. For plant and soil parameters, analysis of variance was carried out and the difference between means was investigated out using the Tukey test.

Results and discussion

Removal efficiency of pollutants in the HSSFs CW

Table 1 summarises the RE values of chemical pollutants. For TSS, differences in RE values between the two CW planted units can be explained by the diverse root length density of the species and time of contact between WW and roots (Vymazal, 2009). In general, BOD_5 and COD RE values were high and stayed within a range consistent with previous HSSFs CW studies treating urban WW (Kadlec et al., 2000). TN RE was lower than the organic matter removal due to low oxygen levels in the system. TP RE average values were lower and probably due to the gradual filling of the sorption sites by the plant roots, the presence of undecomposed plant parts around the substrate surface and the adsorption properties intrinsic to the substrate (La Bella et al., 2016).

Table 1. Chemical composition of the TWW from inlet to outlet in the HSSFs CW. RE from April to September 2016/2017. Two-year average values (± SD) are shown.

Parameter	Influent	Effluent[1]	Effluent[2]	RE (%)[1]	RE (%)[2]
TSS (mg L^{-1})	42.11 ± 1.9	10.31 ± 0.4	11.40 ± 0.4	78.91	71.30
BOD_5 (mg L^{-1})	34.31 ± 0.7	13.42 ± 0.3	13.92 ± 0.3	61.21	59.65
COD (mg L^{-1})	55.92 ± 1.4	18.62 ± 0.2	19.43 ± 0.3	66.41	65.23
TN (mg L^{-1})	21.32 ± 0.4	10.92 ± 0.3	11.21 ± 0.2	49.12	47.21
TP (mg L^{-1})	8.02 ± 0.2	4.85 ± 0.1	4.99 ± 0.1	39.52	37.78

[1] giant reed-planted unit; [2] umbrella sedge-planted unit.

In the case of microbiological level (Table 2), the good aerobic conditions in the planted units eased the production of a greater bacteria biofilm and promoted removal of pathogens, as stated by El-Khateeb *et al*. (2009). For each parameter, RE levels were found to be above 80.00% in accordance with the findings of other studies carried out under similar operating conditions at the HSSFs CW.

Table 2. Microbiological composition of the TWW from inlet to outlet in the HSSFs CW. RE from April to September 2016/2017. Two-year average values (± SD) are shown.

Parameter	Influent	Effluent[1]	Effluent[2]	RE (%)[1]	RE (%)[2]
TC (CFU 100 ml^{-1})	4.44 ± 1.5[3]	3.41 ± 0.9	3.48 ± 1.2	90.58	88.81
FC (CFU 100 ml^{-1})	4.29 ± 1.1	3.36 ± 1.4	3.41 ± 1.3	88.31	87.11
FS (CFU 100 ml^{-1})	3.99 ± 2.5	3.27 ± 1.02	3.38 ± 1.1	81.32	74.60
EC (CFU 100 ml^{-1})	3.21 ± 0.5	2.25 ± 1.2	2.28 ± 0.9	88.91	87.13

[1] giant reed-planted unit; [2] umbrella sedge-planted unit; [3] values are shown as units of Log_{10}.

In this study, average chemical and microbiological parameters results at outlet of the HSSFs CW, such as TP and EC, were not always within the legal limits of the Italian Decree 152/2006 concerning the reuse of TWW for irrigation purposes.

Effects of freshwater and treated wastewater irrigation on yield and quality of tomato fruits

The main factors did not determine significant changes for all plant parameters (Table 3). Significant differences were found between FW- and TWW-irrigated plants concerning TY of fruits. Our findings were in agreement with results obtained by Gatta *et al*. (2015) who stated that the genetic constitution of cultivars, the type of TWW applied and the climate and soil characteristics can play a fundamental role. The highest pH average values were recorded in the FW-irrigated fruits. This was confirmed by other studies (Al-Lahman *et al*. 2003; Cirelli *et al*., 2012; Gatta *et al*., 2015) and highlights that pH is significantly affected by source of irrigation water. Concerning other qualitative parameters of fruit, significant differences were found between the irrigation treatments for SSC, DM, D and Co.

Table 3. Production and qualitative parameters of tomato fruits in response to year and irrigation water. Average values of 2-year tests are shown.

Factor	TY (t ha^{-1})	pH	SSC (° Brix)	TA (g 100 ml^{-1})	DM (%)	D (cm)	Co (a^*/b^*)
Y_1	70.83 b	4.57 a	4.78 a	0.26 a	5.50 a	1.21 a	2.53 a
Y_2	74.78 a	4.56 a	4.78 a	0.27 a	5.49 a	1.21 a	2.54 a
IW_1	66.13 b	4.68 a	4.81 a	0.28 a	5.53 a	1.19 b	2.53 ab
IW_2	75.51 a	4.54 b	4.78 b	0.26 a	5.47 b	1.21 ab	2.52 b
IW_3	76.78 a	4.58 b	4.76 b	0.26 a	5.47 b	1.22 a	2.53 a
Y x IW	n.s.	n.s.	n.s.	n.s.	n.s.	n.s.	**

Means followed by the same letter are not significantly different according to Tukey's test: ** significant at $p \leq 0.01$; n.s = not significant.
Y_1 = 2016; Y_2 = 2017; IW_1 = FW; IW_2 = TWW from giant reed-planted unit; IW_3 = TWW from umbrella sedge-planted unit.

Fruit fresh and skin had different microbial levels. Fruit flesh was uncontaminated whereas fruit skin was greatly contaminated by microorganisms. In both years, a different contamination levels were found in August and September and were probably due to diverse microbial levels in the TWW produced from HSSFs CW (Table 4).

Table 4. Microbial levels in the TWW-irrigated fruits during 2016-2017. Average values are shown.

Parameter	Period			
	August		September	
	Skin	Flesh	Skin	Flesh
FC (CFU 100 g^{-1})	425	0	538	0
FS (CFU 100 g^{-1})	670	0	765	0
EC (CFU 100 g^{-1})	127	0	101	0

In this study, it was observed that the most contaminated fruits were those in contact with the bare soil. As affirmed by Bastos and Mara (1995), the increased soil moisture from TWW irrigation could allow for bacterial re-growth, whilst Irénikatché Akponikpè *et al*. (2011) state that the rough surface of the tomato fruit facilitates microbial contamination, especially in fruits which touch the soil. Al-Lahman *et al*. (2003) sustain that weather conditions, such as moisture, solar radiation and temperature, can significantly affect the microbial contamination on fruit skin.

Effects of freshwater and treated wastewater irrigation on soil characteristics

Soil chemical characteristics as affected by year and irrigation water are shown in Table 5. The main factors did not determine significant changes for all soil parameters. No significant variations in topsoil pH of the FW- and TWW-irrigated plots were recorded due to short-term application of TWW, as sustained by Rusan *et al*. (2007). Soil salinity increased over the two years and was found to be higher on average in the TWW-irrigated soil compared to the FW-irrigated soil and this was probably due to original salt levels in the WW, as reported by Mohammad and Mazahreh (2003). TWW-irrigated soil had a higher average values of TOC with respect to FW-irrigated soil due to higher nutrient content and organic compounds in TWW, as confirmed by various authors (Heidarpour *et al*. 2007; Rusan *et al*. 2007).

Table 5. Chemical characteristics of soil in response to year and irrigation water. Average values of 2-year tests are shown.

Factor	pH	EC ($\mu S\ cm^{-1}$)	TOC ($g\ kg^{-1}$)	TKN ($g\ kg^{-1}$)	$CaCO_3$ ($g\ kg^{-1}$)	P ($g\ kg^{-1}$)	K (ppm)	Na (ppm)
Y_1	7.66 a	191.32 b	7.78 a	1.27 b	1.33 a	0.04 a	555.95 a	93.65 a
Y_2	7.63 b	200.53 a	7.82 a	1.29 a	1.33 a	0.03 a	560.93 a	92.87 a
IW_1	7.65 a	188.76 b	7.70 b	1.24 b	1.32 b	0.03 a	541.73 b	91.05 c
IW_2	7.64 a	198.77 a	7.82 a	1.29 a	1.34 a	0.03 a	563.30 a	93.53 b
IW_3	7.65 a	200.25 a	7.88 a	1.32 a	1.33 a	0.03 a	568.29 a	95.21 a
Y x IW	n.s.	n.s.	**	**	n.s.	n.s.	n.s.	**

Means followed by the same letter are not significantly different according to Tukey's test: ** significant at $p \leq 0.01$; n.s = not significant.
Y_1 = 2016; Y_2 = 2017; IW_1 = FW; IW_2 = TWW from giant reed-planted unit; IW_3 = TWW from umbrella sedge-planted unit.

Concerning N, differences between the FW- and TWW-irrigated soil were probably due to the fact that, in the short-term, the effect of leaching and plant uptake on N content was not significant. In our study, it was observed that Na content did not significantly increase during the 2 years. However, TWW-irrigated soil had higher Na content in comparison with FW-irrigated soil. It is possible to say that, also in the short-term, the continuous use of TWW irrigation could increase the accumulation of Na in the topsoil. Consequently, periodic applications of good quality irrigation water seem necessary to avoid any risk to the soil structure and tomato plant.

Conclusions

In two-year tests, most chemical and microbiological parameters of wastewater were found to be highly compatible with Italian standards for irrigation reuse due to HSSFs CW performance. It was observed that treated wastewater obtained from constructed wetlands can be a source of water for the irrigation of tomato, especially in areas with prolonged water shortage. However, a continuous irrigation with treated wastewater could increase the level of sodium in the topsoil and be negative for soil productivity and plant growth. A careful management and periodic monitoring of soil fertility are, therefore, essential. Concerning tomato, in the short-term, treated wastewater irrigation determined an increase of total yield of fruits in comparison with freshwater irrigation. But additional disinfection techniques seem necessary in order to avoid any kind of health risk for humans due to high level of microbial contamination of fruits. Further research is, then, required to assess the effect of treated wastewater on plant and soil characteristics in the medium and long-term.

Abstract

The problem of water in Libya is caused by the increasing demand for fresh water. The groundwater supply is limited. The water supply will become more problematic with rapidly increasing population and low rainfall. After discovery of hug quantity of fresh groundwater in the deserts the south part of the country, the Libyan Government planned the Great Manmade River project. The Libya authorities designed and installed the hydraulic infrastructure needed to withdraw and transport this fossil water to various demand cites in the northern part of the country where most people live and majority of agriculture activities, Libya such as many Mediterranean countries, especially those in the south of the Mediterranean. facing by problem of the water because of population growth it is so high compare with north of Mediterranean countries. The problem of water – its quantity and quality as well – in the south is exacerbated further by the rapid growth of population, the competition among agriculture, industry and tourism sectors and the extension of irrigation and industrial development. Water scarcity a fundamental problem in Libya and most parts of the world Water shortage are often due to problems of uneven distribution and the management of existing Water supplies in Libya could be improved, Like most countries in the Middle East and North Africa, The Great Man-Mad River project was carried out to transport Fresh water from underground reservoirs in south Libya to more fertile and cultivable land where most people live, through a network of pipes that are buried at a depth of 7 meters under the ground, The pipe is 1.600 km long and its inner diameter is 4 meters, After the termination of all its network the pipes will be approximately 4.000 km long which make it the largest artificial irrigation network in the world The growth of Water demand has a marked impact on the water resources of Libya which suffered serious depletions and quality deterioration

Key worlds: *Mediterranean, Libya water problem, population growth.*

Introduction

Libya is a North Africa country on the south coast of the Mediterranean Sea with a coastline of about 1.900 Kilometers. Apart of Mediterranean Sea coast, Libya has frontiers with six Arabic and non-Arabic African countries, namely, Algeria and Tunisia in the west Egypt in the east, Sudan on the southeast, and Chad and Niger in the south. The country has a small population. The population was about 1.52. million inhabitants in 1954. It occupies a relatively large area of about 1,760,000 square kilometers. It is the fourth-largest country in Africa and seven times as large as Great Britain and Northern Ireland. Approximately 95 % of total land area in the country is desert, while 4 % is grassland suitable for grazing animals, and 1 % is forest (FAO 2012). The most important agricultural zones include Jabal al Akhdar and Jabal Nafusah, Jifara plain, Kufrah and the desert mountains to the south, Croplands cover only 355,000 ha of the total area, pasture and rangeland comprise approximately 13,300,000 ha, and forestlands encompass about

547,000 ha (Alldrissi et al., 1996). Approximately half of all crops are grown in Jabal al Akhdar, and the other half is grown in Jabal Nafusah, Kufrah, and the desert mountains to the south. with 90 % being less than 20 ha, 9 % between 20–100 ha, and 1% larger than 100 ha (Lariel, 2015). Farms that are larger than 100 ha are mostly owned by the government (Laytimi, 2005). Because of the arid conditions in the country, irrigation is becoming a common pursuit to supply water to crops

Fig (1) MAP of Libya Source: http://www.ewpnet.com/libya/river.htm

Libya Like Many countries in the World the Agriculture sector consumes about 80 % of the water, then comes Domestic water in the second level (27%) and Industry sector the last one (3%) , However majority of Libyan people looks the water as free item (DONOT PAY FOR USE WATER), especially Libyan farmers who consume about 80% of the water in Libya, especially after 2011 Arab Spring (Ehdadan_ 2018) .**Water resources in Libya conventional water resources Surface water** Libya's surface water resources are prone to drought in much the same way as in other countries across North Africa, the average annual rainfall for the years 1945–2010 in the eastern region was 350 mm, 254 mm in the western region, 168 mm in the central region; and 22 mm in the Sahara region (an average of 72 mm for north Sahara and 2 mm for south Sahara). Libya is one of the driest countries in the world. Temperatures are very high (Edwin & Ronny, 2005). **Groundwater** Libya depends heavily on grounder water, which accounts for more than 97% of water use (Omar, 2007). The demand for water has more than doubled between 1977 and 1994, thus intensifying pressure on this finite resource (Alghraiani, 2003). Libya has five principal regions with substantial water resources. They are Jifara plain and Jabal Nafusah region the Middle zone; Aljabal al akhdar region; Fezzan region and Kufrah and Assaris region. These regions constitute the transition between Jifarah plain in the west and Al Jabal Al Akhdar and Fezzan and Alharuj Aswad in the south. The current water use is around 400 million m3/yr. Described and illustrated the Groundwater in Libya as the main source of water supply in Libya's five basins; three of them in northern Libya, namely, Jifara plain, EL Jabal Al Akhdar, and EL Hamada, and two in southern Libya, namely, Murzuq and EL-Kufra-Serir **Non-conventional water resources** Due to the increasing demand for water, there is growing competition between the agricultural and industrial sectors for freshwater supplies. Therefore, wastewater has increasingly become the most predominant low cost and reliable alternative to conventional irrigation water in many countries, especially in the arid and semi-arid regions. Reuse of wastewater in urban and peri-urban agriculture is already a widespread practice in different parts of the world (Jiménez et al., 2010a, Winpenny, et al., 2010). It is estimated about 10% of the global population consumes foods grown with wastewater irrigation (WHO, 2006). The Libyan Government has responded to the issue of water scarcity predominately through utilizing fossil groundwater, with only a minor emphasis on integrating non-conventional water such as desalinated seawater, wastewater reuse and the GMMR into national water management. **Desalination** is the second of the non-conventional water resources adapted in Libya (Bashir, 2017). Many desalination plants of different sizes were built near large municipal centres and industrial complexes**. wastewater** According to data obtained from the General Company for water and wastewater (GCWW), there are around twenty-three wastewater treatment plants distributed all over the country. Only ten plants out the total number are working, and in operation, eight plants are out of service, and five plants are being maintained by the company's management teams. (Bashir, 2018) **Great Manmade River Project. (G M R P)** In 1959, oil was discovered in Libya by ESSO, USA company (Later renamed EXXON) and production and export of oil in commercial quantities began in 1961 (Wright, 1981; Vansewll, 1998), and as a result, the Libyan economic situation changed dramatically. The Libyan economy became primarily dependent on the revenues from the oil sector at the same time this America discovered hug of quantity of groundwater. In 1960s as oil exploration moved further south into the Libyan Desert in search of new oil fields, drilling rigs revealed the presence of immense underground water reserves. This discovery was an important trigger for the establishment of a major civil engineering project in the country, the so-called "Great Man-Made River Project". Moreover, the expanding economy led to a growing population along the fertile coastal strip, although the traditional water supplies in the region were inadequate for the needs of the growing population.

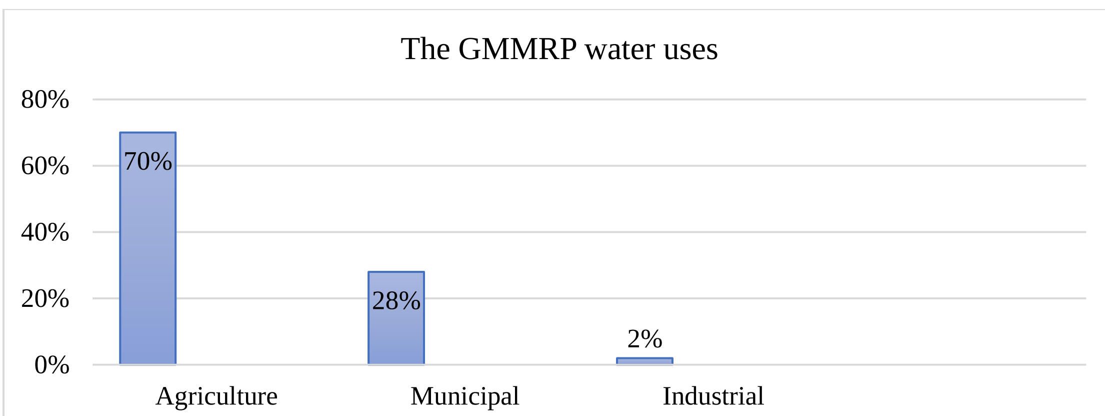

Figure (2) usage of water from the GMMRP. **SOURCE** The Impact of Great Man Made River Project On Libya Agriculture Activities and the Environment PhD Thesis ZIDAN, University of Technology Malaysia 2007.

This project has been divided into five phases.

Phase I of the project is to provide water for Benghazi, the second largest city of Libya. The plan started in 1990 and was completed in 1994. The system can supply 2.000.000 m^3 /day of the water to Benghazi.

Phase II of the project was finished in September 2000. It was the section for supplying 2.5 million tons of water every day to the main city of Tripoli.
Phase III will increase the water flow in Phase I system by 1,680,000 m^3 per day.
Phase IV will provide 1,000.000m^3 per day of water through a pipeline to Tobruk.
Phase V will connect Phases I and II and install two power stations to pump 1,000,000 m3/day of water, and links Phases I and II with a pipeline from Sirt to Tripoli

Material and Methods

The method adopted by the paper is to clarify the water problem in Libya **by knowing the water sources in this country**, which constitute groundwater the largest proportion of its water sources, as well as knowing the solutions undertaken by previous governments to confront this problem in countries where the desert constitutes 90% of its area. And give an overview of the man-made river project, which transports 6 million cubic meters of water per day to coastal areas such as Tripoli and Benghazi the biggest Cities in Libya, the /7/7need for water and the level of its consumption depends on the climate and lifestyle (Gleick, 1996). According to WWAP (2003) a person needs 20 to 50 litres of water every day. For the very basic needs, this quantity reduces to 1.8–5.0 litres per day (Gleick, 1996), and increases to 6–15 liters per day to preserve hygiene (washing the body to avoid contracting skin disease).

Table 1. Water requirement amounts for meeting basic human needs

Basic Human needs	Water requirement
Basic water consumption for survival	2–5
Basic sanitation	8–20
Bathing or showering	6–15
Cooking	4–10

*Source, Gleick, 1996, 1998; Wallace, 2000; WWAP, 2003

Results and Discussion

The demand for water in the country such as Libya 90% is desert it is so high because of the nature of this country, limited of the water resources groundwater share about 97% of the water resources in the country, Libya does not have a permanent river , very little rainfall occurs in north part on Libya 200-250 mm .in south part of Libya the average of rainfall is 2 mm such as Sabha and Murzuq The main reasons for increased desertification in Libya are low vegetation cover resulting from rising air temperatures, and decreasing precipitation . The demand for water has more than doubled between 1977 and 1994, thus intensifying pressure on this finite resource relatively high due to the warm climate. Demand also keeps increasing with time because of the high growth rate of the population. Since the surface water resources of many arid countries are limited, and the management of these sources are still incomplete, there is a growing need to fulfil some part of the demand from groundwater resources. Experience has shown that groundwater abstraction. Libya experiences scarcity of water due to its arid location (Pastel et al., 1996). During the journey to search for oil in the depths of the Libyan desert, underground water reservoirs were discovered, and from here came the idea of transporting water through pipelines for 4000 km to coastal cities such as Tripoli and Benghazi. Northern part of the country, majority of Libyan people looks the water as free item especially Libyan farmers who consume about 80% of the water in Libya, especially after 2011 Arab Spring

Conclusion and suggestions

Considering that there is increasing water demand and decline in water availability and/or reliability, Adoption of other economic tools or agricultural policies in addition to water pricing also will help increase optimization of water use for food production, which will promote effective use of water and reduce the water scarcity problem. These tools such as adoption of modern methods of irrigation, e.g., drip irrigation; planting drought-tolerant crops; reducing the use of chemical fertilizers that require large amounts of water to be useful; encouraging the trend towards organic farming that needs less water; altering the production methods; and using wastewater for supplemental irrigation will positively affect the water use in agriculture and help in developing and improving the existing water resources. On the other hand, the current findings of this study reveal that there are two factors which negatively affect the success of water pricing. These are water consumption and cost of water pumping. Moreover, there is the role of the government in successfully using water pricing as a policy to address the problem of water scarcity. And last but not least, the water price must be set by the authorities in Libya for agricultural, domestic and industrial water, and everyone must pay the value of the water he consumes.

DETERMINATION OF ORGANOCHLORINE PESTICIDES IN SURFACE WATER FROM TIMIȘ AND SIBIU COUNTIES IN ROMANIA

Mădălina Maria JURCOVAN*, Răzvan COTIANU, Mihaela PÎRVULESCU

"BIOTERRA" University of Bucharest, Romania
*Corresponding author: madalinajurcovan77@yahoo.com

Abstract

Organochlorine pesticides (OCPs) are continually detected in the environment due to their increasing applications in agriculture and industry. The presence of OCPs in the environment is not desirable since they are well known to have negative impact in humans, animals and birds. Thus, there has been a continual demand to monitor the presence of OCPs within the environment.
Surface waters play an important role in long range transport of pesticides. Organochlorine pesticides are most often found in the water sources due to their increased persistence in the external environment. In this study were determined some organochlorine pesticides in Târnava Mare River from Sibiu County and Bega River from Timiș County. For the analysis of OCPs was used gas chromatographic method with electron capture detection (GC-ECD) for separation and quantification. The results obtained were below the maximum concentration admitted by Law 458/2002 republished in 2017 (national law, 2017) regarding drinking water quality and according with the requirements of the Drinking Water Directive (Council Directive 98/83/EC/1998) intended for human consumption. The solution to reduce risk of pesticides use is ecological agriculture, which gains increasingly more ground in Romania too.

Keywords: *organochlorine pesticides, surface waters, agriculture, ecological.*

Introduction

Global chemical pollution has become a matter of great concern with the increase in public awareness of environmental problems. Among a large number of man-made chemicals, greater attention has been focused on semi-volatile and persistent organochlorines, such as DDT, HCH, Heptachlor, Aldrin, and their metabolites or degradation products, on account of their high bioaccumulation potential and harmful biological effects. Organochlorine pesticides (OCPs) are among the most widespread and persistent environmental pollutants. They are toxic, highly resistant to degradation and they tend to bioaccumulate through the food chain. (Derouiche *et al.*, 2007) Humans and animals exposed to OCPs can develop various health problems including cancer, genetic variation, diseases of the immune system, reproductive toxicity (Wang *et al.*, 2009), being also potential endocrine disruptors (Zhang *et al.*, 2012). Nowadays, these compounds are forbidden around the world, but due to their physicochemical properties they can still be found at trace levels in the environment (Yuan *et al.*, 2013). Aqueous media can be a suitable compartment to study any type of contamination within a specified geographic area because of its ubiquity and peculiar physical-chemical properties. Monitoring the trace levels of organochlorine pesticides in water is important for human health protection and environmental control (Lu *et al.*, 2011).
The purpose of this study is the drinking water quality assessment, in terms of contamination with organochlorine pesticides in Timiș and Sibiu counties. The concentrations of some OCPs

were determined in surface water samples collected from Bega River (Timiș County) and Târnava Mare River (Sibiu County), using a combined extraction method followed by gas chromatography coupled with electron capture detector (GC-ECD). The study was carried out in different seasons in order to generate a representative database, which can improve our knowledge about the contamination status in these water systems. The study targets the assessment of organochlorine pesticide residues in water bodies of agriculture intensive areas and comparison of these residues in surface water. These measurements can be used as baseline levels to monitor the future changes and to predict their future impact on the population of the area.

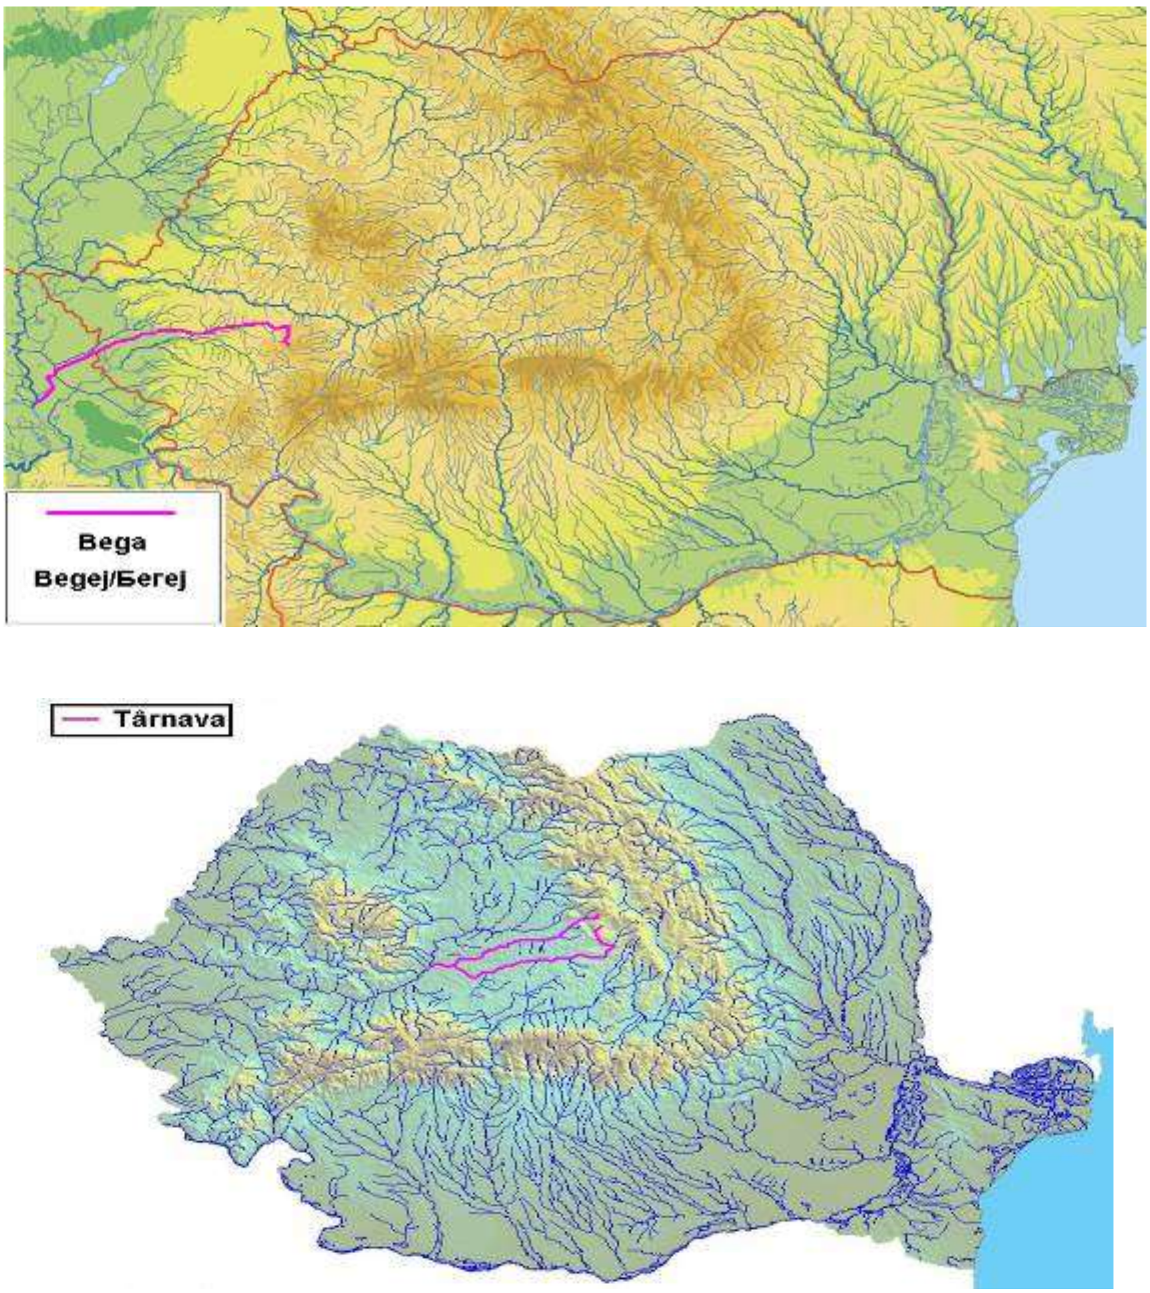

Figure 1. Map of the sampling locations

Materials and methods

Solvents were gas chromatography grade (Merck, Darmstadt, Germany). Mix standard solution 10 μg/ml for each component from LGC Standards, Germany. Ultrapure water was prepared using a Milli-Q water purification system from Millipore (Bedford, MA, USA). The instrumentation used consists in an Agilent Technologies 6890N gas chromatograph (GC) with electron-capture detector (μ-ECD). The schematic diagram of gas chromatography is presented in figure 2. Preparation and bringing to working conditions of the gas chromatograph and column are performed according to the instructions manual for the device.

Water sampling is a very important step in the process of pesticides determination, because collected samples must be representative and must not cause changes in the water composition and quality due to defective techniques or improper conditions of material preparation. Before sampling, the polyethylene recipients are prepared to be clean, rinsed with distilled water, dried and rinsed with dichloromethane, then dried again. Drinking water samples were collected and transported in insulated packages at 6 – 10 ºC to protect them against changes of their chemical properties and deterioration.

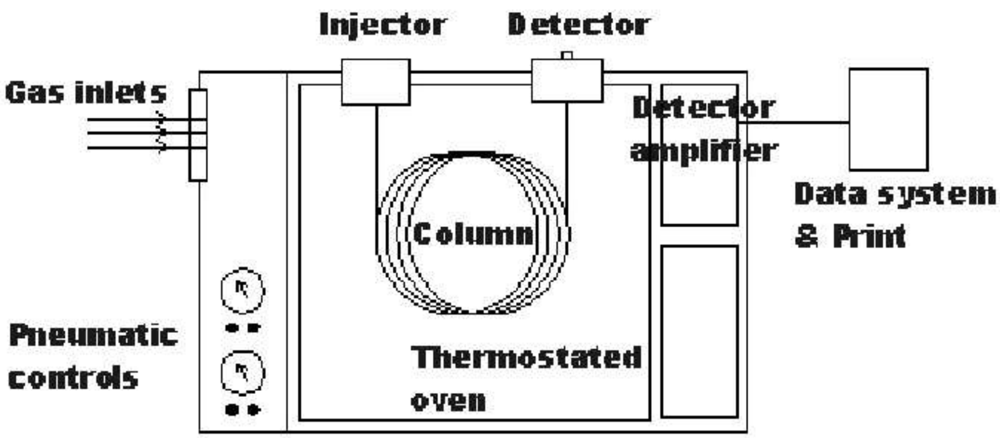

Figure 2. Schematic diagram of gas chromatography

Results and Discussions

Calibration of the method used was performed using external standard calibration curve with different concentration levels of OCPs, spiked in n-hexane (10 ml) using the same procedure for SPME extraction and chromatographic determination, starting with solvent conversion. The working standard solutions were prepared by diluting accurate volumes of mix standard solution of OCPs in n-hexane. The method linearity was studied in the range 0.0010 - 50 μg/l, and the correlation coefficients were higher than 0.985 for all the investigated compounds.

The blank test was performed using 2 l ultrapure water passed through the entire procedure. The detection limits of the entire method varied between 0.0050 ng/l and 0.150 ng/l. Because the analytes are concentrated on the cartridge and fiber, and then are rapidly delivered to the column, minimum detection limits are achieved. The accuracy of the method was determined in terms of recovery experiments by extracting the OCPs from spiked water samples, prepared by adding adequate volumes of mix standard solution to 2 l of blank matrix. The precision, expressed as the repeatability (% RSD) was determined by three consecutive extractions of

OCPs from spiked water samples. The values obtained for recovery and for RSD ranged between 36.5 - 112.2 % and 6.7 - 20.4 %, respectively.
The surface water samples were collected from the two rivers in 2 l pre-cleaned brown glass bottles with glass stoppers.
Upon arrival at the laboratory the samples were filtered through 0.45 μm filter membranes and preserved at 4 °C prior to analysis.
The samples were subjected to the SPE, HS-SPME extractions and then to the GC-ECD analyses, respecting the conditions described in the instructions manual for the device. Fiber blanks were measured before each sample to check the carry-over effect. The results of OCPs concentrations in the studied surface water samples are shown in Table 1.
The results shows that drinking water from the rivers of the two counties (Timiș and Sibiu) have an appropriate quality for the indicator of total organochlorine pesticides, well below the maximum admitted concentration according to National Law 458/2002 (national law, 2017) regarding drinking water quality. This law which regulates drinking water quality in Romania, transposes Directive 98/83/EC on drinking water.
The following organochlorine pesticides were analyzed in the water samples: α – HCH, β – HCH, δ – HCH, γ – HCH, Heptachlor, Aldrin, Heptachlor epoxide, 4,4' – DDE, Dieldrin, Endrin,
β – Endosulfan, 4,4' – DDD, Endosulfan sulphate, 4,4' – DDT.
Hexachlorocyclohexane is a cyclic saturated chlorinated compound that persists in the environment and has eight possible isomers. Despite being a banned toxic substance in most countries, HCH is regularly detected in the aquatic environment.455Only four isomers were of the most commercial importance (α-HCH, β-HCH, δ-HCH and γ-HCH). The latter isomer, gamma-hexachlorocyclohexane (γ-HCH) was a purified form which was widely utilized as a pesticide, due to its potent insecticidal properties. Consequently, when an HCH containing pesticide product contained more than 99% γ-HCH, the substance was termed as lindane.
Heptachlor is applied as a soil treatment, as a seed treatment (maize, small grains and sorghum) or directly to foliage. It is used to control ants, cutworms, maggots, termites, thrips, weevils, wireworms and many other insect pests in both cultivated and uncultivated soils. Heptachlor also controls household insects and pests of humans and domestic animals. In many countries, heptachlor is banned or applied only by subsurface injection. Heptachlor epoxide is not commercially available but is an oxidation product of heptachlor.
Endosulfan is an insecticide still in widespread use in many countries, on crops like cotton, soy, coffee, tea and vegetables, but also banned in 55 countries because of high toxicity to humans and nearly all other organisms, and its persistence in the environment. The principal metabolite is endosulfan sulphate and is regarded as being equally toxic and of increased persistence in comparison with the parent isomers.
Aldrin is a pesticide used to control soil insects such as termites, corn rootworm, wireworms, rice water weevil, and grasshoppers. It has been widely used to protect crops such as corn and potatoes, and has been effective to protect wooden structures from termites. Aldrin is readily metabolized to dieldrin by both plants and animals.
Endrin is a foliar insecticide used mainly on field crops such as cotton and grains. It has also been used as a rodenticide to control mice and voles. It is rapidly metabolized by animals and does not accumulate in fat to the same extent as other compounds with similar structures. It can enter the atmosphere by volatilization and can contaminate surface water from soil run-off. (Lu *et al.*, 2011)

In the European Union (EU), the maximum admissible concentrations (MACs) of OCPs in both the environment and drinking water are 0.1 µg/l for a single compound and 0.5 µg/l for the total concentration of all OCPs (Zhang *et al.*, 2012).

Conclusions

Unprecedented benefits have been obtained using pesticides in controlling disease causing organisms and insects, weeds, and other pests. The mechanism of action that makes them efficient also makes them hazardous to human, animals and environment. It is therefore important to understand associated risks and to limit use of pesticides to minimize possible damage to human health and environment.

The authorities should educate farmers and the public regarding the safe use and handling of pesticides. Lastly, the public should minimize the level of exposure to pesticide residues in food-by-food processing techniques such as washing, peeling, canning, cooking, etc.

The content of pesticides in the water samples analyzed from the two research areas was below the detectable level of < 0.001 µg/l. According to the results obtained in this study, the drinking water quality obtained from the two rivers from Timiș and Sibiu counties does not represent a risk factor for the population health in terms of exposure to organochlorine pesticides.

Good results were achieved and the method used in this study was validated with certified reference materials of OCPs in drinking water.

Abstract

Understanding of composition and connections between the building macromolecules of plant biomass, such as cellulose, hemicellulose and lignin, is main key for their better utilization in biofuels industry. We compared four different plant species which are abundant in the region of the Western Balkans. We investigated the structure of the cell walls, as the main constituent of plant biomass, isolated from branches of softwood (*Picea omorika* (Pancic) Purkine), hardwood (*Acer platanoides L.*), maize stem (*Zea mays L.*) as examples of crop species, and *Paulownia tomentosa* tree as a fast-growing species with a huge biomass yield. For our investigation, we combined Fluorescence-detected linear dichroism (FDLD) method and X-ray Diffraction. We obtained data for anisotropy and crystallography which are a base for prediction of the best and appropriate plant species for easy deconstruction of its biomass. Our results show that Acer branch as a hardwood shows the highest anisotropy and the lowest crystallinity compared to the other species while *Picea Omorika* needles show opposite results as the lowest anisotropy and the higher crystallinity. The results for maize show that the stems are easier for utilization than leaves. The isolated cell walls from leaves of *Paulownia tomentosa* show similar results and good correlation between anisotropy and crystallinity, thus we can conclude that this plant is easy to use in biofuel industries.

Keywords: *cell wall, biofuels, anisotropy, crystallinity.*

Introduction

Plant cell walls are the most abundant renewable and biodegradable composite material on the Earth. The secondary cell walls are rich in biopolymers such as cellulose, hemicellulose and lignin, which are of great importance in the biofuel industry.
The chemical composition and interconnection of the polymers in plant cell walls vary between different plant species and directly affects their application and accessibility for use (Pauly and Keegstra, 2008; Ragauskas et al., 2006). Cellulose consists of linear chains of glucose units linked by β-1,4-glycosidic bonds and is the most abundant component in plant cell walls. A large amount of hydroxyl groups in cellulose is involved in complex intra- and inter-molecular hydrogen bonds and so directly form high-order (crystalline) or low-order (amorphous) regions (Kondo, 2004; Wang, 2008). Amorphous regions in cellulose interact with hemicellulose chains (Atalla et al., 1993; Cosgrove, 2005). Hydroxyl group distribution of the cellulose surface affects a hydrophilic character of this molecule (Perez and Mazeau, 2005). Different hemicelluloses interact with cellulose and lignin, and the strength of the structure depends on this interaction

(Atalla et al., 1993; Barakat et al., 2007; Rueland Joseleau, 2005; Scheller and Ulvskov, 2010). Lignin is the second most abundant polymer on the Earth. It has a complex polymer structure composed of polyphenolic units (coniferyl, syringyl, coumaryl). Each plant species has a specific lignin composition. Trees like softwood and hardwood have lignin content from 30% to 34%, the higher content being in the softwood species. Lignin in herbaceous species is rich in syringil units. Lignin is a major source of large-scale biomass utility.

In our study, we compared the structure of four different plant species: spruce wood (*Picea omorika (Pančić) Purkine*) as an example of softwood, maple wood (*Acer platanoides L.*) and *Paulownia tomentosa* wood as a hardwood species, and maize stems (*Zea mays* L.) as a herbaceous plant and widely used agricultural plant.

In this investigation we measured Fluorescence-detected linear dichroism (FDLD) of cellulose labeled with Congo Red by using differential polarization laser scanning microscope (DP-LSM), which provides information of structural order of cellulose fibers. We also measured cellulose crystallinity in the isolated cell walls from branches and leaves by X-ray diffraction (XRD) method. These two methods have not been combined before for structural characterization of biomass. Thus cell wall structural characteristics and polymer interactions were monitored through structural order of cellulose fibers.

Materials and methods

Plant material: Four different plant species were used. The cell walls were isolated from branches of spruce (*Picea omorika* (Pančić) *Purkyne*, Gymnospermae, conifer), maple (*Acer platanoides L.*, Angiospermae, Dicotyledones, deciduous species), *Paulownia tomentosa* wood, and from maize stems (*Zea mays L.*, Angiospermae, Monocotyledones, grass family).

Isolation of plant cell walls: The extractive-free cell wall material was obtained from the spruce, maple, paulownia and maize. Plant material (1g) was homogenized in 10 mL of 80 % methanol in 50-mL Big Clean tubes filled with a stainless steel matrix for 45 s at a speed of 4.5 m/s, using a FastPrep-24 apparatus (MP Biomedicals, Santa Ana, CA, USA). After stirring for 5 min at room temperature, the sample was again subjected to FastPrep homogenization at the same speed. Such obtained plant material was dried for 72 h at 80 C. Dry homogenates of plant material were ground into a fine powder. To obtain cell walls, 400 mg of powder was homogenized for 5–10 min in 10 mL 80 % methanol. The homogenate was slightly stirred for 1 h at room temperature and centrifuged for 5 min at 1500 x g. Further, the resulting precipitate was extracted twice with 10 mL 80 % methanol. The precipitate was subjected to the following washing steps, according to Strack et al. (1988) and Chen et al. (2000):1 x (1 M NaCl, 0.5 % Triton X-100), 2 x distilled water, 2 x 100 % methanol, 2 x 100 % acetone (each step in 20 mL, 30 min). In each washing step, the sample was homogenized in 20 mL of corresponding solvent and then subsequently stirred for 10 min at room temperature and then centrifuged at 1500 x g for 10 min. The supernatant was subsequently removed. A FastPrep-24 System (MP Biomedicals, Santa Ana, CA, USA) was used in each isolation step for more efficient extraction of the cell wall material. The FastPrep-24 instruments and matrix tubes provide rapid and thorough, automated disruption of plant cell walls, which are difficult to homogenize/lyse.

The X-ray measurements of dry isolated cell walls were carried out by Siemens D-500 powder diffractometer. CuKa radiation was used in conjunction with a CuKb nickel filter. Measurements were repeated for each type of sample (species), and representative diffractograms were shown. The percentage crystallinity of the samples was calculated from the ratio of the area under the

diffraction peaks to the total area under the whole diffraction pattern (Georget et al., 1999; Hermans and Weidinger, 1948). Amorphous background patterns were generated, fitted to and subtracted from each diffraction pattern by using OriginPro 7.5.
In the DP-LSM method, the confocal fluorescence intensity images were recorded on a Zeiss LSM 410 laser scanning microscope (Carl Zeiss Jena, Jena, Germany) equipped with a differential polarization (DP) attachment (Garab et al., 2005; Steinbach et al., 2009). Briefly, the DP attachment modulates the polarization state of the excitation laser beam at 100 kHz between horizontally and vertically linear polarization, using a photoelastic modulator (PEM-90, Hinds Instruments). The FDLD signal, proportional to the fluorescence intensity difference, elicited by two orthogonally plane-polarized beams, was obtained from the demodulation circuit, and images were recorded on the LSM. Using the runtime calculation, the FDLD imaging needs only a single scan and it avoids all the artifacts from the multiple scans (such as sample and light intensity stability, bleaching). The provided pixel values are the average of more than ten cycles of modulation. The images were in resolution of 512 x 512 dots, covering the area of 50 x 50 and 64 x 64 lm. Each image consists of two channels: FDLD channel and fluorescence emission channel. FDLD values for dipoles oriented along the Y axis correspond to 1, while the values of dipoles oriented along the X axis correspond to -1. The samples of isolated cell walls were stained with freshly prepared 2 % (w/v) solution of Congo Red (Merck, Darmstadt, Germany) for 30 min, followed by rinsing in distilled water three times. Congo Red has earlier been used to determine the mean cellulose fibril orientation in plants (Verbelen and Kerstens, 2000). The samples (isolated cell wall fibrillar fragments) stained with Congo Red were excited at 488 nm, and fluorescence emission was observed above 560 nm.

Results and Discussion

Cellulose crystallinity in the samples was followed by X-ray diffraction. Based on the data obtained from the diffraction patterns of the cell wall samples for acer, spruce, Paulownia and maize, by Nara & Komiya (1983); it is obvious that there is a difference in the overall crystallinity of the samples. Table 1 shows that crystallinity is nearly the same (42 %) in the cell walls of softwood and harwood species. Crystallinity of the cell wall of maize is much higher (58 %). The peaks obtained from the diffractograms are typical for cellulose I and are located at $2\Theta \approx 14.9^o$, 16.49^o, 22.84^o (Marchessault and Sundararajan 1983). The peak at $2\Theta \approx 23^o$ generally is described as "highly crystalline" region of cellulose, while a broad peak at $2\Theta \approx 16^o$ is characteristic of the less organized polysaccharide structure (graphs not shown) (Fig. 3). The crystallinity of maize is significantly higher because it contains a lower proportion of lignin compared to woody species, which results in a better packaging and a more ordered distribution of cellulose microfibrils. A percentage of crystallinity of approximately 42% was found in all trees, which corresponds to that calculated by Hulleman et al. (1994) for cellulose in cotton and wood of 40 - 48%.

Table 1. Calculated crystallinity of cellulose for the samples of four plant species

Acer branch %	42.39
Picea branch %	42.08
Maize stem %	57.80
Paulownia branch %	41.84

The FDLD observed by DP-LSM imaging is a suitable tool for mapping of the optical anisotropy of cellulose (marked by Congo red) in the cell wall, that corresponds to the cell wall linear dichroism (Steinbach et al., 2008). The anisotropy of each sample was calculated from the images by Image J program. Results are shown in Fig. 1. High anisotropy was obtained for maple branch, Paulownia wood and maize stems. We found a lower anisotropy for Picea branch. One can assume that high anisotropy indicates a simpler structure and more regular packing of cellulose molecules in hardwood species than in the softwood species.

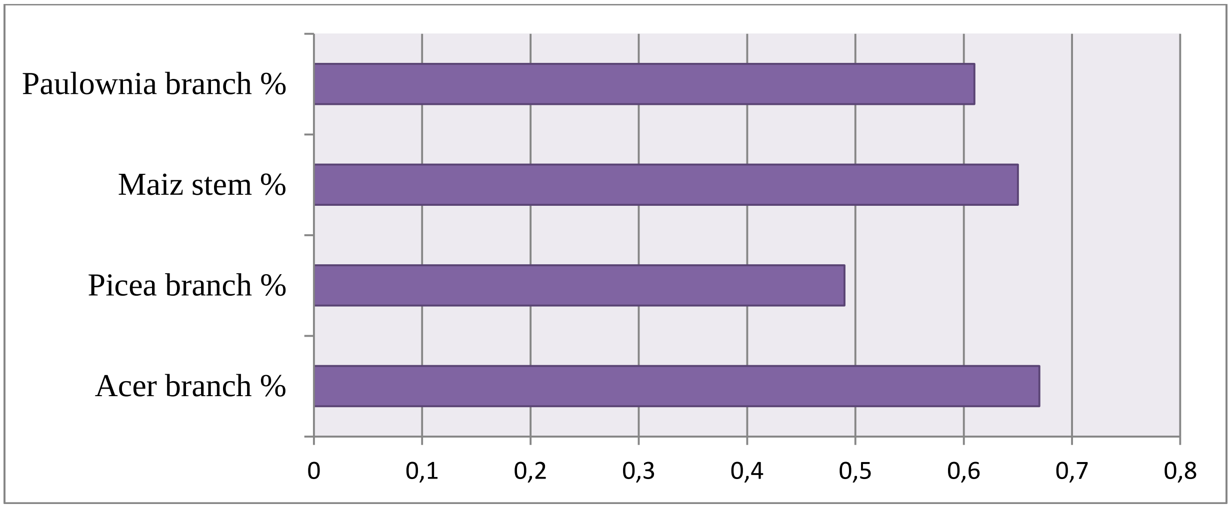

Figure 1. Anisotropy data of the cell walls isolated from the Acer branch, the spruce branch and maize stem calculated from DPLS images

Conclusions

All four different plant species have different chemical compositions and different interactions between the building macromolecules. Through microscopic visualization and X-ray diffraction, we obtained data for anisotropy and crystallography which are a base for prediction of the best and appropriate plant species for easy deconstruction of its biomass structure. Our results show that Acer branch as hardwood shows the highest anisotropy and the lowest crystallinity compared to the other species while spruce needles show opposite results as the lowest anisotropy and the highest crystallinity. The results for maize show that the stems are easy for utilization. The isolated cell walls from *Paulownia tomentosa* show similar results and good correlation between anisotropy and crystallinity, thus one can conclude that plants such as maize and hardwood species, especially Paulownia tree, may be suitable to use in biofuel industries.

Abstract

Soil is one of the most important resources of each state. The research in this study was conducted in order to preserve this very important resource. Humic substances have a positive effect of water-air maintenance and total biological properties of the soil which have a direct impact on plant nutrition and and in the first place on the nutrition of plants with nitrogen.
Humus content is the basic parameter of soil fertility. The paper analyzes humus content of 21 localities in central Serbia. Total is examined 5.313 samples. Results on humus content indicate that there are soils from insufficiently humus to extremely humus. In 92% of the examined soil samples are weak and medium humus, 7% of the soil is very humus a only 1% insufficiently humus. The obtained results can be related to the natural properties of soil types on the examined plots, but also to the way of applying fertilizers on them. Natural climatic processes and the impact of anthropogenic influence, man continuously affect changes in soil quality. All plots are mapped and based on the obtained results recommendations are given agricultural producers on repair measures and application of organic and mineral fertilizers.

Key words: *Soil, conservation of resources, humus content, repair measures, mapping.*

Introduction

Land is one of the most important natural resources of any country. As the basic means of agricultural production, its economic importance is determined by fertility, which is the ability of the soil to provide plants with the necessary nutrients, water, air, heat and other factors during the vegetation period. In order to achieve high and stable yields and increase the quality of fruits in crop, vegetable and fruit production, it is important to know both the characteristics of the soil and the requirements of cultivated plants. Knowledge of these parameters enables the correct application of agrotechnical and ameliorative measures (Janković et al., 2020).
Mapping the fertility of agricultural land with digital sampling records and software platform for recommendations-tips on fertilizer use, represents the application of science for soil conservation of the Republic of Serbia and reducing the negative effects of uncontrolled fertilizer application with digital soil sampling records and electronic database of chemical analyzes and recommendations to farmers use of fertilizers (Janković et al., 2021). Humus is a guarantee of soil fertility, it is formed in the process of decomposition of soil organic matter by microbiological means. The content of humus in the soil is conditioned by the type of soil because different types of soil and processes in them determine the degree of decomposition of organic matter and conversion into humic compounds. The humus content in the soils is different and therefore the soils are divided into: insufficiently humus 1% humus, poorly humus 1-3%

humus, medium humus 3-5% humus, highly humus 5-10% humus, extremely humus 10 and more% humus (according to Kotzman).

Mineralization of humus releases plant nutrients in an accessible form and a significant amount of energy important for soil processes. Previous research has shown that humus has several times higher absorption capacity than mineral colloids. Humus particles have an electric charge on the surface, which has an attractive force towards the subject (aqueous solutions of soil minerals and compost decomposition products) due to the opposite charge. The solution on the surface of humus particles, which binds the cohesive force of the electric charge, does not leach into the lower layers of the soil, but remains in the root zone of plants (Popović, 2002; Aziz 2009; Gajić, 2006; Dugalić and Gajić, 2012; BIO IS, 2014;).

Cultivation and uptake of organic constituents affect many soil characteristics including its humus as one of the most sensitive properties, as well as group and fractional composition. Changes in the content and group and fractional composition of humus affect the current pedogenetic processes and other soil characteristics (Molnar, 1997; 2001; Islam and Weil, 2000; Kastori et al., 2006; FAO, 2006; EC 2010; Cupać et al., 2007).

Agricultural advisory and professional services of Serbia have been working for many years on the control of soil fertility on the farms of agricultural producers and give them recommendations for proper fertilization and soil repair. This measure is important for: preservation of the land of the Republic of Serbia; environmental protection; reduction of negative effects of uncontrolled application of fertilizers; education of agricultural producers for proper use of fertilizers; development and planning of agricultural production on the principles of sustainable development. On the territory of Serbia, the representation of types of agricultural land ranges from very fertile (chernozem, grove, alluvium) without limiting factors in agricultural production to those of medium and low fertility (smonica, pseudogley, semigley) (Marschner et al., 2001; Fraga et al., 2014; Stevanović et al., 2016). The aim of this study was to determine the humus content at 21 sites in Serbia in order to ensure the proper use of mineral and organic fertilizers.

Materials and methods

Fertility control of arable agricultural land in central Serbia in 2020 and advising agricultural producers on the basis of control was carried out by the Agricultural Advisory and Expert Services of the Republic of Serbia in advisory work, to determine the level of nutrients in agricultural land, in order to ensure proper use of mineral and organic fertilizers. Chemical analysis of the samples was performed by accredited laboratories that have a certificate of laboratory accreditation issued by the Accreditation Body of Serbia in accordance with the requirements of the valid standard SRPS ISO / IEC 17025. Determination of humus in the laboratory was done according to Kotzman, volumetric method. Division of soils into categories according to humus content is shown in Table 1.

Table 1. Division of humus according to Kotzman, volumetric method

Humus content	% of humus
Insufficient humus	1
Low humus	1-3
Medium humus	3-5
High humus	5-10
Extremely humus	10 and more

The paper analyzes 21 localities in central Serbia by the Agricultural Advisory and Expert Services of Central Serbia. Based on the available data in the software platform for the needs of research in this study, the humus content in the Republic of Serbia was determined with the mapping of the examined plots. The average area of sampled plots by PSSS and municipalities was 0,63 ha and the maximum was 1,58 ha, which clearly indicates the fragmentation of plots in central Serbia. For the research in this paper, for each of the 21 localities, 253 samples were used, which were distributed by categories from insufficiently humus to extremely humus soil. The total number of soil samples on which the research was conducted was 5.313.

Field research included soil sampling, which was performed using an Android application on a mobile phone with automatic recording of GPS coordinates. The sampling procedure was performed in the field according to a unique methodology with the accompanying necessary documentation in accordance with the standards. Data were used from the software platform, with data on sampler, number and area of cadastral parcel, cadastral municipality and land class, sampling depth, GPS sampling coordinates, crop, test results, planned yield, recommended amounts of pure nutrients, lime material, minerals and organic fertilizers, recommendations-tips for fertilization and land repairs for field, vegetable and fruit crops for a particular agricultural producer and PSSS. Laboratory tests included analysis of the basic chemical properties of agricultural soil: acidity, carbonate content, humus content, total nitrogen, and readily available forms of phosphorus and potassium. Fertility control of agricultural land was done with digital sampling records and a software platform for given recommendations-tips on the use of fertilizers.

The results of the performed research are presented on the basis of mathematical-statistical methods and procedures that were applied for the processing of the original data and for the analysis and evaluation of the obtained and arranged results. This approach includes all applied research methods in laboratory conditions and field materials. In relation to the methods of experimental research, the presentation of the results is of an analytical nature. This enables a more detailed and complete presentation of all achieved research results. The results of the research performed in this paper are presented in a table according to the applied processing of the original data. The results of the research are grouped and presented as follows: Number of samples by categories and average values by categories.

Data analysis. All data for evaluation were presented in average. Excel 2013 software was applied to create the database and figure.The percentage of humus content in soil was tested using multiple regression models.

Results and Discussion

Table 2 and Figure 1 shows the number of samples by categories of humus content for 21 examined localities, as well as the cumulative and percentage share of each category for all examined localities.

Out of a total of 5.313 samples examined for all examined localities, there were: insufficiently humus 52, weakly humus 2.403, medium humus 2.481, highly humus 360, extremely highly humus 17 samples.

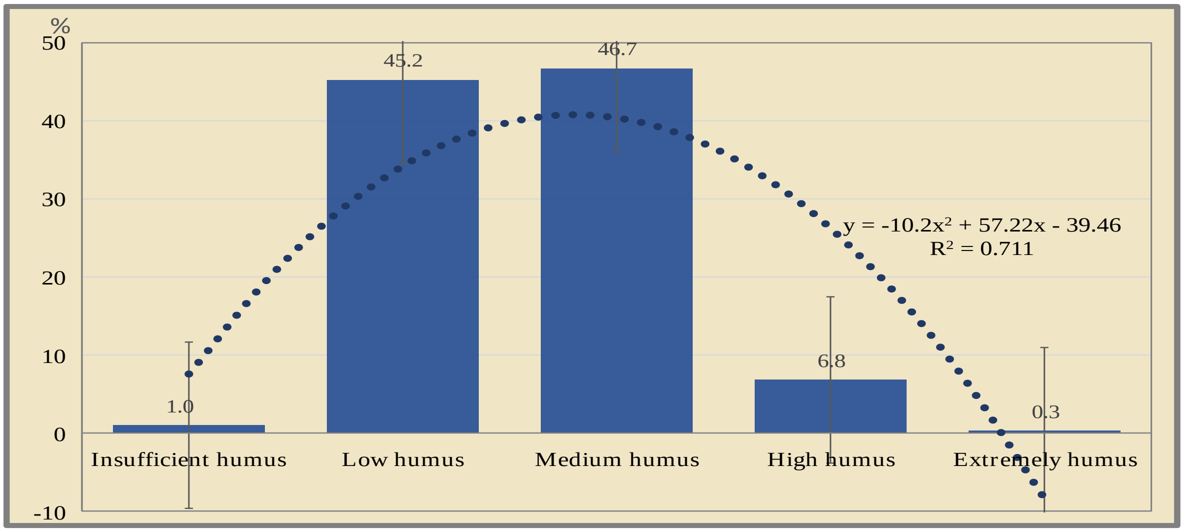

Figure 1. Percentage share of each category humus content in examined soil

The percentage share of samples by categories for all examined localities was: insufficient humus 1%, low humus 45.2%, medium humus 46.7%, high humus 6.8%, extremely humus 0.3% of samples. The most represented samples were in the category of medium humus 2.481, ie. 46.7%. In the category of extremely humus, there were at least 17 samples, that is 0.3%.

Table 3 shows the average values of humus content by categories for each individually examined locality, as well as the average values for all localities by categories. Observed for all localities, the lowest average value in humus content of 2.41% was recorded for the locality PSSS Smederevo. Observed for all localities, the highest average value in humus content of 4.84% was recorded for the PSSS Uzice locality.
Observed by categories, the average values of humus content were as follows: insufficient humus 0.58%, low humus 2.33%, medium humus 3.72%, strong humus 6.02%, extremely humus 12.50%.

In accordance with our research are the results of Sekulić et al. (2010) where the authors state that it is an analysis of over 77,000 samples of plowland in AP Vojvodina indicated that 39% of the samples belong to the category of low humus soils with the organic matter content ranging from 1% to 3%. The category of soils well provided with humus (3% to 5%) included 60% of the analyzed plowland of Vojvodina. Organic matter content in Vojvodina soils is under strong anthropogenic influence, and it is not advisable to remove harvest residues and use them as biomass without prior soil analysis.

Conclusion

The content of humus in the soil is conditioned by the type of soil because different types of soil and processes in them determine the degree of decomposition of organic matter and conversion into humic compounds.

The most represented samples were in the category of medium humus 2,481, ie. 46.7%. In the category of extremely humus, there were at least 17 samples, ie. 0.3%.

Observed for all localities, the lowest average value in the humus content of 2.41% was recorded for the PSSS Smederevo locality. Observed by categories, the average values of humus content were as follows: insufficient humus 0.58%, low humus 2.33%, medium humus 3.72%, strong humus 6.02%, extremely humus 12.50%.

Observed for all localities, the highest average value in humus content of 4.84% was recorded for the PSSS Uzice locality.

Abstract

Cities play an enormous role in societies and daily human lives. Around 68% of the world population is projected to live in urban areas by 2050. Rapid urbanization has separated human beings from nature exposure, and one way of bringing nature back and integrating it into urban infrastructures is the careful planning and management of urban green resources (e.g. urban gardens, parks, woodlands, etc.). The overall goal of this study was to examine urban greenery research focus and trends using bibliometric methods. A search was conducted using Scopus to identify English language papers on urban greenery published in peer-reviewed journals between 2010 and 2020. In order to identify themes focuses, content analysis was conducted to analyze the keywords, specifically the frequency of occurrence of the articles' keywords. Overall, 7045 publications related to urban greenery research were obtained as the data for this study, where more than 60% of all papers published, fall into the category of environmental science. Evaluation of the keywords used in papers published over the last decade shows that the tendencies of the body of literature related to this topic are mostly oriented towards land use planning. Observed publication trends and publication characteristics, as well as disciplinary contributions, are further discussed.

Key words: *urban greenspace, key word, Scopus, article.*

Introduction

Spending time in natural environments has been found to promote human health and well-being. Particularly important are contacts with nature in urban surroundings, where providing natural green elements is of the utmost importance. According to UN report (2019), 55% of the world's population is currently living in urban areas, and if we look at the projected data, the percentage goes even higher, as 70% of the world population is projected to live in urban areas by 2050. As urban areas expand, understanding what benefits urban greenery brings to overall biodiversity and society has become increasingly important. Biodiversity is of the utmost importance in human-managed ecosystems. Urban cities comprise a range of habitat types with different kind of anthropogenic pressure, and such variability affects species composition (Lepczyk et al., 2017), where cities often contain more threatened species per unit area than non-urban areas (Ives, 2016). Urban greenery was found to contribute also to the indoor environment via the influence on the climate, energy use, air quality, sonic environment as well as aesthetic quality (Wang et al., 2014), playing an important role in urban planning and design.
Many studies have already reported a positive relationships between urban natural elements and human health and well-being (Groenewegen et al., 2006; Gopal and Nagendra, 2014; Wang et al., 2019), where researchers even tried to quantify the ideal amount of time spent outside in natural environments (120mins per week) to boost overall health (White et al., 2019)

As urban green spaces supply different social and environmental ecosystem services that benefit local people (Kabisch et al., 2015), scientists in the various fields focus on these important parts of the urban environment, particularly those coming from urban planning, environmental management and public health. In this study, we aim to analyze the research on urban greenery (based on the online database) over the last 10 years. Specifically, the objective is to discuss publication trends and describe publication characteristics, as well as disciplinary contributions.

Materials and methods

In order to establish the number of published papers in urban greenery related topics, we used Scopus database. This database has a broad coverage and many authors have confirmed the advantages of using Scopus to implement a bibliometric analysis (Montoya et al., 2018; Giraldo et al., 2019). The search terms for the data were set as " urban greener* OR urban park* OR urban woodland* OR urban forest OR urban green element* OR urban green space* OR urban tree* OR urban green area*. The terms were searched within the "article title, abstract, keywords" option and the results were refined by year (2010–2020). We limited our search to English language only, as it is considered to be the most widely used language in scientific publications. Data collection was conducted on May 17, 2021. We limited our search only to articles, and we excluded other document types.

Scientific production over the given time frame was analyzed both by absolute and relative number of papers extracted from the database, bearing in mind scientific production in general is constantly expanding from year to year, with growth rates from less than 1% up to the middle of the 18th century, to 8 - 9% to 2012 (Bornmann and Mutz, 2015). To get the relative values, we divided the number of papers per year (with our combination of search terms) by the total number of published papers per year. In order to analyze keywords used by the authors, we firstly calculated the frequency of occurrence of the articles' keywords, and then ranked them.

Results and Discussion

Overall, 7045 publications related to urban greenery research were obtained as the data for this study. Scientific output on urban greenery is growing, as shown by the relative number of papers in each year (published from 2010 to 2020) where the trend line clearly demonstrates an upward trend (Fig. 1).

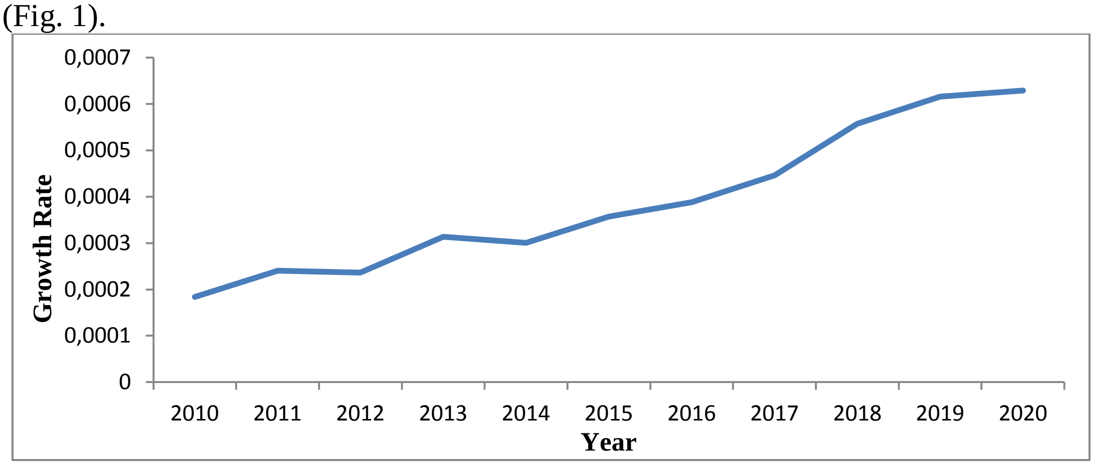

Figure 1. Relative growth rate of scientific production on urban greenery (the number of papers on urban green research divided by the total number of published papers per year).

More than 60% of all papers published, fall into the category of environmental science (Table 1). However, this is a very broad category, so looking more closely at specific journals in which the papers were published can offer a better understanding of disciplinary contributions when it comes to urban greenery research.

Table 1. Number and percentage of papers broken down by SCOPUS subject categories (decreasingly ordered by the number of papers). Only the top 10 Scopus subject categories are shown.

Subject area	Number of papers (%)
Environmental Science	4405 (62.5)
Social Sciences	2251(32.0)
Agricultural and Biological Sciences	1687(23.9)
Engineering	946(13.4)
Energy	745 (10.6)
Earth and Planetary Sciences	714 (10.1)
Medicine	532 (7.6)
Business, Management and Accounting	303(4.3)
Biochemistry, Genetics and Molecular Biology	287(4.1)
Computer Science	210(3.0)

All retrieved papers were published in a wide range of 160 different scientific journals (Fig. 2). The top 3 most active journals are *Urban Forestry And Urban Greening*, *Sustainability* and *Landscape And Urban Planning*.

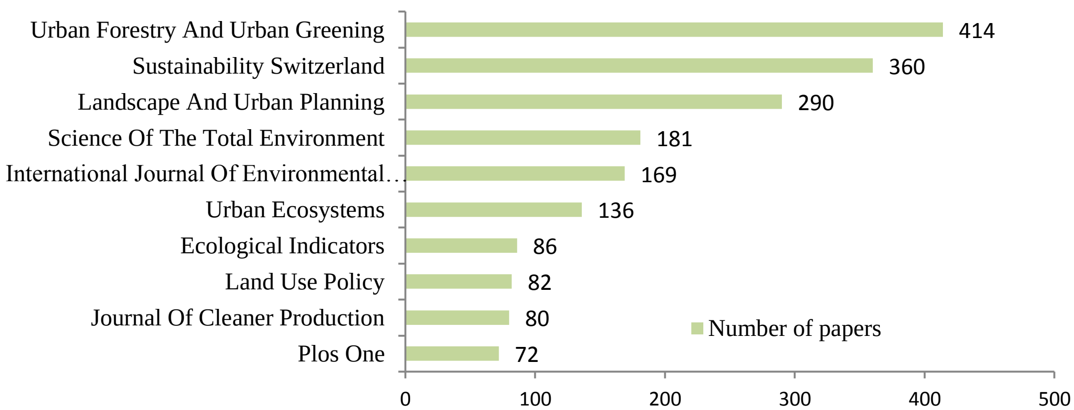

Figure 2. Number of papers published in different journals over the last decade

The most cited article on urban greenery was published by the Solar Energy journal in 2014 and it is focused on green roof mitigation technologies to fight heat island and improve comfort in urban environments. Next two highly cited papers are also related to ecosystem services important for urban planning and economic-decision making, published in Ecological Economic and Science, respectively. Bearing in mind that academic impact is frequently measured through citation counts (Tennant et al., 2016), findings show that research on regulating ecosystem services provided by urban greenery currently has the strongest impact. This is in accordance with the recent bibliometric analysis regrading global research of greenery systems carried by Chàfer et al. (2021), which revealed that green roofs is the main topic studied over the 1974–2019 period, as a result of increased awareness of environmental issues. Interestingly, almost

40% of papers are open access papers. Taking into account that open access papers often get easier into societal discussion, such papers could have greater societal impact (Tennant et al., 2016), thus influencing public and local policies.
Keywords analysis revealed "urban planning" can be found in more than 1300 articles, while at the same time "human" is not in the top five keywords (Fig. 3).

Figure 3. Distribution of different keywords in research papers dealing with urban greenery topics

When speaking about urban planning and sustainable development, in order to design more sustainable cities, one should be sure that needs of local people are met (Derkzen et al., 2015). A recent study found that the cultural services are the major feedback variables of the public supporting green spaces distributing in urban areas (Chang et al., 2017), which has shown to be of the utmost importance during the COVID-19 pandemic, when citizens strongly expressed the need for urban green areas integrated within the urban fabric (Ugolini et al., 2020).

Conclusion

Urban greenery has a wide variety of ecological, social and economic benefits. Evaluation of the keywords used in papers published over the last decade shows that the tendencies of the body of literature related to this topic are mostly oriented towards land use planning (taking into account regulating ecosystem services as primary).

SURVIVAL OF MICROORGANISMS IN CRUDE OIL POLLUTED SOIL

Timea HAJNAL JAFARI*, Dragana STAMENOV, Simonida ĐURIĆ

Faculty of Agriculture, University of Novi Sad, Dositeja Obradovića Sq. 8, 21000 Novi Sad, Serbia
*Coorresponding author: mikrobiologija@polj.uns.ac.rs

Abstract

Soil pollution by crude oil can occur naturally via spillage, accidents or improper disposal of crude oil and related products. Indigenous soil microorganisms such as bacteria, yeasts and filamentous fungi can use crude oil hydrocarbons as food and source of energy. They transform the complex organic compounds into less toxic or non toxic substances such as carbon dioxide, water and fatty acids. The aim of this research was to follow the survival of microorganisms in crude oil polluted soil in *in vitro* conditions. Two dosages of crude oil were tested (5 and 20 g kg^{-1}). Total number of bacteria, actinobacteria, fungi, aminoheterotrophs and azotobacter were monitored during six months period. Addition of crude oil negatively affected only the number of actinobacteria and azotobacter and the number decreased in relation to the control at the beginning of the experiment. Six months later, the total number of bacteria did not change significantly (log No 7.83 to log No 8.96 g $soil^{-1}$, respectively), regardless of the amount of added crude oil. Number of fungi decreased (log No 3.79 g $soil^{-1}$) as well as the number of azotobacter (log No 3.88 g $soil^{-1}$). The obtained results suggested that the autochthonous soil microorganisms adapted well and had high survival rate.

Key words: *microorganisms, crude oil, survival, pollution.*

Introduction

Soil pollution with crude oil and its products can occur during exploitation, processing, storage, transport and by accidental spillage (Pinedo *et al.*, 2013; Veerapagu *et al.*, 2019). When it happens, a huge environmental threat emerges. However, for microorganisms the crude oil could be a substrate for growth, an energy source and sources of carbon, nitrogen and sulfur (Talaiekhozani *et al.,* 2015). The most commonly used hydrocarbons are C1-C40 alkanes, cycloalkanes, benzene, ethylbenzene, toluene, numerous heterocyclic compounds (Beškoski *et al.*, 2012). Microbes transform the complex organic compounds into less toxic or non toxic substances such as carbon dioxide, water and fatty acids. Microbial degradation of hydrocarbon could take place under aerobic and anaerobic conditions and is influenced by temperature, soil pH, nutrients availability etc. On the other hand, the influence of oil on microorganisms is a gradual process, in which the microorganisms with the ability of salt tolerance, anaerobic metabolism or oil degradation potential continue to flourish in culture (Shaoping *et al.,* 2021).

Dominant bacterial species that use oil carbohydrates belong to the genus *Nocardia, Pseudomonas, Bacillus Acinetobacter, Flavobacterium, Micrococcus, Arthrobacter, Corynebacterium, Achromobacter, Rhodococcus* while *Rhodotorulla, Candida, Fusarium, Aspergillus, Mucor, Penicillium, Trichoderma* and *Phanerochaete* are the most important fungi (Koshlaf and Ball, 2017; Piñón-Castillo *et al.*, 2017). Ikhajiagbe and Ogwu (2020) found six bacterial and nine fungal species in crude oil-polluted soil from 16 different sites in their study.

Bacterial count in crude oil-polluted sites ranged between 1.51 and 5.43×10^5 CFU g^{-1} soil while fungal count varied between 0.44 and 3.49×10^5 CFU g $soil^{-1}$. Common microorganisms' species were *Bacillus subtilis* and *Aspergillus niger*.
The presence of indigenous microbial population, their survival and reproduction in crude oil reservoirs is advantageous for the implementation of methods known as Microbial Improved Oil Recovery-MIOR (Wood, 2019). *Pseudomonas aeruginosa, Bacillus licheniformis, Xanthomonas campestris* and *Desulfovibrio desulfuricans* are some of the common bacterial species used in oil recovery processes (Singh et al., 2007). Isolation and characterization of microorganisms with high survival rate and crude oil degrading ability is important in order to remediate the polluted sites with these organisms by means of bioaugmentation.
Having that in mind, the aim of the research was set up. The survival of autochthonous microorganisms in crude oil polluted soil in *in vitro* conditions was monitored during six months in order to screen for potential crude oil degraders.

Material and methods

Soil for the study was humofluvisol. Control treatment was only watered while in other treatments 5 and 20 g kg^{-1} of crude oil was added. Experiment was carried out in 12 L pots. 70% FWC was maintained throughout the experiment. Each treatment had three repetitions. The experiments lasted six months, starting May till October 2019 in *in vitro* conditions. First sampling was carried out one week after the addition of crude oil. The soil samples for microbiological analyses were collected and placed in sterile polyurethane bags and kept at a temperature of 4°C. Laboratory measurements were performed in the microbiological laboratories of the Faculty of Agriculture, Novi Sad (Serbia). The microbiological analyses included determining the total number of bacteria, actinobacteria, fungi, aminoheterotrophs and azotobacters. The number of microorganisms was determined using the dilution method (Trolldenier, 1996). The following nutrient media were used (Hi Media Laboratories Pvt. Limited, Mumbai, India): nutrient agar for the total number of bacteria, synthetic agar for the number of actinobacteria, potato dextrose agar for the number of fungi, meat peptone agar for the number of aminoheterotrophs, and mannitol salt agar for the number of azotobacters. Inoculated Petri dishes were placed in thermostat and incubated at constant temperature of 28 °C. The incubation period depended on the tested group of microorganisms and varied between two and 10 days. After incubation, the plates were inspected. The number of microorganisms was calculated using formula A×B×C/D, where A is average number of microorganisms per 1 gram of absolutely dry soil, B is coefficient of correction per 1 ml (2—when 0.5 ml of soil suspension was inoculated; 5—when 0.2 ml of soil was inoculated), C is soil dilution, D is mass of 1 g of absolutely dry soil-drying at 105°C for 4 h (Jarak and Djuric, 2006). The number of microorganisms was calculated in one gram of absolutely dry soil ($CFUg^{-1}$ soil) and expressed in a *logarithmic* graph.

Results and discussion

The number of investigated groups of microorganisms was high at the beginning of the experiment (Fig. 1). Addition of crude oil only affected the number of actinobacteria and azotobacter and they number decreased in relation to the control. Total number of bacteria, aminoheterotrophs and fungi were higher than the control treatment.

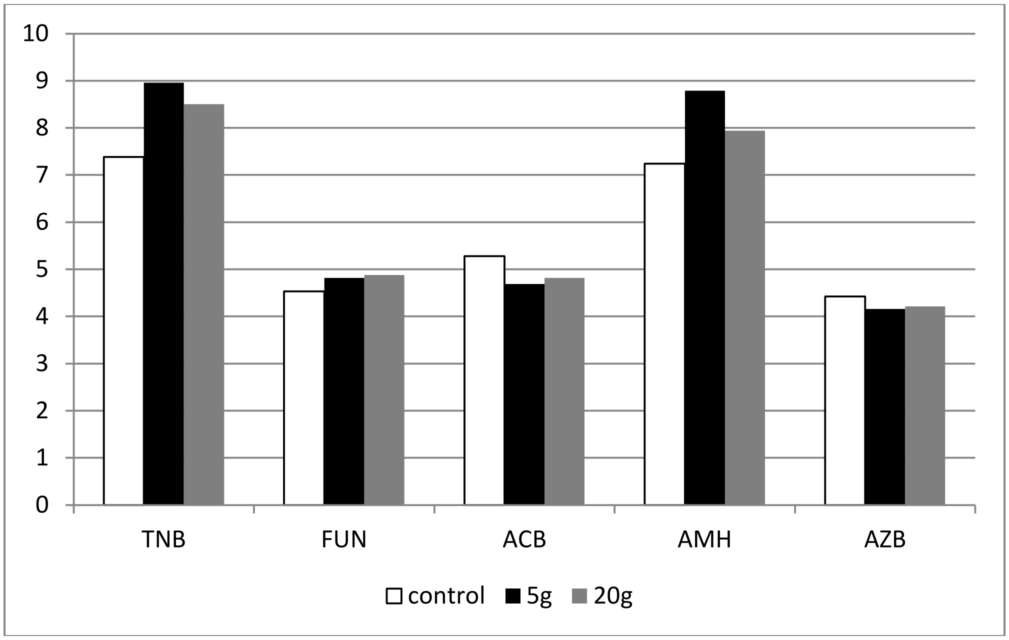

Fig. 1. Number of microorganisms in soil at the beginning of the experiment (log No g^{-1} soil)
TNB-total number of bacteria; FUN-fungi; ACB-actinobacteria; AMH-aminoheterotrophs; AZB-azotobacters

Six months later, the total number of bacteria did not change significantly, regardless of the amount of added crude oil (Fig. 2). Number of fungi decreased as well as the number of azotobacter. The number of actinobacteria and aminoheterotrophs were a little higher than the number in the watered treatment.

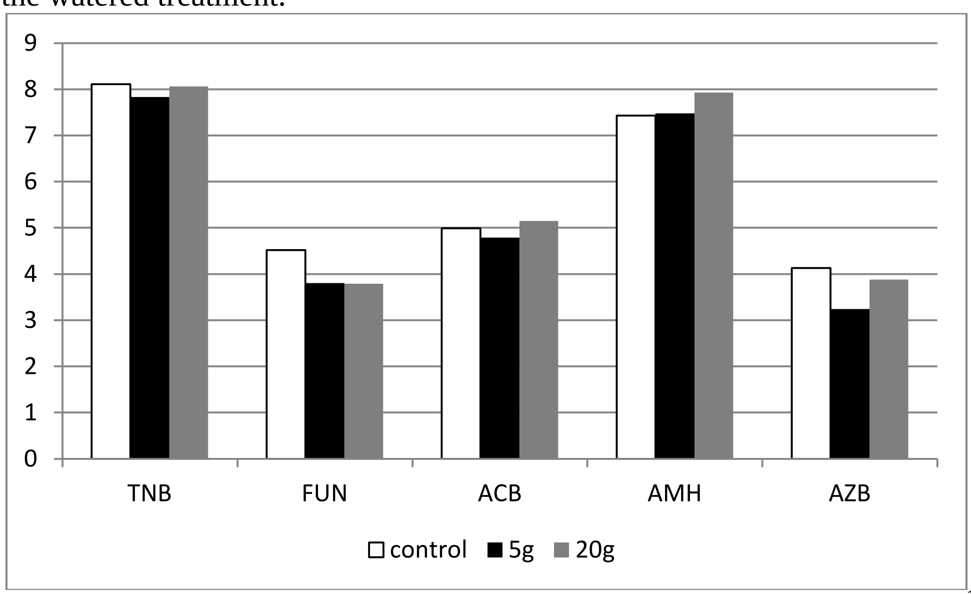

Fig. 2. Number of microorganisms in soil at the end of the experiment (log No g^{-1} soil)
TNB-total number of bacteria; FUN-fungi; ACB-actinobacteria; AMH-aminoheterotrophs; AZB-azotobacters

These results are in accordance with the results obtained by Li *et al.* (2000). They conducted an *in-situ* experiment in eastern China with polluted soil with petroleum hydrocarbons at concentrations up to 200 g kg^{-1} dry soil. The qualitative assessment of bacterial microflora identified dominant bacteria species from genus's *Xanthomonas*, *Bacillus* and *Hyphomicrobium*. The number of bacteria was of order 10^7 CFU g^{-1} soil. Bacteria contain different enzymes that breakdown hydrocarbons in soil. Voiculescu *et al.*, (2003) identified 23 taxonomic groups of bacteria belonging to the family *Enterobacteriaceae* and genera *Pseudomonas*, *Achromobacter*, *Alcaligenes*, *Aeromonas*, *Vibrio*, *Microbacterium*, *Flavobacterium*, *Corynebacterium*, *Mycobacterium*, *Arthrobacter*, *Brevibacterium*, *Nocardia*, *Bacillus*, *Micrococcus*, *Staphylococcus* and *Sarcina*. Filamentous fungi that were actively engaged in crude oil degradation in soil were species from genus *Aspergillus spp.*, *Penicillinium sp.*, *Paecilomyces sp. and Fusarrium* sp. Agu *et al.*, (2015) isolated heterogeneous bacteria from oil polluted soil. They belonged to the genus *Aeromonas* spp., *Staphylococcus* spp., *Corynebacterium* spp., *Micrococcus* spp., *Bacillus* spp., *Pseudomonas* spp., *Corynebacterium spp.*, *Pseudomonas spp.*, *Aeromonas spp.*, *Staphylococcus spp.*, *Micrococcus spp.*, *and Bacillus spp*. The total count ranged from 0.22×10^7 to 2.83×10^7 CFU g^{-1} soil. They argued that the ability of the microorganism to survive is associated with its ability to use crude oil as carbon source but were also affected by abiotic factors such are temperature, nutrients availability and oxygen content in soil.

In this research, the amount of degraded hydrocarbons was not monitored. However, it can be assumed that degradation processes occurred and certain amount of end products were used and/or released by the microorganisms. Usually, microorganisms adapt very well in short period of time and start the degradation pathways through gradual transformation of contaminants into intermediates of the central metabolism. Hyun *et al.* (2008) and Nam *et al.* (1998) found that the degradation rate of petroleum hydrocarbon pollutants is generally higher during the early stage when the pollutants are easily available. In later stages the contaminants bioavailability is limited as a result of hydrocarbons sequestration. It means that once that stage has been reached no further degradation occurs during remediation.

This experiment showed that the indigenous soil microorganisms were not affected negatively by the addition of different amount of crude oil. They adapted to the presence of the contaminant, probably used it as energy and nutrient source and consequently had high survival rate. Some of the microorganisms could be screened for their oil degrading ability and potentially used as remediation agents

Conclusions

Addition of crude oil affected the number of actinobacteria and azotobacter and the number decreased in relation to the control at the beginning of the experiment. Six months later, the total number of bacteria did not change significantly (log No 7.83 to log No 8.96 g $soil^{-1}$, respectively), regardless of the amount of added crude oil. Number of fungi decreased (log No 3.79 g $soil^{-1}$) as well as the number of azotobacter (log No 3.88 g $soil^{-1}$). The obtained results suggested that the autochthonous soil microorganisms adapted well and had high survival rate.

Abstract

One of the major consequences of anthropogenic influence is the evident decrease in the diversity and number of insect pollinators. Being highly vulnerable ecosystem service, mainly due to agricultural intensification, the spread of diseases and parasites, and pesticide pollution, loss of pollinator diversity may lead to loss of other species that directly or indirectly rely on them and could have significant economic impacts by reducing crop pollination services. In this study, we examined the relationship between environmental variables (altitude, distance from the nearest agricultural area, grazing intensity, and mowing) on the composition and abundance of pollinator species. Pollinators were sampled on the territory of the Autonomous Province of Vojvodina in the Republic of Serbia, on four types of habitats categorised according to the CORINE land cover classification as classes 2.1.1 Non-irrigated arable land, 2.4.3 Land principally occupied by agriculture, with significant areas of natural vegetation, 3.1.1 Broad-leaved forest and 3.2.1 Natural grassland. Our results showed a significant correlation between the composition of pollinator species and the overall set of environmental factors. We found that forest, followed by grassland habitats, had the most diverse pollinator communities. Localities under grazing and mowing appeared to be less diverse in pollinators, whereby agricultural areas had the lowest pollinator diversity. Our findings suggest that the diversity of pollinators is highly influenced by land use and confirm the importance of forest habitats in agricultural landscapes such as Vojvodina Authonomous Province in Serbia as important refuge habitats for foraging and nesting of pollinators.

Keywords: *pollinator diversity, pollinator abundance, habitat types, land use.*

Introduction

Insect pollinators provide essential ecosystem services by pollinating over 85% of all known plant species (Grimaldi and Engel, 2005; Ollerton et al., 2011). A wide range of plants whose survival depends on pollination include crops, fruits, nuts, vegetables and cereals (Gordon and Davis, 2003; Klein et al., 2007). Furthermore, many plant species are more sensitive to the deficiency of pollinators than to the lack of other resources (Burd, 1994; Ashman et al., 2004). Insect pollination is vital for agricultural food production and sustenance of 80% of wild plant species (Potts et al., 2010). When it comes to the impact of pollination on agricultural production, Williams (1994) states that 84% of the crops grown in Europe are directly dependent on pollination, and Klein et al. (2007) claim that 87 crops, which is 70% of the 124 key plant species that humans use directly in their diet worldwide, have a dependence on insect pollinators. Habitat and climate changes caused by anthropogenic factors have a negative impact on many taxa, including pollinators. Given the declining diversity and abundance of pollinators (Dias et

al., 1999; Klein et al., 2007) and the identified decline in at least one region or country on every continent (except Antarctica), this issue has been the subject of research for many years (AllenWardell et al., 1998; Kremen and Ricketts, 2000; Biesmeijer et al., 2006, Potts et al., 2010). Other factors that lead to a decrease in the number of pollinators are: intensification of agricultural production, cultivation of monocultures, spread of diseases and parasites, use of pesticides, urbanisation and reduction of available niches necessary for feeding and reproduction of pollinators (Allen-Wardell et al., 1998; Kevan and Phillips, 2001; Biesmeijer et al., 2006).
Different anthropogenic disturbances and the intensive management of agroecosystems have a severe impact on the biodiversity of pollinators. In order to secure pollinator-friendly habitats and advance pollinator conservation it is essential to investigate the impact of influential abiotic traits on important pollinator groups.
In this paper, we analysed the relationship between environmental variables and insect pollinator composition in Vojvodina region (North Serbia). The following abiotic traits were considered: altitude, distance from an agricultural area, grazing intensity, and mowing.

Material and Methods

The paper is based on a sample of pollinators (bees and hoverflies) that were collected during the three years of fieldwork (2011-2013) on four habitat types (Mudri-Stojnić et al., 2012; Markov et al., 2016). A map with sites is shown in Figure 1.

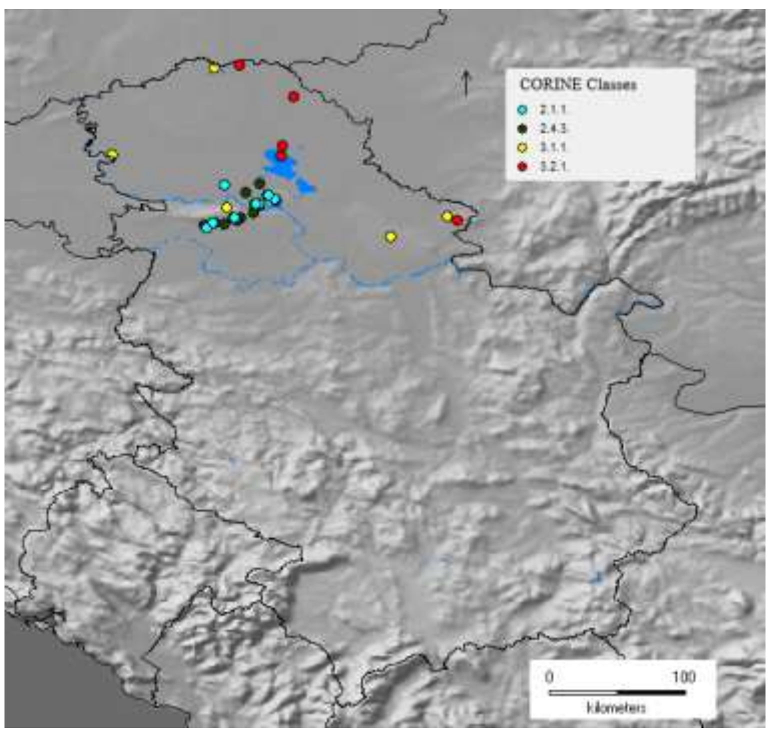

Figure 1. Sampling sites.

To examine the strength of the relationship between the explanatory variables and the species data set, multivariate analysis was conducted in the software package CANOCO 4.5 (Ter Braak and Smilauer, 2002). The dependent variables were tested by indirect gradient length analysis

using the DCA method to determine the most appropriate ordination method (detrended correspondence analysis) (Leps and Smilauer, 2003).
Taking into account the gradient length obtained by DCA analysis (2.89), a limited (constrained) canonical redundancy analysis (RDA) was performed. The influence of four environmental variables on the composition and distribution of pollinator species was tested: altitude, distance from the agricultural area (DAA), grazing intensity (grazing) and mowing. Different CORINE Land Cover habitats (2.1.1., 2.4.3., 3.1.1. and 3.2.1. codes) were considered as qualitative, categorical variables. A Monte-Carlo permutation test with 499 permutations was used to determine whether the examined environmental variables had a significant effect on the composition of pollinator species (Ter Braak and Smilauer, 2002).

Results and Discussion

The RDA diagram (Figure 2.) shows the sample areas (26 in total) and examined environmental variables. RDA analysis showed a significant correlation between the composition of pollinator species and the total set of environmental predictors ($F = 3.52$; $P = 0.002$ with 499 permutations). The variables that generated the longest arrows are DAA (distance from agricultural area) and mowing.

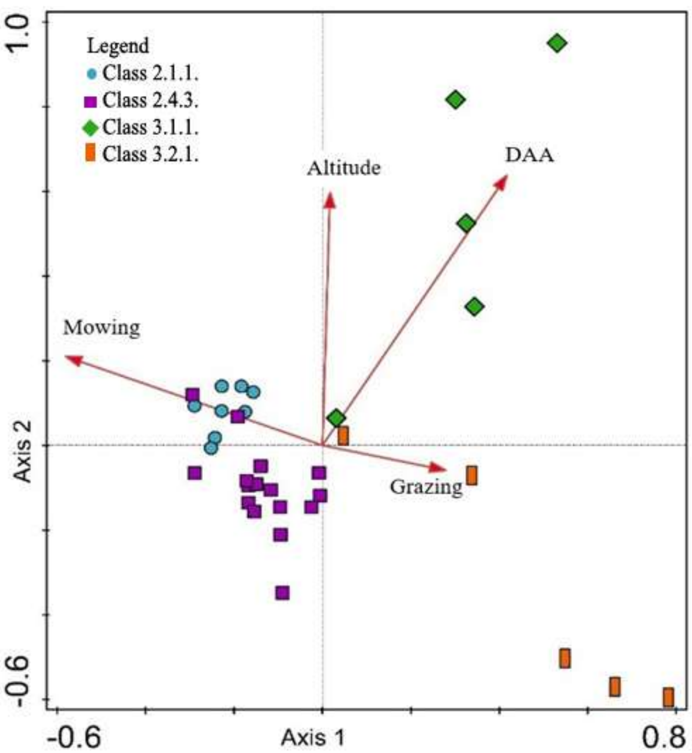

Figure 2. RDA ordination plot with statistically significant environmental variables and species diversity within sample areas (CORINE habitat types).

In Figure 3. it can bee observed that the first two ordinates, or dimensions (Dim 1 and Dim 2), explain 64% (cumulative percentage) of variability in relation to pollinator species abundance and environmental factors. The first ordinate represents the gradient of spatial variables (altitude

and distance from the agricultural habitat), and the second one represents the gradient of management activities (grazing and mowing).
The largest number of insect pollinator species was found on the land cover type broad-leaved forest (CORINE code 3.1.1), followed by natural grasslands (CORINE code 3.2.1), and land principally occupied by agriculture, with significant areas of natural vegetation (CORINE code 2.4.3). The least number of species was found on non-irrigated arable land (CORINE code 2.1.1). Ricarte et al. (2011) investigated the diversity of hoverflies in different habitat types (forest, shrubby and grassland areas) and their results also demonstrated a greater abundance of species in forest habitats. Forests provide a wide range of resources and microhabitats, acting as a shelterbelts in grassland-dominated areas (Ricarte et al., 2011). Within the agricultural setting of Vojvodina, Fruška gora and Vršački breg, can be considered as key reservoirs providing abundant resources for pollinators.

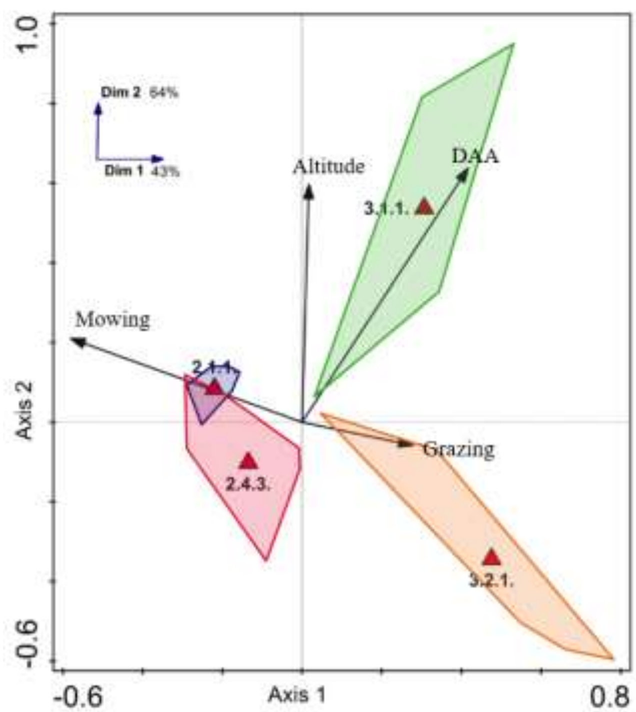

Figure 3. RDA ordination plot of environmental variables and grouped CORINE habitat types. Categorical variables (CORINE habitat types) are represented by red triangle.

The greatest diversity of pollinator species in forest habitats (Fig 2., Fig 3.), can be explained by the preference of hoverflies towards more heterogeneous habitats. Investigated forest habitats of high complexity and microhabitat diversity provide a wide range of food resources, nesting sites and meet different specific requirements of pollinator species. For example on Fruška gora site, pollinators were collected within forest stands and marginal forest habitats near the streams. In Vršački breg, pollinators were sampled in habitats dominated by mixed stands of downy oak (*Quercus pubescens* Willd.), Hungarian oak (*Quercus frainetto* Ten.), Turkey oak (*Quercus cerris* L.), sessile oak (*Quercus petraea* (Matt.) Liebl.), pedunculate oak (*Quercus robur* L.), and stands comprised of common hornbeam (*Carpinus betulus* L.), silver lime (*Tilia tomentosa* Moench.) and common beach (*Fagus sylvatica* L.) Sites on Subotica sands are characterised by acacia forest with a ground floor consisting of species from the buttercup family (Ranunculaceae). In Deliblato sands, pollinators were sampled in habitats dominated by acacia forest with ground cover species from the grass family (Poaceae), pea family (Fabaceae) and teasel family (Dipsacaceae) such as *Knautia sp*..

Grazing sites demonstrated significant species diversity, lower than forest habitats, however far higher compared to agricultural sites. Open habitats are an excellent food source for many species of bees and hoverflies, due to their dependence on the flowering plants, and essential nesting sites for ground nesting pollinator species. Species diversity in open habitats as well as statistically significant impact of grazing and mowing on the pollinator species composition, indicate the importance of preserving these habitat types and preventing succession, i.e. excessive growth of woody plants.

Although there is a relatively small difference in altitude between investigated sites (range from 69m to 347m), statistical analysis showed that altitude significantly impacts the composition of pollinator species. Considering that landscape heterogeneity increases with altitude, it is expected that sites at higher altitudes demonstrate greater species richness. Additionally, forest sites are within protected areas with significantly reduced human impact, while sites at lower altitudes are under intensive agricultural production, monoculture fields, and herbicide use.

Although monocultures (e.g. sunflower) are a suitable food source for certain pollinator species, the conversion of wild flower habitats into monocultures results in significant depletion of food sources for a large number of hoverfly and bumblebee species (Osgathorpe et al., 2011). In addition, specialised species are generally more sensitive to changes in land-use patterns within agricultural areas (Kleijn and Raemakers, 2008), whereby pesticides (e.g. neonicotinoids) lead to adverse changes in pollinator behaviour, which is manifested in the reduced search for food (Whitehorn et al., 2012).

Agricultural intensification usually results in expansion of infrastructural structures, such as roads, which can lead to isolation of pollinator populations over several years. This might explain statistically significant correlation between the composition of pollinator species and the distance from the agricultural area.

Conclusions

Our study demonstrates that the composition of pollinator species on four types of habitats in Vojvodina is closely related to environmental factors (altitude, distance from the nearest agricultural area, grazing intensity, and mowing), where forest had the most diverse pollinator communities, while agricultural areas had the lowest pollinator diversity. Our findings suggest that the diversity of pollinators is highly influenced by land use and confirm the importance of forest habitats in agricultural landscapes such as Vojvodina as important refuge habitats for foraging and nesting of pollinators. Additional field studies are necessary to improve the assessment of pollinators responses to abiotic drivers.

RASPBERRY PRODUCTION AND ECONOMIC VALUE OF INSECT POLLINATION OF RASPBERRY IN SERBIA

Zlata MARKOV RISTIĆ*, Snežana POPOV

University of Novi Sad, Faculty of Sciences, Department of Biology and Ecology, Novi Sad, Serbia
*Corresponding author:zlata.markov@dbe.uns.ac.rs

Abstract

The Republic of Serbia ranks among the largest producers of raspberry on the global market, with an annual production of circa 120,000 tons and an export of 80,000 tons. Although commercial raspberry cultivars are largely self-fertile and self-pollinate autogamously, without insect pollination the fruits are small or crumb. Insects that are mainly used to pollinate commercial raspberries are honeybees. In this research, we analyse the production of raspberries in the Republic of Serbia, for the whole country and separately for the northern and southern region during the period from 2010 to 2020, as well as estimate the economic value of insect pollination (EVIP) ecosystem service of raspberry in the same decade. Likewise, we presented the total value of raspberry crop (TVC) to emphasize the importance of insect pollination to the yield. In Serbia, the annual yield of raspberries ranged from 70,000 tons in 2012 to 127,000 tons in 2018, but over 90% of the yield is produced in the southern region. Considering producer price per metric ton, annual raspberry production and dependence upon the insect, the estimated EVIP ranged from approximately 48 million EUR in 2011 to 117.5 million EUR in 2020. In the observed period, the TVC has been followed the EVIP's trend to conclude, insect pollinators represent a significant share of TVC; they have a substantial positive impact on raspberry production, therefore conservation activities and good management practices are needed to maintain and improve the ecosystem pollination service in relation to this Serbian brand.

Keywords: *pollination service, EVIP, raspberry yield, honeybees*.

Introduction

Globally, the production of pollinator-dependent crops has increased during the last several decades, even more rapidly than pollinator-independent crops (Aizen et al., 2008; Garibaldi et al., 2011). Growing need for food has resulted in expanding of both markets and agricultural production. Increased food demand is also reflected in the production of raspberries worldwide, where the global harvested area has been more than doubled since 1986, reaching 127,578 ha in 2019 (FAOSTAT, 2021). The Republic of Serbia is one of the world's leading raspberry producers, with 80,000 tonnes of annually exported raspberry and steady expansion of land under raspberry cultivation (Stojanović et al., 2018).

Red raspberry (*Rubus idaeus* L.) grown for commercial purposes is predominantly self-fertile (Żurawicz, 2016), but due to the specific morphology of the flower, complete self-fertilization is not possible (Shanks, 1969). However, in the presence of insect pollinators and their raspberry flower visitation, the fruit has a greater weight and the increased number of drupelets (Shanks, 1969; Cane, 2005).

Unfortunately, agricultural intensification has a negative impact on many wildlife species (Robinson and Sutherland, 2002; Benton et al., 2003), including insect pollinators (Winfree et

al., 2009; Garibaldi et al., 2011). The abundance and diversity of wild insect pollinators have decreased in many regions, mainly due to agricultural land expansion and intensification (Potts et al., 2010). Because of apparent declines in a range of pollinator species worldwide, and potential pollinator deficit to produce entomophilous crops, there is a rising concern about the sustainability of pollination services (Steffan Dewenter et al., 2005).
In order to support pollination services in agroecosystems, it is necessary to develop appropriate management practices that can serve to conserve pollinators (Velthuis and Van Doorn, 2006). Economic valuation of insect pollination is of big importance when it comes to informing conservation efforts, providing information needed for prioritizing species and their habitats. Ecosystem services valuation can help identifying the benefits provided by ecosystems and biodiversity that are often left unrecognized and/or underestimated when it comes to decision - making in natural resource management. Due to the above-mentioned reasons, assessing the economic value of ecosystems and their services has been gaining significant attention in the scientific community worldwide (Perez-Verdin et al., 2016; Picanço et al., 2017; Porto et al., 2020).
This study aims to (i) provide an overview of raspberry production in the past decade in Serbia and (ii) estimate and analyse the economic value of insect pollination (EVIP) of the raspberry production in Serbia, which could assist in providing guidelines for the conservation of ecosystem pollination service. EVIP of raspberry is calculated to emphasize the economic importance of pollinators for agricultural production. The value obtained in this way should serve decision-makers but also other stakeholders as a guideline for conservation.

Material and Methods

Economic value of insect pollination of raspberry is calculated according to Gallai et al. (2009) methodology. The dataset used contains information on producer price, annual raspberry production as well as on the impact of insect pollination on raspberry. According to Klein et al. (2007), the ratio of raspberry dependence on pollination was estimated to be 65%.
This value indicates that due to the lack of pollination, raspberry yields would be reduced between 40% and 90%, so pollination is specified as "essential".
EVIP is calculated by multiplying the quantity of produced crop, the producer price per unit mass and the ratio of raspberry dependence on pollination. The result of multiplication of the first two parameters represents the producer price. The output data of this analysis are the value of the annual production of raspberries, the value of the contribution of insect pollination and EVIP.
Data on producer price and production for the whole country and separately for Serbia's northern and southern region from 2010 to 2020 were provided from the Statistical Office of the Republic of Serbia (SORS, 2021). For comparative purposes, the prices were converted into euros (EUR) according to the value of the national currency for a given period in the archives of the National Bank of Serbia (NBS, 2021).

Results and Discussion

The production area and total raspberry yield in Serbia, (as well as for the northern and southern part of the country depicted separately), are shown in Figures 1 and 2. Production area in Serbia increased from 11,500 ha in 2010 to 24,000 ha, as registered in 2020 (Fig. 1). The northern and southern part of Serbia also showed an upward trend when it comes to the production area. In the northern part the area increased from 471 ha in 2010 to 2,242 ha by 2020, while in the southern part, from 11,119 ha (2010) to 21,786 ha (2020). When it comes to the total raspberry yield, it was 83,870 t at the beginning of the observed period, afterwards in 2012 a decline to 70,320 t can be noticed, followed by an increase in yield. Another decline was recorded in 2017 (109,742 t), after which the yield of raspberries increased to 118,674 t by 2020. Similar oscillations of raspberry yield occurred in the northern and southern part of the country (Fig. 2). Despite a growing production area, the total yield did not follow this upward trend, which can be primarily attributed to the poor weather conditions over specific years with decreasing yield.

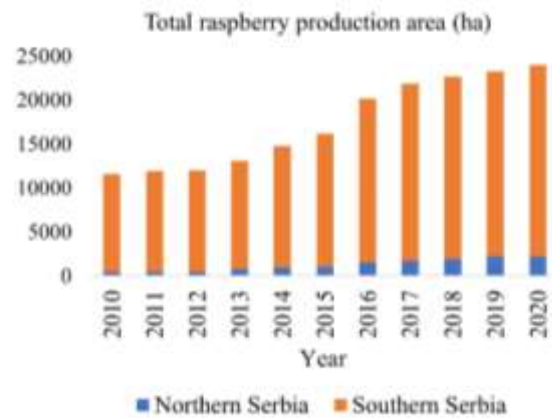

Figure 1. Total production area of raspberry (ha) in Serbia and separately in northern and southern part of country for the period 2010-2020.

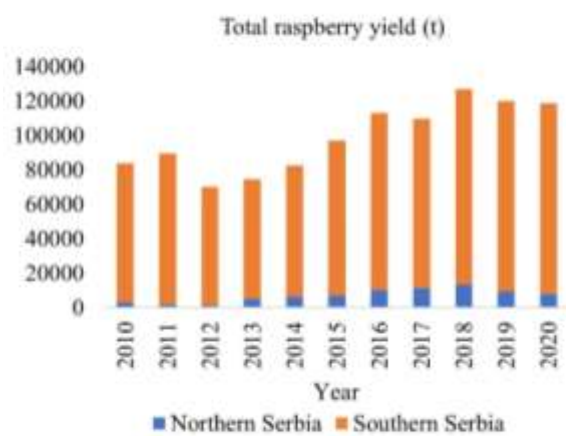

Figure 2. Total yield of raspberry (t) in Serbia and separately in northern and southern part of country for the period 2010-2020.

According to the bioeconomic approach, the EVIP for raspberries (in EUR) was estimated to range from approximately 48 million in 2011 to 117.5 million in 2020. To emphasize the importance and contribution of insect pollination to the yield of raspberries, the value of the Serbian raspberry crop is presented in Figure 3. The value was the lowest in 2011 when it was around EUR 74 million, while the highest recorded value was in 2020 (approximately EUR 181 million).

If the pollination services were to decline, the quality of the fruit would be drastically reduced (Andrikopoulos and Cane, 2018), which would consequently have a negative impact on individual producers and the economy in general. For raspberry, floral visitors promote increased quality of the fruit, which is an indirect and complex benefit to measure, however extremely important for the agricultural market. The obtained values of insect pollination of raspberries, combined with production data, represent a guideline for maintaining the ecosystem service of raspberry pollination and planning appropriate management practices. In this case, only the direct use value for agriculture is included in calculating EVIP. Nevertheless, the assessment result indicates that the investment in maintaining the services provided by insect pollinators to raspberries is justified, given that pollinators are threatened by various factors such as the use of harmful pesticides (Walker et al., 2017) or habitat destruction (Ollerton et al., 2014).

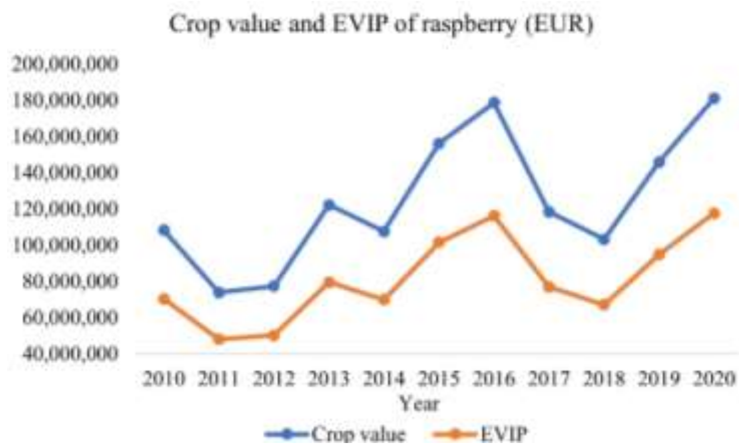

Figure 3. Crop value and Economic value of insect pollination (EVIP) of raspberry in EUR for period 2010-2020

Acknowledging the benefits of insect pollinators for the cultivation of raspberries, reflected in EVIP (even in such a simplified way), brings additional attention to this group of organisms in conservation practice. The EVIP cannot be used as the only source of information, but it can be implemented in a more comprehensive program that would aim to maintain the ecosystem service of raspberry pollination and improve yields. In this case, it means providing financial resources for the protection of wild insects pollinators and thus meeting their environmental requirements as well as enabling the direct benefit of their service through agriculture (de Snoo and de Leeuw, 1996). This aspect of (legal) protection of wild pollinators, specifically wild bees, is especially neglected in Serbia, where the Regulation on the declaration and protection of protected and strictly protected wild species of plants, animals and fungi contains only one bee species (Službeni glasnik RS, broj 36/09).

Wild pollinators can increase the production of raspberries and, in that sense, thay could be considered as an essential natural resource (Sáez et al., 2018; Andrikopoulos and Cane, 2018). However, wild pollinators are not numerous enough for adequate pollination when it comes to intensive raspberry production. In this paper, only the direct use value of insect pollinators regarding raspberry production is presented, which limits providing specific management guidelines for increasing and maintaining pollination services. Nevertheless, according to the obtained EVIP for raspberries and the apparent importance of this insect group, some general guidelines can be provided:

- to maintain raspberry yield, it is necessary to understand and meet appropriate habitat requirements for specific pollinator species (Shuler et al., 2005), e.g. nesting sites in forest patches or dead trees left (Westrich et al., 1996);
- in order to provide enhanced food supplies for insect pollinators, a diversity of flower resources should be locally present (Westrich et al., 1996; Goulson, 2003);
- raspberry fields should be enriched with flower paths and hedges around the fields, small forest patches and/or least individual trees, which increases the likelihood of colonization of many bee species (Steffan-Dewenter et al., 2002);
- insecticides, especially those that can contaminate pollen and nectar should be avoided, preventing the loss of entire pollinator populations (Delaplane and Mayer, 2000).

The financial burden in implementing these and other similar recommendations can be mitigated through agri-environmental incentive programs where farmers who apply biodiversity protection strategies are adequately compensated for this activity.

Conclusions

Additional research on benefits of insect pollinators together with conservation activities could help increase and stabilize insect pollination services and increase its capacity with positive externalities on agricultural raspberry production. Additionally, better understanding of the benefits that wild insects bring to the agricultural production could lead to easier implementation of sustainable and cost-effective agricultural production by the farmers (e.g., investing less in renting hives). Moreover, many users of other ecosystem services that indirectly depend on pollinators would also benefit. Finally, conservation efforts to maintain insect communities that have impact on raspberry yields would also positively affect a range of ecosystems' processes. By assessing the value of insect pollination services regarding raspberries production, the need for investment in its preservation and maintenance becomes obvious and justified.

Abstract

Invasive alien species pose a significant threat to biodiversity. Non-native plants often have dramatic impacts on the resident vegetation by modifying its composition and structure, decreasing native species abundance and richness via competition, predation, hybridization and indirect effect. The aim of our study was to report that selected invasive plants (*Helianthus tuberosus*, *Heracleum mantegazzianum* and *Fallopia japonica*) altered soil microbial indices and physicochemical properties. The research was carried out during a vegetation season (summer 2017) on Lekárovce and Opátka localities of South-Eastern Slovakia from the depth of 0.15 – 0.20 m. Soil reaction, soil moisture, soil organic carbon, soil basal respiration and soil enzyme activities (urease, FDA, beta-glucosidase, acid and alkaline phosphatases) were determined. Our study showed changes in soil samples with the observed invasive plants compared to the control sites. The results suggest that studied non-native plants have ability to change content of soil moisture. Soil reaction was also affected by invasion, while soil organic carbon was not significantly changed. Determining the intensity of soil respiration is of great importance for assessing the biological activity and the rate of mineralization processes in soil ecosystems. Our findings show reduced soil basal respiration in the presence of invasive plants, especially in *F. japonica* vegetation. The results of soil enzyme activity showed significant changes between invaded and control sites. Based on the results we assume that biology of the invasive plants had the high impact on soil systems and microbial indices might be considered as an indicator of environment disturbances.

Keywords: *Microbial indices, Invasive plants, Physicochemical properties.*

Introduction

Human activities (such as travel, artificial planting, etc.) has contributed to the spread of non-native plant species in ecosystems, and some of them have become invasive. The invasion of non-native plant species is one of the most important components of global change. The number of invasive plant species their distribution are increasing in many parts of the world. Invasive plants are found to spread even in the ice-free Islands of Antarctica despite the Antarctica treaty. Many species have been introduced accidentally (e.g., in water ballast, in soil, or as crop seed "contaminants"), but some have been intentionally introduced as ornamentals, food, or fiber products. Plant invasions can reduce the stability of the ecosystems by changing the supply of resources or by changing the trophic structure and its relationships (Čerevková *et al*., 2019; Fitoussi *et al*., 2016). The negative impact of non-native species on ecosystems is evident (Vitousek *et al*., 1996), but several authors have shown some positive features of exotic plants

(Dudek *et al*., 2016). Invasion of exotic plant species might alter many ecosystem properties, including important soil function and characteristics. Moreover, the same species can have the different impact on soil system, depending on local conditions (Dassonvile *et al.*, 2008). Because invasive plants can survive in harsh conditions and their ecology in polluted sites is very important, the study of Bobuľská *et al*. (2018) showed that some invasive species might be considered as a potential accumulator of risk elements. Relationships between alien plant species and their aboveground effects have been relatively well studied, but little is known about the effects of invasive plants on diversity and activity of microbial population. Microbiological characteristics are very often and effectively used as indicators of soil quality, because the large surface area, reactivity, distribution, generation time and diversity of the soil microflora allow a virtually immediate response to any changes (Kubát *et al.*, 2002). Microbial parameters are useful in monitoring environmental changes, but the determination of only one attribute is of no significance for the soil and its changes in the environment. Several studies show that non-native plant species might alter soil conditions such as soil moisture, organic matter, as well as other chemical and physical soil indices (Bobuľská *et al*., 2016; Duda *et al*., 2003).
The aim of this study was to investigate the relationship between selected biochemical soil properties and invasive plants on two studied localities.

Material and Methods

Sites description
The present study was carried out in two localities of Košice Basin (Lekárovce and Opátka) on Southeast of Slovakia (Figure 1) in June 2017. Both localities have invasion of *Helianthus tuberosus*, *Heracleum mantegazzianum* (Lekárovce locality) and *Fallopia japonica* (Opátka locality). The dominant soil type is Fluvisol that is a genetically young soil in alluvial deposits. Apart from river sediments, they also occur on alluvial plains, river fans, valleys and tidal marshes on all climate zones (Jordanova, 2017). Fluvisols belong to a group of high productive arable lands on which cereals, root crops and industrial crops are grown. In some parts, fluvial soils are used as a vegetable land. They are located on the floodplains of rivers, and their development is repeatedly disrupted by floods. Thus, the soil profile is enriched with the sludge sediments (Vilček and Zverková, 2015).

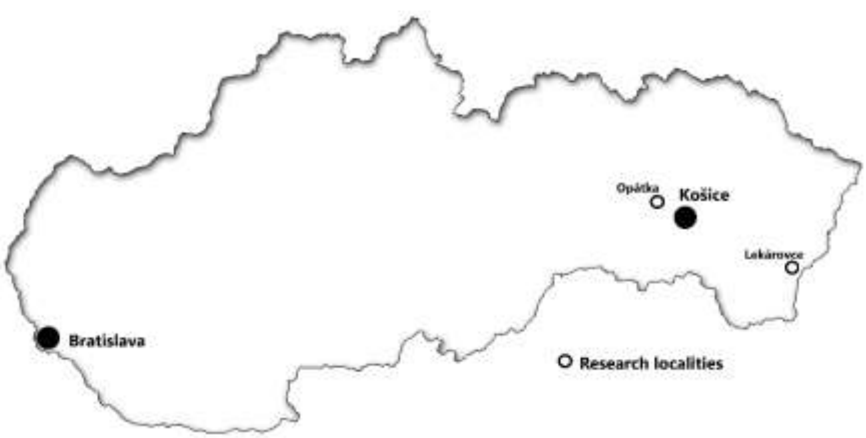

Figure 1. Experimental localities of the studied area in Košice Basin.

Soil sampling

All three selected invasive species formed dense patches on the research localities. Thus, invaded and non-invaded (control) sites were clearly recognized. After removal of surface litter, soil samples were collected in three replicates at the depth of 0-20 cm from each site and transported to the laboratory. In laboratory conditions, the soils were sieved using 2 mm mesh. Sieved soil samples were divided into two parts. Air-dried soil samples were selected to analyse chemical properties and another part stored at 4°C for soil physical and biological indices.

Soil analyses

Air-dried soil samples were used to measure soil reaction and organic carbon content. Soil pH was detected in a 1:3 mixture of soil and 0.01 M $CaCl_2$ solution using a digital pH meter. Soil organic carbon was determined by the Turin's method (Fiala *et al.*, 1999). Gravimetric soil moisture was calculated on 10 g of fresh subsamples after drying in a 105°C oven for 24 h. Soil basal respiration was measured by the CO_2 released from 100 g samples of field moist soil in 500 mL hermetically sealed flasks at 25°C for 48 h. CO_2 was captured by its reaction with NaOH (1mol L^{-1}) and titrated with HCl (0.5 mol L^{-1}) after the addition of $BaCl_2$ (1 mol L^{-1}). The concentration of the released carbon was estimated in μg C-CO_2 g soil dry^{-1}day^{-1} (Alef and Nannipieri, 1995). Enzymatic activity was determined using field-moist soil and each enzyme assay was performed as described in Table 1. Statistical analyses were done in R studio program (R Core Team).

Table 1. Incubation condition of selected enzymes with biochemical indicators.

Enzyme	Incubation condition					Reference
	Substrate	Buffer (pH)	Temperature (°C)	Soil (g)	Time (h)	
URE	Urea	6.7 (PB)	37	5	24	(Khaziev, 1976)
FDA	Fluoroscein diacetate	7.6 (PPB)	30	1	1	(Green *et al.*, 2006)
BGL	4-Nitrophenyl glucopyranoside	6.0 (MUB)	37	1	3	(Eivazi and Tabatabai, 1988)
$PHOS_{AL}$	p-Nitrophenyl phosphate	5.0 (AB)	37	5	3	(Grejtovský, 1991)
$PHOS_{AC}$	p-Nitrophenyl phosphate	10.0 (BB)	37	5	3	(Grejtovský, 1991)

URE (urease activity); FDA (fluorescein diacetate activity); BGL (beta-glucosidase activity); $PHOS_{AL}$ (alkaline phosphatase activity); $PHOS_{AC}$ (acidic phosphatase activity); PB (phosphate buffer); PPB (potassium phosphate buffer); MUB (modified universal buffer); AB acetate buffer); BB (borate buffer).

Results and Discussion

Soil physico-chemical properties and microbial indices from selected localities that present invaded and non-invaded (control) ecosystems are shown in Table 2. In our study, the status of invasion had significant impact on soil physico-chemical properties and microbial indices on soil ecosystem.

Table 2. Means ± standard errors of soil physico-chemical properties and microbial indices in the soil samples in invades and non-invaded (control) sites.

Status/Parameters	pH	SM	C_{ox}	SBR	URE	FDA	BGL	$PHOS_{AL}$	$PHOS_{AC}$
H. tuberosus	7.1 ±0.2	16.4 ±1.2	1.9 ±0.4	153 ±25	0.31 ±0.02	14.4 ±0.6	14.3 ±1.9	339 ±19	215 ±27
HT (control site)	6.5 ±0.2	15,8 ±1.6	1.7 ±0.3	212 ±	0.19 ±0.01	25.6 ±0.4	18.6 ±1.0	306 ±14	579 ±35
H. mantegazzianum	7.1 ±0.1	18.7 ±1.0	1.8 ±0.4	183 ±31	0,07 ±0.01	12.2 ±0.7	14.8 ±1.5	358 ±21	279 ±36
HM (control site)	6.5 ±0.3	17.6 ±1.3	1.6 ±0.2	219 ±19	0.22 ±0.01	17.9 ±0.3	17.2 ±0.7	426 ±14	387 ±26
F. japonica	7.7 ±0.1	17.4 ±1.1	3.8 ±0.5	132 ±36	0.43 ±0.03	37.7 ±0.5	38.2 ±1.1	430 ±25	309 ±33
FJ (control site)	7.4 ±0.1	16.4 ±2.6	3.7 ±0.3	329 ±41	0.22 ±0.01	19.6 ±0.1	37.7 ±0.6	360 ±31	275 ±28

SM (soil moisture, %); C_{ox} (organic carbon, %); SBR (soil basal respiration, μg C-CO_2/g soil /24 h); URE (urease activity, μg NH_4/g soil/24 h); FDA (fluorescein diacetate activity, μg FS/g soil/1 h); BGL (beta-glucosidase activity, μg pNP/g soil/1 h); $PHOS_{AL}$ (alkaline phosphatase activity, mg P/g soil/3 h); $PHOS_{AC}$ (acidic phosphatase activity, mg P/g soil/3 h).

The results show that soil moisture is higher in all invaded systems compare to the control sites. The study of Ehrenfeld (2003) also confirmed that invasive plant species have ability to alter soil moisture content. This might be explained by the fact that invasive plants have shallow root system and lower water supply. Soil pH is one of the most important chemical parameter that affects the solubility of soil substances, and therefore their usability by living organisms. According to Sheahan *et al*. (2012), soil pH is important factor of soil fertility, despite the fact that it changes dynamically depending on the internal and external factors. Increased soil acidity inhibits the activity of beneficial bacteria, thereby reducing the activity of the soil ecosystem. The results revealed that all invasive species are able to increase the value of pH, which was also reported in several other studies (Bobuľská *et al*., 2019; Čerevková *et al*., 2019; Zhang *et al*., 2009). Content of organic carbon was slightly higher in invaded ecosystems, but this trend was not statistically observed. Generally, invasive species form dense covers, they are fast growing, produce large amount of litter and therefore are considered to alter nutrient cycling and significantly change soil organic matter (Metcalfe *et al*., 2011). Some studies show that invasive species were able to increase the content of organic carbon (Tong *et al*., 2011; Wang *et al*., 2018), but the results of Feng *et al*. (2019) show the opposite trend.
Determining of intensity of soil respiration is of great importance for estimation the biological activity in soil ecosystem and the rate of mineralization processes. The soil basal respiration did not statistically vary between invaded and control sites (with the exception for *F. japonica* sites), but had tendency to be higher in natural habitats. The FDA measures the enzyme activity of a microbial population and can provide an estimate of the total microbial activity in environmental samples. Activity of FDA showed higher values in native ecosystems with the exception of *F. japonica* that provided higher activity of this parameter. Activity of beta-glucosidase was significantly lower in sites for *H. tuberosus* and *H. mantegazzianum*, while this enzyme did not significantly change in *F. japonica* sites. The opposite trend was observed for activity of soil urease, where its value increased in invaded systems, except *F. japonica*. Urease activity

depends on soil moisture, soil reaction, content and quality of humus, as well as the total content of soil nitrogen (Ehrenfeld, 2003). Both phosphatases, acid and alkaline, showed the changes due to the status of ecosystems. In soils with low phosphorus content, soil phosphatase activities are very important. The activity of soil phosphatases is a condition for making organic phosphorus available to plants. Phosphatases have different optimal pH values and are divided into acidic and alkaline.

The effects of invaded plant species on soil properties were generally significantly different between invaded and non-invaded sites (Table 3).

Table 3. The values of Mann-Whitney nonparametrical test for comparison soil properties between invasion status (invaded vs. non-invaded) regardless to invasive plant species

Parameter		**U**	**z**	P value
pH	Between invaded and non-invaded sites	30	4.58	0.0002 *
SM		103	−2.61	0.009 *
C_{ox}		100	−2.69	0.89
SBR		200	0.02	1.0
BGL		68	3.55	0.008 *
FDA		186	−3.6	0.009 *
URE		55	−3.9	0.0001 *
$PHOS_{AC}$		161	−1.04	0.29
$PHOS_{AL}$		90	2.96	0.36

SM (soil moisture), C_{ox} (soil organic carbon), SBR (Soil basal respiration), FDA (fluorescein diacetate activity), BGL (beta-glucosidase activity), URE (urease activity), $PHOS_{AL}$ (alkaline phosphatase activity), $PHOS_{AC}$ (acidic phosphatase activity), * $P < 0.05$.

Conclusions

In this study, we estimated the changes occurring in soil physico-chemical properties and microbial indices due to exotic invasion in two localities of southeast Slovakia. It was observed that selected non-native plant species (*Helianthus tuberosus*, *Heracleum mantegazzianum* and *Fallopia japonica*) significantly affected soil physico-chemical properties (soil moisture, soil reaction) and microbial indices (activity of beta-glucosidase, urease and FDA). Thus, we can conclude that invasive species augment soil properties and stablish themselves. Moreover, our results also suggest that activity of soil enzymes, as well as other soil physico-chemical properties can be widely used as an indicator of changes in natural ecosystems.

Abstract

Current and former mining activities in Slovakia and related industrial activities focused on ore processing have significantly affected the quality of the environment. Pollution of such sites affects all components of the environment, the health of living organisms, including humans. The research was carried out in Nižná Slaná former mining area during the summer of 2019. The soil samples were taken from the vicinity of mining bodies – tailing pond and abandoned area of the ore processing plant. The aim of the study was to determine the level mercury pollution in the surrounding of mining bodies in the Nižná Slaná former mining area, and to evaluate the influence of pollution to the selected biological and chemical soil properties. The total content of mercury was determined by a direct mercury analyzer (AMA-254). Nutrients (Ca, Mg, K and Na), the activity of soil enzymes (urease, acid, and alkaline phosphatase, FDA, and *β*-glucosidase), and soil pH was determined in laboratory conditions. Mercury pollution in the evaluated area was expressed by contamination factor (C_f). Limit value of mercury in soil samples exceeded the permissible limit value at all sampling sites. Contamination factor reached extremely high values, expressing very high contamination at all sampling sites. Higher values of mercury in soil ecosystem have an inhibitory effect to the soil enzymes, but nutrient seems to be resistant. The soil reaction was higher (alkaline), which is probably due to the presence of sludge from the sludge in the soil environment.

Keywords: *Tailing pond, activity of soil enzymes, nutrients, contamination factor*.

Introduction

Mining and smelting activities have a long tradition in Slovakia (Rybár et al.,2006). It was first mentioned in documents from the 4th century, with the biggest expansion during 13. – 14. century. From the beginning it was only surface mining, later it was switched to deep extraction, which had a much greater impact on the landscape. In the places where mines occurred, were created processing plants areas and the number of mining bodies usually used for secondary (waste) material storage (Dudek, 2005).Tailing ponds and the areas of former processing plants represent the remains of mining activities in former mining areas. In addition to negatively changing the appearance of the landscape, they are also a source of hazardous elements - heavy metals, that enter the environment and change its properties (Demková et al., 2020). Bad soil quality in the former mining areas, predominantly in the vicinity of the mining bodies is long time serious environmental problem (Guo et al., 2017). Mercury is considered one of the most dangerous heavy metal, because of toxicity, high persistency in ecosystem and bioaccumulation ability in the food chain (Árvay et al., 2017). Because of its toxic effect on human health, mercury contamination is a significant concern worldwide **(**Beckers and Rinklebe, 2017). Mining and smelting activities contribute to the increase of mercury content in the environment (Liu et al., 2021). It has been shown several times that soil properties, such as soil reaction, the activity of soil enzymes, or the content of nutrients are changing under the influence of environmental loads, which has a negative effect on the quality of the soil environment (Demková et al., 2019). Additionally, soil enzymes are very often used as bioindicators of soil quality because they react quickly to environmental stress, and they are very sensitive to the changes in the soil's ecosystem (Wyszkowska et al., 2002). It also has been found that soils polluted by risk elements have reached a low value of nutrients what leads to the decreased soil fertility and health (Fazekašová and Bobuľska, 2012). The aim of the study was i) to determine the content of the mercury in the soil samples sampled in the vicinity of the two mining bodies – tailing pond and area of the former processing plant, ii) to evaluate the level of pollution by mercury using the contamination factor (C_f), iii) evaluate the influence of the soil pollution by the mercury to the selected soil properties – the activity of soil enzymes, soil nutrients and the soil pH, iv) to determine the differences in the soil properties between two different types of sampling sites (tailing pond and area of former processing plant).

Materials and methods

Mining activities in the Nižná Slaná village in Slovakia, which is the object of the study, were focused on iron and precious metals extraction. The need to process the extracted ore material required the construction of a processing plant. After more than six centuries of intensive mining and processing activities, the mining activity in Nižná Slaná was definitively finished in 1996. The remnants of mining activities in this area include an extensive tailings pond, several heaps, and an abandoned area of an ore processing plant. The mentioned mining bodies are a source of undesirable substances such as heavy metals. Soil (substrate) samples (0-10 cm) were taken during summer 2019 from the tailing pond and its surrounding (n=6) and from the area of the processing plant (n=6) in the cadastre of Nižná Slaná village (Slovakia). Subsequently, the soil was manually cleaned of dead plant parts, dried at room temperature, sieved (<2mm), homogenized, and stored for analysis. Soil reaction was determined as follows: 25 mL of 0.01 M CaCl2 was added to the 5g of soil. After one hour of shaking the pH was measured using InoLab pH 720-WTW. The content of nutrients (Ca, K, Mg, Na) was measured using ICP-OEC Agilent 720 (Agilient Technologies, Germany). The activity of acid (ACP) and alkaline (ALP) phosphatase was determined by Grejtovský (1991), the activity of urease (URE) by Khaziev (1976), the activity of ß-glucosidase was determined by Eivazi and Tabatabai (1988), and activity of fluorescein diacetate (FDA) was determined by Green et al. (2006). The level of soil pollution by mercury was expressed by contamination factor (C_f) which was calculated as follows (Hakanson, 1980):

$$C_f^i = \frac{C_{0-1}^i}{C_n^i} \qquad (1)$$

where: C_{0-1}^i is the total concentration of the mercury in soil and C_n^i is the background level of mercury, which was 0.08 mg.kg^{-1}(Čurlik and Šefčík 1999). Hakanson (1980) divided contamination factor values into 4 classes, listed in the Table 1.

Table 1 Classes of the contamiantion factor values according Hakanson (1980).

contamination factor value (C_f)	Level of contamination
C_f^i<1	low contamination
if 1≤ C_f^i<3	moderate contamination
3≤ C_f^i<6	considerable contamiantion
C_f^i ≥6	very high contamination

All statistical analyses were performed using R studio (R Core Team 2012). Non-parametrical Mann-Whitney U test was used to express the significant differences in soil characteristics between two types of sampling sites (tailing pond – TP and processing plant areas – PP). Spearman's correlation coefficient was used to determine the relationships between soil characteristics determined in soil samples.

Results and discussion

The limit value of mercury for Slovak soils is set by Act. No 220/2004 Coll of Laws to 0.50 $mg.kg^{-1}$. Based on the results obtained we can conclude, that at all sampling sites above the limit value of mercury was determined (Table 2). According to mercury pollution, it is very often linked to mining activities and the industrial activities associated with it (Higueras, 2014). The area of the Nižná Slaná is included in the list of environmental burdens in Slovakia, mainly due to the danger arising from the tailings pond located above the village (Enviroportal, 2014). Soil pollution usually has an inhibitory effect on the activity of soil enzymes, although different enzymes have been found to respond differently to soil pollution (Duan et al., 2018). All evaluated soil enzymes gave a negative (not significant) correlation with the mercury content (with exception of ACP) (Table 3). Acid phosphatase gave a positive correlation with mercury content what is a sign, that acid phosphatase is the most resistant to mercury pollution. Zheng et al. (2019) consistently with our results, confirmed that soil phosphatase activity was least affected by the mercury content of the soil. For soils contaminated with heavy metals is also typical, that the values of the soil reaction are in the lower values (Hohl and Varma 2010). In our case, the soil pH values ranged between 3.73 – 7.36, which are relatively high values for this type of soil. On the contrary, Martinez et al. (2020) have documented that the pH values of sewage sludge use to reach strongly alkaline values, which was confirmed by our results. Additionally, the correlation between soil pH and mercury content was found positive, which is also not obvious in polluted soils. All evaluated soil enzymes gave a significant positive correlation between themselves and a negative correlation with soil pH. Consistently with our results, Taylor et al. (2002) have found a negative correlation between pH and soil enzymes. Soil pH gave a significant positive correlation with Ca and Mg ($p<0.01$**), and a significant negative correlation with K and Na ($p<0.01$**).

Table 2. Total content of Hg [mg kg^{-1}], nutrients (Ca, K, Mg and Na [mg kg-1] soil pH, and soil enzymes: FDA [µg FS/ g soil h], BG [µg p NP/ g soil 1h], URE [mg NH_4^+Ng^{-1}24h^{-1}], ACP [mg P q^{-1} 3h^{-1}], ALP [mg P q^{-1} 3h^{-1}] determined in soil samples sampled in the surrounding of tailing pond (TP) and processing plant area (PP).

K									**-0.71****	0.42
Mg										-0.35

The results of Mann-Whitney U test confirmed that sampling localities significantly differ in the content of ACP, ALP and Na ($p<0.05$*) (Table 4).Based the results we can conclude that the content of ACP, ALP and Na reached higher values at TP localities comparing PP.

Table 4. The results of Mann-Whitney U test expressing the differences in soil characteristics between different types of sampling sites.

soil characteristics		U	Z	p
Hg	Between different samplin g sites	13.0	0.46	0.50
pH		14.0	-0.56	0.57
FDA		9.00	1.36	0.17
BG		10.5	1.12	0.26

URE	9.00	1.36	0.16
ACP	7.00	1.68	**0.05***
ALP	6.00	1.84	**0.05***
Ca	17,00	-0.08	0.93
K	12.00	0.88	0.37
Mg	11.00	0.74	0.27
Na	6.00	1.84	**0.05***

*p<0.05

Contamination factor values ranged between 257 to 23.6 in the samples from tailing pond, and between 194 to 18.8 in the samples from the surrounding of processing plant area (Figure 1). Based the Hakanson (1980) classification, at all evaluated sampling sites very high contamination by mercury was determined (C_f>6). Fazekašová and Fazekaš (2020) used contamination factor for evaluation the soils sampled in urban area of Nižná Slaná. The results showed very high contamination by mercury.

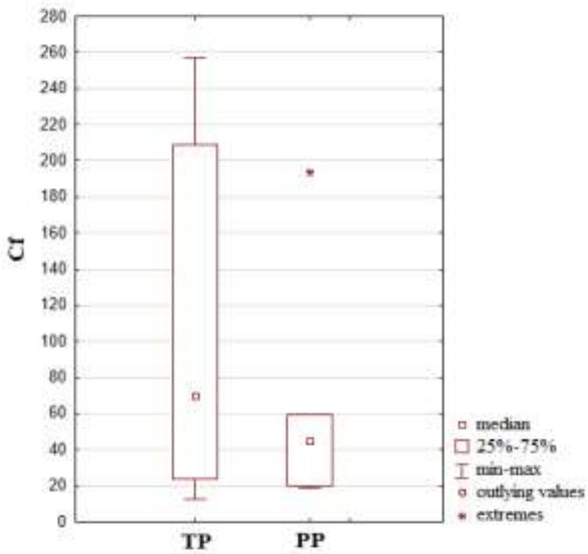

Figure 1 Boxplot expressing the mercury contamination factor values determined for two types of sampling area (TP – tailing pond, PP – processing plant area)

Conclusion

Environmental burdens in the form of old mining bodies are a threat to the surrounding environment due to insufficient security and almost no remediation interventions. The release of risk elements from them has a negative effect on the quality of the soil environment, its health, and fertility. The results showed, that the surrounding of taling pond and processing plant area in Nižná Slaná village is very high contaminated by mercury. No significant correlation between the content of mercury and the activity of soil enzymes, soil pH, and nutrients was found. Soil pH reached high values, which is not typical for such king of polluted area. Soil pH significantly positively influenced the content of Ca and Mg, and significantly negatively influenced the content of K and Na. Acid phosphatase, which was found as the most resistant to mercury pollution, significantly negatively correlated with Ca and Mg.

Abstract

Bosnia and Herzegovina has large areas of unused agricultural land that are very suitable for the development of livestock, which has recently become increasingly important in sustainable food production. Environmental management of livestock is imposed as one of the main challenges in politics of environmental protection. Entity legislation, in the field of environmental protection is a framework for environmental management in Bosnia and Herzegovina. Environmental management for large farms is a mandatory part of the environmental permit. The environmental permit is one of the main instruments of environmental policy at the local level in Bosnia and Herzegovina for agricultural business and food producers of eggs, meat, milk and other livestock products. The paper analyses the arguments for obtaining environmental permits for poultry farms in the municipality of Srbac. The research method is based on desk analysis. The subject of the analysis is 30 arguments obtained from local environmental permits, collected by authorised professional companies in the field of environmental protection from the entity of the Republic of Srpska. The collecting period of arguments was from 2011 to 2021 years. Desk analysis allowed identifying the main pollutions on poultry farms production from all elements of the environment and proposed the measures to reduce these contaminants respecting the regulations to national legislation. Finally, discussion and conclusion state the importance of the principles of circular economy in environmental management of livestock for transition to sustainable business of food production.

Keywords: *Bosnia and Herzegovina, sustainable food production, environmental management of livestock, environmental permits for poultry farms, circular economy.*

Introduction

Bosnia and Herzegovina (BiH) is a country with large areas of agricultural land suitable for livestock. Livestock in BiH has a long tradition and livestock products from this area are regionally known in the Southeast part of the European Union (EU). The production of food for the human population is the second goal of the Agenda 2030 for sustainable development.[9] Fassio and Tecco (2019) state that human nutrition depends on 5 animal species (primarily: meat, milk and eggs production). On the basis of this food production, commercial agricultural food production or agricultural business was created. The development of agricultural business has also contributed to countless environmental pollution. The assumption is that 1/5 of the total pollution on the planet earth is caused by agricultural business, i.e. commercial food production. Sustainable food production has become one of the key challenges of environmental

[9] Source: Agenda, 2018

management. Environmental management is directly related to three important principles viz. reduce, reuse, and recycle (RRR). These three principles are the basis of the circular economy (Andersen, 2006).
The concept of circular economy is a holistic framework and in addition to the positive economic effects of food production, it also takes into account the negative effects on the environment (Fogarassy and Finger, 2020). This growth concept is important because the opinion that the economy should grow primarily on natural resources without restrictions has been deviated from. The concept of circular economy is primarily implemented by entrepreneurship in order to make it sustainable, i.e. circular entrepreneurship or circular business (Abad-Segura et al., 2020). Paulik (2018) state that the implementation of the circular economy principles into agricultural business is only possible through environmental management. Environmental management of food business in BiH is a mandatory part of the environmental permit (EP) and its measures to prevent pollution. This paper presenting the current practice of obtaining EP and using the principles of circular economy in order to assess the contemporary state of sustainable agricultural business and food production.

Materials and Methods

The EP is mandatory for all large livestock farms that are in the system of food production for the human population on the territory of Republic of Srpska/BiH. In order to implement the standards of circular economy (RRR) through sustainable business - sustainable food production, it is necessary to identify the largest emissions - pollutants produced by livestock farms, its causes and the consequences if they stay or accumulate in the environment, to obtain a completed picture of economic gains and losses in one production cycle. The Law on Environmental Protection (Official Gazette of Republic of Srpska, No. 71/12, 79/15, 70/20) defines the issuance of EP and the Rulebook from the same Official Gazette defines all facilities that can be built and put into operation only if they have an EP.[10]Official Gazette of Republic of Srpska, No. 124/12, under item "dj" are defined facilities used in agriculture that require an EP. According to the Law on Environmental Protection (2012, 2015, 2020), it is obligatory to enclose argument for environmental protection (AEP) with the request for the issuance of an EP. AEP need to be prepared by an accredited professional institution for environmental protection registered on the territory of the Republic of Srpska/BiH.[11] The same AEP need to be submitted to the competent environmental protection institution for approval of EP issuance. The competent institution for issuing an EP may be a unit of local self-government (municipality or city) or the competent ministry of ecology[12] (if the production capacity is higher which requires an environmental impact assessment[13]).
AEP explains all significant farm pollutants that may affect environmental elements, all living things and human health. Monitoring is based on applicable laws and rulebook's for the territory of the Republic of Srpska (primarily the Law on Protection of Air[14] , Water[15] and Land[16], Waste

[10] Source: Rulebook on facilities that can be built and put into operation only if they have an environmental permit, 2012

Managament[17], Nature Conservation[18], Animal Husbandry[19], Protection and Welfare of Animals[20], Veterinary Medicine[21], and relevants rulebook's[22,23,24,25,26,27,28,29,30,31]). On the other hand, measures to prevent or reduce pollutions are determined. Measures for environmental protection are proposed on the basis law, best available techniques and technologies[32,33]. In this way, ecological management on farms is established, as a precondition for the implementation of circular economy standards, i.e. the achievement of the sustainable development goals.
The method of work is a desk study on 30 subject AEP, collected from authorized professional companies[34], in the production of broilers in the municipality of Srbac, Republic of Srpska/BiH, with a capacity of 8000 to 50 000 broilers, for which the EP is issued by the local municipality.[35] Environmental management was analyzed through the content of the AEP. The content of the AEP is prescribed by the Law on Environmental Protection.[36]
Presented results (Tables 1, 2, 3) shows emissions/pollutants listed in all AEP or those that are most frequently repeated as major pollution points on farms. The examination involves professional description of the occurrence of these pollutants, a pollution professional measure or solution (respecting the law and greatest available techniques/technologies/practice) and monitoring (according to relevant rulebooks). The tables present environmental farm management system. In professional discussion, are presented the shortcomings and advantages of environmental management on farms in the Republic of Srpska/BiH, according to circular economy principles based on professional practice (EU practice) and science-policy evidence (international environmental agreements and national legislation). In the conclusions is given the final assessment of the system of environmental management of Republic of Srpska farms, as well as proposals for further development of the concept of circular economy for sustainable food business.

Results and Discussion

The most common emissions to air that are recognized on all farms are: gases from metabolic processes, odors from the decomposition of fertilizers, suspended particles during daily feeding and gases from boiler rooms (Table 1.). None of presented emissions are not subject to monitoring. Regular monitoring of gases from boiler rooms, according to the current legislation

in the Republic of Srpska is done for boiler rooms over 250 kW.[37] Smaller farms have decreased boiler rooms. However, there is a large number of smaller farms with minor boiler rooms on the territory of the municipality of Srbac, and the law did not provide their monitoring if there is a large number of smaller boiler rooms in the same area. This is the first recognized lack of legislation for the territory of the Republic of Srpska/BiH.

In addition, there is no monitoring of gases from metabolic processes inside or near the object. Given that these gases are an integral part of the production process, and that they can negatively affect human health and the environment, it is necessary to set limit values within the facility and regular monitoring, similar to those in EU countries (such as Germany or Austria). This is the second recognized lack of legislation in the Republic of Srpska/BiH.

Also, odors from the decomposition of fertilizers have a very strong and adverse effect on human health and the environment. A situation of poor storage or non-existence of a lagoon for manure is very common. According to the EU Nitrates Directive[38], proper management of the permanent and construction of the lagoon is mandatory. It is necessary to implement EU legislation in Republic of Srpska/BiH. The third shortcoming of the legislation in RS was recognized there.

Finally, the problem of airborne particles was recognized during the daily feeding of broilers. The big problem here is the technology of food production, as well as the technology of automatic feeding. BiH legislation does not define the use of the best available technologies (eco-technologies) in the process of food production. This was recognized as the fourth shortcoming of the legislation in RS.

Table 1. Negative impact on the air

The emission *(negative impact on the air)*	1. Products of intensive metabolic processes in the form of a gaseous phase (during the ventilation of the poultry farm, carbon dioxide (CO^2) and water vapor, as well as dust and ammonia (NH_3) are emitted into the atmosphere).
	2. Decomposition of broilers manure creates unpleasant odors through various gases of ammonia (NH_3) and hydrogen sulfide (H_2S).
	3. Dust during mixing of animal feed or feeding, delivery and removal of growing broilers (down).
	4. Boiler chimney emissions up to 200 kW - flue gases and solid particles.
The professional explanation of the problem	1. Inadequate ventilation of object; Poor technical and technological solutions for air conditioning.
	2. Non-existence of lagoon or object for manure.
	3. Inadequate ventilation of the object.
	4. Poor heating management; Failure to maintain the chimney and boiler room system.
A professional measure to reduce or solve a problem *(techniques, technologies)*	1. Use technically correct devices and equipment to reduce emissions of pollutants into the air and prevent incidents; Ventilation of the installation of object should be reported in such a way that it satisfies the conditions prescribed by the broilers breeding technology, i.e. to

[37] Source: Rulebook on facilities that can be built and put into operation only if they have an environmental permit, 2012

[38] Source: Nitrates Directive, 1991

	satisfy the required quality and quantity of air exchange, as well as the condition of minimizing the spread of unpleasant odors outside the production object; Maintain the ventilation system in the farm's production premises in good condition in order to eliminate unpleasant odors in the environment; Sprinkle zeolite preparation on the floor of the farm in order to reduce the intensity of unpleasant odors (reduces the concentration of NH_3 and CO_2).
	2. After the cleaning of the object, broilers manure with a mat (fertilizer) should be temporarily disposed of in the designated area - lagoon within the subject plot (which needs to be built), protected from atmospheric influences and without the possibility of spreading unpleasant odors to the environment or export them directly to agricultural areas; In order to reduce the emission of unpleasant odors into the air, spread the manure on the ground during the cold weather without winds, and plow it immediately.
	3. Checking the correctness of the system for filling and emptying food silos; Checking the ventilation system periodically.
	4. Use environmentally - friendly fuel - wood, well dried; Clean the chimney regularly and maintain the boiler room.
Monitoring	1. NO.
	2. NO.
	3. NO.
	4. NO.

The most common emission to water recognized by all farms is improper storage of permanent (Table 2.). The constant has large amounts of nitrates and nitrogen that dissolve well with water. If the soil does not receive these substances adequately, groundwater pollution can occur. The big drawback is that the EU Nitrates Directive[39] has not been adopted in BiH. This problem of legislation is the same as the fourth recognized lack of legislation in the Republic of Srpska.

Table 2. Negative impact on the water

The emission *(negative impact on the water)*	Inadequate storage of fertilizers can contaminate the soil, and directly groundwater, primarily with nitrates (NO_3) or nitrogen (N).
The professional explanation of the problem	Non-existence of lagoon or adequate storage for litter; Nitrates dissolve well in water, and excessive amounts of nitrates in the soil cannot be used by agricultural crops, but they are leached from the soil and thus can cause groundwater pollution.

[39] Source: Nitrates Directive, 1991

A professional measure to reduce or solve a problem *(techniques, technologies)*	Construction of a lagoon which has implemented system for separation of urine and other aqueous impurities from feces.
Monitoring	NO.

The most common emissions to soil recognized by all farms are the discharge of wastewater after cleaning the facility and inadequate storage of dead broilers (Table 3.). It is mandatory to implement biosecurity measures on farms, which include regular disinfection, desinsection and deratisation of the object's on the end of each turn. Disinfection is often done unprofessionally and without clearly defined chemicals that are environmentally friendly for release into the environment. It is usually practice of farms, to do not meet the basic criteria of environmental protection for outfit, equipment and objects in animal husbandry in the Republic of Srpska/BiH. Legislation is not fully defined for environmental protection in this area. This is the fifth recognized lack of legislation in the Republic of Srpska/BiH.
In addition, inadequate storage of dead broilers can cause various types of diseases on the site and attract the attention of stray and wild animals. According to the valid veterinary legislation, proper storage of this type of waste is mandatory. In practice, this type of waste is resold to pet food manufacturers.

Table 3. Negative impact on the soil

The emission *(negative impact on the soil)*	1. Improper cleaning, i.e. washing and sanitation of the poultry object before the introduction of a new turns.
	2. Mortality of chickens, 2-4% of total production.
The professional explanation of the problem	1. Inadequate object without concrete channels - drains and collectors; Disinfectants with wastewater reach the surrounding soil.
	2. Inadequate storage of organic waste - dead broilers can cause disease and the arrival of stray animals at the site.
A professional measure to reduce or solve a problem *(techniques, technologies)*	1. Construction of new object or adaptation of existing object to the needs of production capacity with the installation of environmental wastewater collectors; Use of environmentally-friendly disinfectants.
	2. Adequate storage of this type of waste, freezing and further sale for processing of pet food or adequate recycling in production; Build a fence around the building and restrict access to stray or wild animals.
Monitoring	1. NO.
	2. NO.

Standards of circular economy, waste reduction, reuse and recycling are not present/or implemented prctice to a large extent on the surveyed farms. Waste reduction measures are not clearly defined according the Waste Framework Directive.[40] Also waste reuse measures, such as biomass for energy conversion or heating at the site in question, have not been recorded on any farm. In addition, none of the farms has the practice of collecting gases (through extraction and environmental technologies) that should be used as an energy source in the production of electricity or heating. However, it is a good practice to sell dead broilers for further use in the production of pet food. Recycling, i.e. sorting of recyclable waste is defined by measures of AEP.

Conclusion

Environmental management of livestock at the local level in the entity of the Republic of Srpska/BiH has major legal shortcomings in terms of defining pollution, measures and monitoring. Therefore, sustainable management of food production in accordance with the principles of the circular economy is not entirely possible at the local level. This could be a problem hampering the realization the second goal of Agenda 2030 for sustainable development viz. food security and nutrition and sustainable agriculture.

The link between sustainable development – circular economy – environmental farm management – sustainable agricultural business – sustainable food productions is neither recognized in BiH nor implemented in the legal and institutional framework. Therefore, it is necessary to improve the legal regulations in BiH on the example of environmental permits and environmental management of farms in the ares of local level, primarily the implementation of EU directives (such as Nitrates Directive) in the entity legislation to set Circular Economy (RRR) standards for sustainable agricultural production and sustainable food production.

ASH CONTENT OF SOME OAK SPECIES

Gülnur MERTOĞLU ELMAS*, Beyza KARABULUT

Department of Forest Industry Engineering, Forestry Faculty, Istanbul University-Cerrahpasa, 34473, Istanbul, Turkey
*Corresponding author: mertoglug@iuc.edu.tr

Abstract

Oak, which is a member of the Fagaceae family, has a wide distribution in Turkey and there are 18 oak species naturally. They are mostly trees, some are tall shrubs, deciduous or evergreen plants in winter. The general area of oak forests in Turkey is 5.152.561.8 hectares in total. Oaks are divided into three groups as white oaks, red oaks and evergreen oaks according to the anatomical structure of their wood, leaf and bark characteristics and the ripening time of their fruits. Oak is valuable for Turkey in terms of species diversity, the area it covers, the use of wood and by-products. Oaks are used in areas such as furniture, plywood, carving, parquet, and building materials. Within the scope of this study, ash determination tests in oak woods were carried out from stem-woods. The ash amounts of sessile oak *(Quercus petraea)*, Hungarian oak *(Quercus frainetto)* and brash (Turkish) oak *(Quercus cerris)* were determined and the ash amounts were found to be respectively 0,41%, 0,51% and 0,57%. It was measured that the average ash amounts of oak species was 0,49%. When the average ash amounts of oak species we compared with broadleaves species ash amounts; it was determined that ash, poplar, maple, alder values we close to each other. Average ash of oak species, it is higher than coniferous species and higher than oak and beech, and lower than chestnut in the Fagaceae family. It is suggested that oak ash can be used in agriculture and soil nutrition for plants.

Keywords: *Wood ash, Fagaceae, Oak, Oak ash.*

Introduction

Quercus L. (Oak); it is a member of the Fagaceae family, which hosts 8 genera, including *Fagus* L. (beech) and *Castanea* L. (chestnut), and 620-750 species of these genera. Distributed in temperate and sub-tropical regions of the northern hemisphere. There are 18 species of oak naturally in Turkey. They are mostly trees, some are tall shrubs, deciduous or evergreen plants in winter. The general area of oak forests in Turkey is 5.152.561,8 hectares in total. Of this, approximately 2,105,937.4 hectares are plantation and the remaining 3,046,624.4 hectares are degraded, coppice and bush. Oaks are divided into three groups as white oaks (section: *Quercus*), red oaks (section: *Cerris*) and evergreen oaks (section: *Ilex*) according to the anatomical structure of their wood, leaf and bark characteristics and ripening time of their fruits (Akkemik 2018, Yaltirik 1984, URL 5).

Wood oak used building timber, soil, bridge construction, small ship construction, agricultural equipment, machine building, furniture, parquet, veneer timber, fence posts, traverse, wood charcoal, plywood, carving. Fruit and leaves are also used as animal feed (Ertas 1996, Yaltirik 1984, URL 5).

The oaks analysed within the scope of this study sessile oak (*Quercus petraea*), Hungarian oak (*Quercus frainetto*) and brash (Turkish) oak (*Quercus cerris*). These oaks were compared with

coniferous species (softwood), broadleaves species (hardwood) and Fagaceae family by ash determination.
Sessile Oak (*Quercus petrea*); It is the species with the widest distribution area among the oak species found in our country. It spreads naturally in most parts of Europe, the Caucasus, Iran and Turkey. It belongs to the group of white oak trees and is used in barrel production (Sahin 2016, Ozturk 2013).

(a) (b) (c)
Figure:1: Sessile oak (a) gallnut, (b) stem, (c) leaf (URL 2)

Hungarian Oak (*Quercus frainetto*); It spreads naturally in northwest Turkey, southeast and middle Europe, South Italy and the Balkans. It is one of the most preferred broadleaves species by the forest products industry. Belongs to the group of White oaks (Ozturk 2013, Sahin 2016).

(a) (b) (c)
Figure:2: Hungarian Oak (a) leaf, (b) stem (c) gallnut (URL 3)

Brash (Turkish) Oak (*Quercus cerris*); It spreads naturally in Western Turkey and most of Anatolia, in Central and Southeastern Europe. The feature that distinguishes it from other species is that the female flowers have hairy auricles. It is in the group of red oaks (Ozturk, 2013).

(a) (b) (c)
Figure:3: Brash (Turkish) (a) stem, (b) leaf, (c) gallnut (URL 4)

Wood is a chemically complex material and there are many chemical components in it. Most of the wood consists of organic (almost 99%) and a small amount of inorganic (about 1%) materials (Fengel and Wegener, 1989).

Inorganic materials are also in the ash formed as a result of the burning of wood. Ash content in temperate area is between 0,1-1%. The amount of ash in local tree species is 0,1-0,5% compared to the dry weight of the wood. While calcium (almost 70%), potassium and magnesium are present in the ash at a high rate; sodium, iron, sulphur, phosphorus, silicon, chlorine, aluminum and lithium are also found in small quantities. The mineral composition of wood undergo change depending on the habitat, climate, age, cutting and location of the trees (Fengel and Wegener 1989, Bozkurt and Erdin 2013).

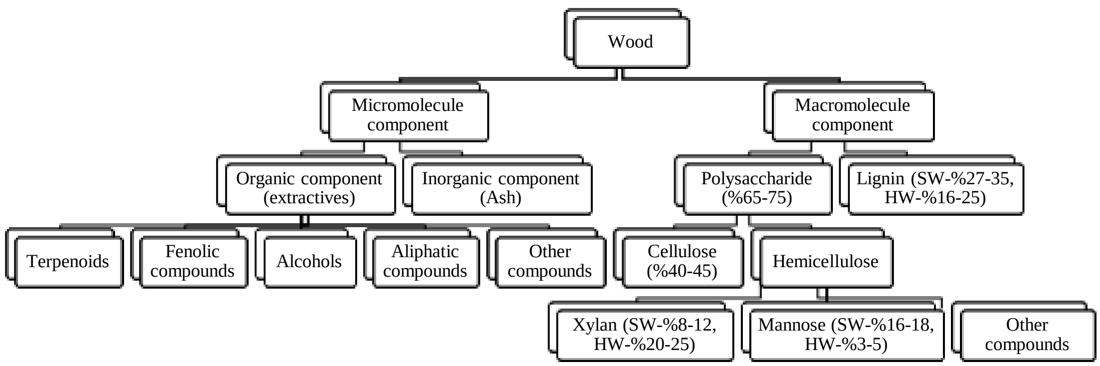

Figure:4: Chemical Component of Wood (Fengel and Wegener, 1989) (SW=Softwood (Coniferous species) HW=Hardwood (Broadleaves species))

The ash obtained as a result of wood burning is 1% of the wood weight. Wood species, humidity, specific gravity, ash and extractive materials are the parameters that affect the thermal values of wood. Since a certain part of the heat generated by combustion evaporates the water in the wood, the amount of moisture increases while the calorific value decreases. The calorific value also increases with the increase of extractive materials. As the amount of ash in the wood and bark increases, the calorie value decreases (OGM Bioenergy Report, 2019).

The stem-wood value of the oak is 4620 kcal/kg, and the branch-wood value is 4692 kcal/kg. While the average gross calorific value of stem-wood is 4664 kcal/kg, it is 4620 in branch-wood. The gross calorific value of oak is close to the stem-wood average (Erten and Onal, 1985). The thermal degradation of broadleaves species are lower than those of coniferous species, which is explained by the presence of heat-sensitive pentosans in broadleaves species (Atilgan and Peker, 2015).

Broadleaves species generally produce more ash than coniferous species (Fengel and Wegener, 1989). Elemental percentage in broadleaves species stem ash; potassium 20,4%, calcium 19%, phosphorus 4,2%, magnesium 3,6%, manganese 0,8%, iron 0,5%, zinc 0,4%, sulphur 2,1%, boron 0,05%, copper 0,04% (URL 1). Wood ash contains 5-30% carbon. The density of wood ash decreases with increasing carbon content. It depends on parameters such as chemical and physical properties, combustion temperature, species of wood (Siddique, 2008).

On average, the content of macrostructural materials in the ash of oak wood; total carbon 190,3 g/kg, total nitrogen 8,7 g/kg, phosphorus 22,9 g/kg, potassium 127,7 g/kg, calcium 268,8 g/kg, magnesium 34,9 g/kg and sulphur 24,3 g/kg. The content of the heavy metals in oak wood as an average; cadmium 10,4 g/kg, lead not found, zinc 592,2 g/kg, copper 197,6 g/kg, manganese 840,2 g/kg, nickel 32,8 g/kg and crom 27,3 g/kg (Becher *et al*., 2018).

The highest macrostructural material in oak wood ash is calcium, followed by total carbon. The lowest is total nitrogen. Manganese is the most in heavy metal content and followed by zinc. Lead has not been found, and cadmium is the lowest.

Macro elements in red oak ash *(Quercus rubra)*; aluminum 6,8 mg/kg, calcium 366 mg/kg, iron not measured, potassium 60,8 mg/kg, magnesium 52 mg/kg, manganese 14,9 mg/kg, sodium 0,8 mg/kg, phosphorus 15,6 mg/kg, sulphur 18 mg/kg, silicon not found. Macro elements in White oak; aluminum not determined, calcium 314 mg/kg, iron 0,9 mg/kg, potassium 102,5 mg/kg, magnesium 75,7 mg/kg, manganese 1,4 mg/kg, sodium not determined, phosphorus 5,6 mg/kg, sulphur 12,1 mg/kg, silicon 1,3 mg/kg (Pitman, 2006).

About 70% of the ash is considered garbage and is collected in the landfill. 20% is used for soil reinforcement, since it contains all essential minerals except nitrogen, it is a source of nutrients for plants, and when it is returned to the soil, it has a calcifying effect. It is used as fertilizer in agriculture. Two important properties of wood ash are its high pH and neutralizing capacity. Wood ash recycling is a possible way to prevent the increased acidity of the soil, and in forest ecosystems the addition of ash usually increases with dose. The remaining 10% of wood ash is used in various fields such as construction materials, metal recovery, pollution control, cleaning, public health, insulation, preparation of some foods (Karltun *et al.,* 2008, Sidduque 2012, Naylor and Schmidt 1986, Augusto *et al.,* 2008, Campbell 1990, Alptekin 2019).

Materials and Methods

Oak wood samples were obtained from Istanbul Fatih forest (Bahcekoy, Istanbul). Firstly, the bark parts of the samples were removed and wood cut into chips with a thickness of 2 or 3 mm. The screening process (40 mesh) was applied by grinding in a Wiley blade mill.

Dry matter determination of oak woods was carried out according to TAPPI T412 om-06 and ash determination according to TAPPI 211 om-85 standard.

Results and Discussion

The average dry matter ratio was found to be 90% in brash (Turkish) oak (*Quercus cerris*), 78% in sessile oak (*Quercus petraea*) and 90% in Hungarian oak (*Quercus frainetto*).

Sessile oak was the lowest, brash (Turkish) oak and Hungarian oak was the highest value. Percentages of ash determination in oak species; it was determined as 0.51% in Hungarian oak, 0.41% in sessile oak and 0.57% in brash (Turkish) oak. The average ash percentage is 0.49%. The highest was brash (Turkish) oak, the lowest was the sessile oak.

The comparison of oak species was made over the stem-wood values. Compared to coniferous species, the average ash of oak species was higher. As seen in Figure 5; oak species compared to broadleaves species; they have close values with ash, poplar, alder and maple.

Compared to the Fagaceae family (oak, chestnut and beech) given in Figure 5, the average ash of oak species is higher than that of beech, but lower than that of chestnut.

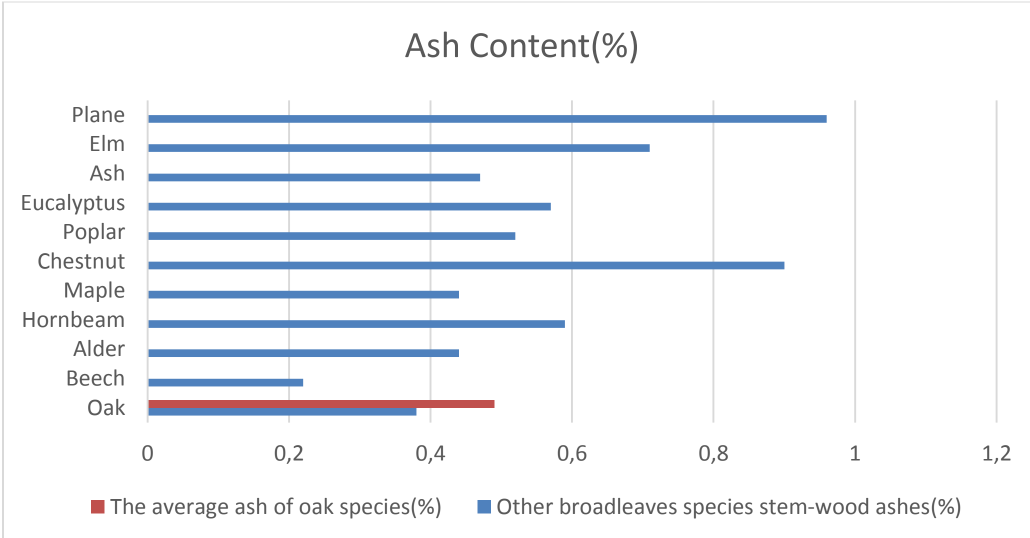

Figure:5: Compared with broadleaves species and ash average of oak species

Conclusions

The average ash of oak species; it is higher than coniferous species and close to some of the broadleaves species (ash, poplar, maple, alder), and higher than oak and beech, and lower than chestnut in the Fagaceae family. Oak wood ash can be used in agriculture and in soil for plant nutrition.

Abstract

The use of waste paper as a raw material in the production of paper and cardboard is increasing day by day. Recycled paper is obtained by collecting and classifying waste paper and repulping it through the recycling process. The most commonly used waste paper types in recycling process are old corrugated cardboard, white office paper, old newspapers and magazine paper and waste paper mix consisting of a mixture of one or both of them. Non-fiber resources that vary according to the type of waste paper are removed in recycling processes. The heterogeneous waste paper raw material is desirable to form homogeneous pulp suitable for paper production. Recycling of waste paper and cardboard provide a new product with economic added value and appreciation. Increasing the production of recycled papers decreases the cutting of trees and this ensures the sustainability of forests and prevents the releases of hazardous chemicals to environment. Knowing the impact on quality parameters is important to analyze changes in fibers obtained from waste paper and cardboard recycling. Recycled fibers are rigid and more fragile than virgin fibers because they lose their flexibility. The bonding potential in the fibers is lesser and their surface areas are narrow and swelling properties of fibers are low. As they have undergone hornification, their breaking length and burst strength are low, while tear strength is high. Since the fine fibers are abounding, their opacity is high and their brightness is low. Ash content of recycled papers differs according to type of waste paper.

Keywords: *Waste papers, Recycled papers, Recycled fibers, Fiber morphology***.**

Introduction

Recycled paper is the paper produced as a new product by collecting, classifying (according to BS EN 643, 2014) of the waste papers and recycling them into pulp again. The most recycled waste paper sources are; mixed waste papers, old corrugated cardboard, white office papers, old newspaper and magazine papers. Those that are not recycled in terms of hygiene and cleaning; toilet papers, paper and towel wipes etc. are cleaning papers. In waste paper, depending on the type of waste paper, non-fiber resources; filler, starch, adhesives, staples, dye, coated materials, ink etc. are found. It is desirable to form the most suitable homogeneous pulp for paper production from the heterogeneous raw material coming from a wide variety of waste paper sources (Atik and Ok 2017, Akyıl 2018, Kırcı 2003).

The increase in consumption along with the growing population causes an increasing occurence of waste paper and cardboard, and a decrease in raw materials and natural resources. In order to ensure the sustainability of the raw material, the emergence of a new product with economic added value by applying the recycling process to paper and cardboard wastes gains importance.

The paper industry is one of the industries that widely uses the recycling process. According to the annual report of SKSV; while the total amount of recycled (domestic and imported) waste paper was 4,352,106 tons in 2019, it increased to 4,669,326 tons in 2020 and increased by 7,3%. Paper and cardboard industry recycling (total domestic waste paper amount/consumption) in Turkey in 2020 is 46,8%. The recycling rate for only packaging paper and cardboard is 59,5%. Total waste paper use is 3,627,052 tons in 2020 (SKSV, 2020).

Recycling Process

The efficiency is between 80-90% due to fiber losses in the recycling process and additives added to the fibers (Atik and Ok, 2017). The recycling processes of waste paper are respectively; pulping, screening and cleaning, dispersion, deinking and bleaching.

a)Pulping: It is the unit that enables the fibers of waste paper to be separated with the help of water and turned into pulp. Here, non-paper materials and ink and filler are removed (Kırcı 2003, Scott 2019).

b)Screening and Cleaning: It is the process of removing materials outside the paper, which are undesirable due to the size and magnitude of the pulp. In cleaning, very small solid materials are separated from the pulp (Kırcı 2003, Scott 2019).

c)Dispersion: It is the part where dirt and ink particles on the surface of the fiber are removed so that they are not visible in the final product and dispersed in the pulp suspension. Re-fibering of recycled paper by dispersion becomes easier (Kırcı 2003, Scott 2019).

d)Deinking: It is the section where the printing inks in the waste papers are removed. Parts of ink detached from the fiber surface are removed during screening, cleaning, flotation and washing of the waste pulp suspension. The effectiveness of ink removal varies with the size, shape and density of the ink particles (Kırcı 2003, Scott 2019).

e)Bleaching: The color of the pulp is lightened by the use of chemicals that decolorize the dye and colored lignin structures in the pulp. This process is preferred in the production of limited and high quality pulps (Kırcı 2003, Scott 2019).

Recycling effects less mechanical damage to the fibers during the pulping process. Chemical pulp causes fiber damage, changes in fiber morphology and chemical composition of the fiber. Mechanical pulping, on the other hand, is a harder process that often causes severe mechanical damage to the fibers, fiber shortening and the formation of fine fibers (Keranen and Retulainen, 2016).

Interactions between fiber properties and process variables

During the recycling process, the fiber dimensions of the waste pulp can be affected by the pulper (pulping), dispersion unit and refining processes. The fiber sizes mentioned here are; fiber dimensions, including the length of individual fibers and the cross-sectional areas of the fibers (Ellis and Sedlachek, 1993). As the recycling of papers is repeated, mechanical fragmentation occurs in the fibers, the debrises (fine fiber) in the pulp are removed during the screening and cleaning processes. The strength of the pulp decreases with each recycling process (Kırcı, 2003).

Advantages of Recycling

Since the raw material is waste paper, the dependence on the forest decreases, while the cutting of trees is prevented, the sustainability of the forests is ensured. Waste paper recycling processes are carried out easily, using less chemicals and less energy compared to wood pulp production. If secondary fibers are compared with primary fibers, they can be recycled 5 or 6 times. Filling and covering materials can easily adhere to the fibers. On account of the repetitive recycling of waste paper, water pollution, air pollution and water use are reduced. Recycling of waste will reduce the need for raw materials and contribute to the country's economy (Akyıl 2018, Bekiroglu and Mertoglu Elmas 2017, Kumar *et al.*, 2019).

Disadvantages of Recycling

Waste papers that are not classified well can cause problems when processing. During the recycling of waste paper, high fiber losses are experienced. As the number of recycling increases, the strength properties of the fibers decrease. Rising prices of chemicals, energy and waste paper can direct manufacturers to cheap, alternative fiber sources (Kırcı 2003, Sahin 2016).

Quality parameters of Recycled Paper

Waste paper is a used paper from virgin or secondary pulp. Therefore, the raw material of recycled paper quality has to be kept within certain limits, and this is often difficult. In order to ensure the desired production quality, the quality of recycled paper must be carefully determined and these quality variables must be kept under control. Important variables affecting quality parameters; fiber properties, strength properties, optical properties, ash content and contaminants.

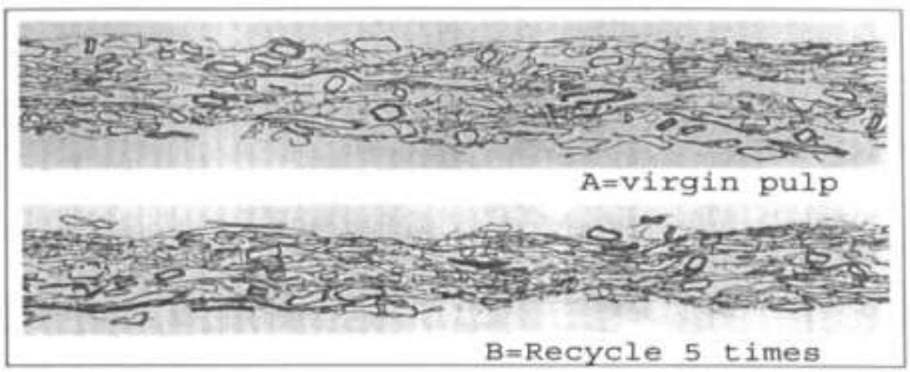

Figure:1: Primary fiber and 5 times recycled secondary fiber (Nazhad, 2005)

Secondary fibers are shorter than primary fibers, have a rigid structure, narrow surface areas and lower bonding potential. Fiber surfaces may be contaminated with resin and fatty acids. These materials reduce the surface energy of the fibers. At the same time, the swelling or plastification properties of the fibers are low, the fine fibers are high, and the individual fiber resistance is low. Theoretically, long fibers have higher strength properties than short fibers. The physical strength properties of papers produced from secondary fibers are lower than papers produced from primary fibers. The reason for this is the changes in the structure of cellulose as a result of drying (Nazhad 2005, Sahin 2014).

Cellulose fibers swell when treated with water, and shrink when water is removed. This situation is important for paper formation. In recycled papers, cellulose undergoes both a physical and chemical change. When dried fibers come together with water again, they lose their swelling properties in water. The condition in which this inhibited recurrent swelling occurs is called hornification (Minor 1994, Laivins and Scallan 1993). Hornified fibers are stiffer due to internal collapse and more resistant to fibrillation due to strong intrafiber bonding of polysaccharides at or near the fiber surface. The hydrophilic feature of hemicelluloses like cellulose in the building blocks of fibers allows the fibers to swell. If the hemicelluloses are removed from the cell wall, the swelling property of the fibers is negatively affected. Hornification reduces the tearing, bursting, folding resistance and density of the paper. There is a decrease in the resistance properties until the 4th recycling (Atalla and Minor 1992, Laivins and Scallan 1993, Pönni *et al.*, 2012, Sahin and Uner 2004).

Hubbe *et al.* (2007) explained the loss of swelling property of cellulose fibers during drying and rewetting, the decrease in flexibility of the fibers, the reduction of their surface area, and the fine fibers formed in the beaten paper. It has been mentioned that the changes in the strength properties of the paper due to the shortening of the fiber length, the fragilty of the recycled fibers increase and accordingly they are susceptible to breakage during refining.

Wistara *et al.* (1999) stated that the recycling process increases the amount of acid in the fibers and decreases the free surface energy. They explained that the formation of this situation may occur due to the deterioration of hemicelluloses, the increase of carboxylic groups on the surfaces or oxidation. According to AFM (atomic force microscope) and SEM (scanning electron microscopy) data, they claimed that fine fibers increase in recycling. In particular, they explained that the fine fibers increased the degree of crystallinity.

Diniz *et al.* (2004) reported that hornification, which causes a decrease in the hydrogen bonding potential of the fibers during the production of recycled papers, cannot be fully explained, but as a result of the studies, hydrogen bonding occurs after drying or water removal of cellulose fibers.

Ellis and Sedlachek (1993) studied the effect of recycled fibers on breaking length. They found that as the number of recycles increased, the breaking length decreased. In addition, they looked at burst resistance. They found that the burst resistance decreased (from 500 kPa to 300 kPa) with increasing recycling number. In addition, as the number of recycling increases; it has been reported that the tear strength increased by more than 20% and the stiffness property increased by more than 10%. At the same time, as the number of recycling increases; the apparent density (10%), elasticity-tensile (approximately 12%), breaking length (close to 20%), folding resistance (approximately 35%) and bursting resistance (approximately 40%) were also examined to decreases.

Wistara and Young (1999) reported that the strength properties and density of recycled papers decreased. While tearing resistance showed different properties from breaking and burst resistance, they explained that there was an increase in the first recycling result and a decrease in the second recycling. They explained that hemicelluloses are effective in regulating the physical strength properties of fibers in recycling.

Nazhad (2005) mentioned that the recycling effect on fiber properties depends on pulp making or papermaking background, but these effects disappear after the fifth cycle, even in the worst case scenario, recycled pulp loses 10-30% of its normal strength after the fifth cycle. He explained that breaking strength affects parameters such as fiber strength, fiber dimensions, and fine fibers density.

Atik (1999) used three types of paper as newsprint (recycle 6 times), white paper (recycle 6 times) and brown kraft (recycle 7 times) paper, applied recycling processes and performed the physical strength tests of the paper. He stated that there was not much change in the density of the paper after several recycles, and that recycling processes changed the physical strength properties of the paper. He explained that the tear strength started to decrease after the first recycling.

Sutjipto *et al.* (2008) found that as the recycling number of non-beaten softwood pulp increased, the tear, stress-breaking strength decreased, while the density first increased and then remained constant. In addition, as the number of recycling increases, the resistance properties in pulps of beaten softwoods increase; stress-breaking, apparent density decreased, and tearing increased.

Howard and Bichard (1992) found that the strength values (breaking length, burst index, tearing index) and density of bleached and beaten sulfate pulp were higher than those of sulphide pulp.
Gloss is one of the important optical properties. The gloss value is required to control the processes inside the factory such as fiber composition, ink content or deinking efficiency of the waste paper and to determine the performance of the machines. The gloss of recycled pulp controls not only the amount of ink but also the distribution of particle size. Ink particles smaller than 50 μm cannot be resolved individually by the human eye, but their presence reduces gloss and gives the pulp a gray tint. Ink particles over 50 μm appear as speckles. It has been stated that the opacity of the recycled papers from waste papers has increased (Bajpai 2014, Sahin 2014).
Waste paper as recycled paper raw material contains fillers and other additives besides fiber. Ash is important for the determination of the amount of inorganic materials originating from the filler in the pulp. The amount of ash varies according to the quality of the waste paper. Mixed office paper waste (15-35%), coated papers (25-35%) have the highest ash rates. Fillers and coating pigments with mineral content are used extensively in such papers (Kırcı 2003, Karıncalıoglu 2010).
Particles with a lower specific gravity and above 0.04 mm^2 are defined as dirt (Levlin and Söderhjelm 1999, Sahin 2014). One of the characteristics that can be used to distinguish the different grades of recycled paper is the nature of the additives and the fiber-free materials used in their manufacture. These materials should be treated as contaminants during recycling because they interfere with the recycling process and are often difficult to remove. Generally, non-cellulosic materials consistute 1-50% of the total weight of the recycled paper. Primary non-cellulosic contaminants include (Balos and Patterson, 1993):

- Fillers: kaolin, titanium dioxide, calsium carbonat and talk
- Resins, natural resin and wax
- Starch and gum
- Dyes and pigments
- Inks
- Hot melts, plastic veener and asphalt
- Styrofoam (solid foam) and treated tapes
- Heavy materials

Recycled paper materials, products made from secondary fiber, can be characterized by examining the relationship between the original sources of the fiber, and the recycled paper is usually recycled to a grade of similar or lower quality to the original (Balos and Patterson, 1993).

Conclusions

The quality parameters of recycled paper obtained from different sources of waste paper and cardboard were investigated. The quality parameters of recycled paper and cardboard are; fiber, strength and optical properties, ash content and contaminants. Quality parameters varied according to the class of waste paper and cardboard. Fiber loses swelling property in water and undergoes hornification, loses its stretching properties and becomes plastic, its bonding potential decreases, and individual fiber resistance is low. While the burst and breaking resistance of recycled papers is low, they have high tear resistance. Due to the ink content and the excess of fine fibers, the changes in the optical properties occur in the form of an increase in opacity, while the brightness and whiteness decrease. Since ash contains fillers and additives other than fiber, the amount of ash is high.

Abstract

A global shortage of conventional pulpable raw material is seen there were attempt in this century. Search for new fiber annual wood sources against hardwood has been underway during the last few decades. On the other hand, there were attempt to find and develop new fiber supplies such as wood particularly annual plants for paper and pulp industries. *Rumex crispus* L. plant is widely available in Turkey. Its extracts are known to have antimicrobial properties. It is thought that *Rumex* crispus will be used in the production of special papers due to its antimicrobial properties and also to obtain dyes. The anatomical image was taken in cross-section from the tubers of *Rumex crispus* L. and its relation to the fiber structure was investigated. Depending on the fiber properties obtained, the potential of these types to be used as raw material in paper production has been evaluated and discussed. Therefore, according to Shultze method were macerated *Rumex crispus* L. root samples and prepared microscopic slides for measuring fiber dimensions. In tests, fiber length, fiber width (diameter), lumen diameter and cell wall thickness were measured. When the fiber lengths of *Rumex crispus* L. annual plant are compared with annual plants such as hemp, barley straw, oat straw, rye straw, which are still in use, the shorter fiber dimensions show that it will allow its use in pulp like these plants. Also, it can be said that the pulp obtained from *Rumex cripus* L. which has a yellow pigment feature, can be used in the production of artistic special papers.

Key words: *Fiber properties, Rumex crispus* L., *annual plants, pulp, paper.*

Introduction

Using non-wood fiber for pulp and paper industry has seen huge demand in the world as a raw material. Also, the use of non-wood fibers is an increasing trend due to shortage of wood fibers and environmental considerations. Generally the commonly used non-wood pulp raw material sources are residues of agricultural plants such as bagasse, (straw and the silical associated problems), flax hemp kenaf (its inherently low lignin content and therefore higher cellulose content), jute (to produce specialty paper).
The trend towards alternative non-wood fiber sources is increasing in order to be an alternative to substitute wood sources such as decreasing broadleaves hardwoods and softwood a shortage of wood fibers and to find solutions to environmental concerns by evaluating the use of agricultural residues. Although until recently the use of non-wood fibers for pulp and papermaking was concentrated in countries where there are limited supplies of wood, even countries that no longer have sufficient wood supply due to environmental concerns shows a growing trend. This can be expected to grow further and the future said with confidence. Non-wood plant fibers appear to have as potential as traditionally produced pulp and papermaking raw material.

Rumex crispus (Labada) is a perennial vegetative cycle plant that can grow up to 150 cm tall. Most of the lower leaves are structured as substitute-like, reverse-spare-like and with widths greater than 3 times longer. The leaf stem is above, corrugated and has the largest plant cluster. (Chandra, 1998).

The plants can be found in non-cultivated, empty agricultural fields, in swampy areas and along road sides. It flowers during the period, May to August and can extensively be found in the following provinces of Turkey: Çanakkale, Istanbul, Bolu, Kastamonu; Coruh, Kars, Izmir, Ankara, Tunceli, Diyarbakır, Konya and Gaziantep (Davis,1965-1985; Yaltirik and Efe,1989; Mertoglu-Elmas *et al.* 2012)

Plant's roots and leaves are boiled for tea making. Leaves are also consumed in various ways. It grows extensively in Turkey.

A yellow colored pigment which is an antraquinone derivative, 1,5-dihydroxy-3-methoxy-7-methyl-antraquinone, can be extracted from *Rumex crispus* L. lumped root (Başkan *et al*., 2006). It has been proposed that the naturally colored special paper for using in the artistic field and in the packaging industry. This is very important specially using natural dye instead of synthetic dye (Mertoglu-Elmas *et al.* 2012).

The fibers of broadleaves woods (hardwoods) are shorter than those from coniferus (softwoods). Some annual's fibers are longer than hardwoods and softwoods. These fibers impart excellent optical properties to paper, however blending with softwood pulp is usually demanded to develop physical properties of paper.

The aim of this research was to determined the fiber dimensions of *Rumeks crispus* root and as well as fiber their suitability properties for pulping as an alternative fibre supply.

Materials and Methods

Naturally grown *Rumex crispus L.*samples were supplied from Atatürk Arboretum Bahçekoy, Istanbul, Turkey. As seen in Table 1 the specimens had average diameters approximately 4.0cm and 1.50m in heigth. Its roots were dried and chipped to prepare for fibering process. Fibering process of samples was performed according to Shultze's macerattion method (Mahesh *et al.* 2015; Chamberlain, 1915). After the fibers were thoroughly washed, they were mixed in the mixer for 3 minutes. The resulting fiber suspension was filtered in a Buchner funnel using a fine mesh strainer. Then, the fibers remaining on the strainer were placed in small-sized tubes for protection by adding glycerine to prepare microscope slides. While the mixture consisting of fiber and glycerin spreads homogeneously, it is dropped on the slide, a coverslip is placed on it and stabilized with varnish. When the suitability of raw materials for papermaking is evaluated, fiber dimensions such as fiber length, width, wall thickness and lumen width and provide important clues about the possibilities offered by the raw material for pulp production. In the measurements; fiber length, fiber width (diameter), lumen diameter and cell wall thickness were determined with an optical microscope (Leica DM2500, Istanbul, Turkey) in according to with TAPPI T232 cm-85 (1985) standarts.

Results and Discussions

Considering the fiber properties of *Rumex crispus* L., the possibilities using it as a raw material in the pulp and paper industry have been estimated through an analysis of results obtained from preliminary evaluation study of fiber morphology consist of fiber dimensions. *Rumex crispus* L.

root anatomic image was shown in Figure 1. As seen in Figure 1 tracheas were in the form of homogeneously undistributed clusters and their rays show a thick structure.

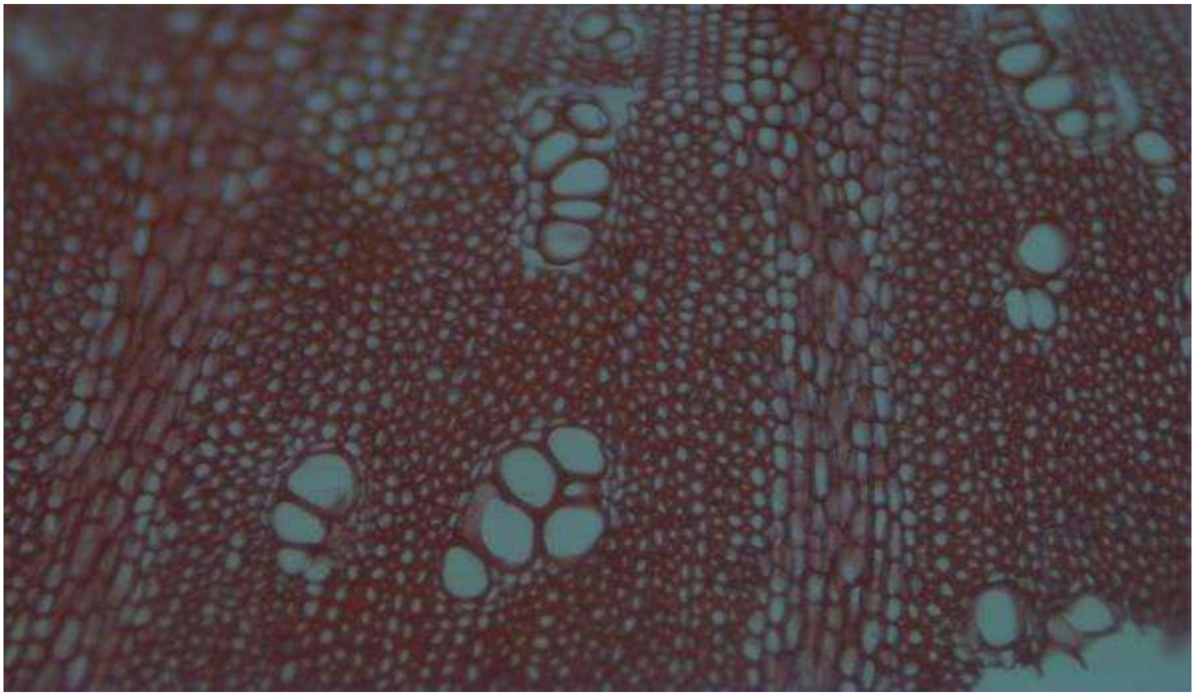

Figure:1: Image of a cross-section of the root of *Rumex crispus* L.

Images length of Rumex crispus L. was given in Figure 2.

DBH: Diameter at breast height

Fiber structure

Morphological fiber dimensions are length, width, cell wall, and lümen radius. Fiber dimensions act as indicators providing essential preliminary information about suıtability for pulp production and usability as wood raw material (Dinwoodie 1965; Bostancı 1987).

Suitability of wood and annual plant used as a raw material for paper production from pulp is evaluated over the resistance characteristics of pulp thorough the fiber length and fiber width. Fiber length affects paper strength properties positively. Cell wall thickness influences the

strength of individual fibers. The tearing resistance of paper made from very thin-walled fibers is quite low. Paper provides extremely thick-walled fibers exhibit low resistance and bulk due to insufficie flattening during paper formation (Elmas *et al*. 2018).
It has been observed that the average fiber length of the annual plants *Rumex crispus* plant (21.6mm), longer than the fiber length of cotton linter (7mm), close to the fiber length of hemp (bast) (25mm), oil flax (30mm). However, it was found that oat straw (44mm), barley stalk (47mm), rye straw (50mm) and hemp husk fibers had shorter fiber lengths (Atchison 1993; Atchison, 1997; Mengeloglu and Alma 1999 and Zomers *et al*,1995). The fiber length of *Rumex crispus* L. was typically in the middle class of long fiber sequence of annual plant species.
For the production of delignified pulp of hemp, organosolv processes can offer economical and environmental advantages, "hemp core and bast fibers can be readily pulped" (Zomers *et al*. 1995).
Comparing the fiber lengths of the *Rumex crispus* L. annual plant still in use with oil hemp, barley stalk, oat stalk, rye stalk have shorter fiber sizes, which indicates that it will allow their use in fiber pulp like these plants.

Conclusions

Rumex crispus L. has the potential as a sustainable raw material in paper production as a non-wood annual plant. Suitability of annual plant used as a raw material for paper production from pulp was evaluated over the dimensions of fiber thorough the fiber length and fiber width. Fiber length affects paper strength properties positively. The fiber length of *Rumex crispus* was typically in the middle class of long fiber sequence of annual plant species such as oat straw barley stalk, rye straw, which indicates that it will allow their use in fiber pulp like these plants.

Abstract

Irrigation is extremely important for food security and reducing the risk of drought. Approximately 70% of water is used in irrigation at a global level. The quantity and quality of water resources are decreasing due to climate change, increasing population and frequent droughts. This requires the reduction and efficient use of water used in agricultural irrigation. For this reason, the crop yield to be obtained by additional irrigation water applied considering the irrigation and operating costs and net margin per unit land area-NM (US\$ ha^{-1}) as well as the irrigation water productivity-WP_I (kg m^{-3}) and net economical water productivity- $NEWP_I$ (US\$ m^{-3}) are also important components for assessment of irrigation schemes. Because, the farmers and irrigation schemes are an economic enterprise that aim at higher profit by increasing the yield to be obtained from the unit area. In addition, WP_I is also an indicator of whether the irrigation water is used effectively. However, the water productivity begins to decline while irrigation water yields increase. Connecting this approach, the right of the intersection of the irrigation water-yield curve and the irrigation water-water productivity curve shows unnecessary excess irrigation water application. Thus, it can be decided at which point the irrigation can be stopped. This can give more optimal irrigation strategy. In this article, the relationships between WP_I, $NEWP_I$ and NM are evaluated and discussed using some experimental results in semi-arid regions.

Key words: *water productivity, water economic productivity, irrigation management.*

Introduction

Water use in agriculture plays a key role for food security in the world. Water saving technologies and efficient use of water, prevention of water loss have become important for water user sectors. Agriculture is the sector that uses the most water, and modernization of irrigation systems and appropriate irrigation management are required. This is achieved by accurately determining the crop water requirement and knowing the water productivity and economic return of irrigation.

Efficient and sustainable use of water resources has become inevitable due to some main reasons such as global climate change, drought, increasing population, increase in irrigated lands, excessive use of water in agriculture using traditional irrigation in all over the world. In addition, water demands have increased because of the growing population and developing industry. Consequently, more efficient use of water in agriculture has become significant because of the largest water user sector.

Engineers and irrigation scientists have used water/irrigation use efficiency to describe how effectively the water supplied to plants is used and how much water is wasted in the field, farm, command area or irrigation scheme level. Thus it is defined as "the ratio of irrigation water used by the crops in a farm or irrigation district area during plant growth period to the water diverted from a river or other reservuar.
Improvement of agricultural water productivity and irrigation efficiency is a critical response for increasing water scarcity and the sustainability of ecosystems and natural life, to meet demands of indutries and cities (Sharma et al., 2015). Thus, the analysis of water productivity and/or irrigation efficiency which is critically important to food production and food security (Perry 2011, Çetin and Kara 2019).
There are many different and evaluation criteria for irrigation and/or irrigation schemes depending on the study purpose due to irrigation is a very complex and has many components in practice. In this article, "irrigation efficiency-IE" (%), "irrigation water productivity-WP_I" (kg ha^{-1}), "net economical water productivity-$NEWP_I$" (\$ m^{-3}) and "net margin per land area" (\$ ha^{-1}) are discussed for the assessment and analysing of agricultural irrigation. Because, these assessment criteria are more usefull for the evaluations that directly affect agricultural irrigation management which are important in terms of guiding technical and practical issues and decision makers.

Basic Definitions on Assessment of Irrigation Management

Previously, in most publications, "water use efficiency-WUE" was used for both the water use rate and the crop yield per volumetric unit water (water productivity-WP). However, in recent years, WUE or irrigation efficiency (IE) and WP have been used as two different concepts with different meanings (Pereira et al., 2012). Thus, IE is an indicator how much the water diverted from the source is used by the plants and its unit is %. In other words, it is the ratio of the irrigation water used by the plants to the amount of water diverted from the reservuar. Water prodctivity (WP_{ETc}) is production of biomass and/or crop yield per crop evapotranspiration. Irrigation water productivity (WP_I) is defined similarly biomass and/or crop yield per amount of irrigation applied and the unit is kg m^{-3}. The considerations and assessments in this article are based on irrigation water productivity (WP_I) because the amount of irrigation water used in a farm and/or irrigation scheme is more important for farmers and irrigation authority. IE interests mainly the water districts or management agencies, while WP interests more farmers and research community. WP better explains to perspectives linking water usage with production levels and economic benefit. IE is an indicator of how effectively or beneficially the water supplied to the system is used, while WP is the total amount of production obtained against unit water (Levidow et al., 2014).

Irrigation efficiency

In an irrigation event, there will be some water losses due to evaporation, channel seepage and in-field farming practices. The important thing is to convey and use water with minimum water loss. "Irrigation efficiency" defined and used herein associated water conveyance and field water application efficiency. The most ideal irrigation efficiency is about 70% in surface irrigation, 80-85% in sprinkler and 90-95% in drip irrigation (Irmak et al., 2011). The concept of irrigation efficiency used here can also be defined total irrigation efficiency. This definition and its numerical results reflects about the efficiency of irrigation infrastructures, an irrigation network and/or irrigation in a farmer's field and irrigation management. Irrigation efficiency can be, thus, calculated the formula given below.

$$IE = \frac{Qa}{Qd} \times 100 \qquad (1)$$

Where, IE is irrigation efficiency (%), Qa is amount of irrigation water applied into the plant root zone by plants (m^3 or $m^3\ h^{-1}$), Qd is amount of water diverted from the reservuar (m^3 or $m^3\ h^{-1}$).

Irrigation water productivity

Irrigation water productivity (WP_I) in agriculture is defined as the ratio between the actual crop yield achieved (Ya) and the water use, expressed in kg m^{-3} (Pereria et al., 2016; Cetin and Kara, 2019; Fernandez et al., 2020).

$$WP_I = \frac{Ya}{IWA} \qquad (2)$$

Where WP_I is irrigation water productivity (kg m^{-3}), Ya is crop yield (kg ha^{-1}) IWA is irrigation water applied ($m^3\ ha^{-1}$)

Net economical water productivity

Net economic water productivity ($NEWP_I$) is the economic return to a unit of water. $NEWP_I$ is, thus, the ratio of net margin per irrigated area to amount of irrigation water applied per irrigated area (Fernandez et al., 2020; Uygan et al., 2021). To determine it is important for the basin and obtain the costs and process of the products. This is more important to the farmer than the biophysical water productivity as it means income but the cost of tradeoff negates (Oweis et al., 2017). $NEWP_I$ together with WP_I are useful and important for deficit irrigation and/or water scarcity.

$$NEWP_I = \frac{NM}{IWA} \qquad (3)$$

$NEWP_I$ is net economical water productivity (US$ m^{-3}), NM is net margin per unit land area (US$ ha^{-1}), IWA is irrigation water applied ($m^3\ ha^{-1}$).

Net margin per land area

The net margin is more important for farmers. They must consider this as well as irrigation water productivity and/or net economical water productivity. The net margin is depended mainly on the irrigation water applied in arid and semi-arid regions even if other inputs affect also. Net margin per land area was computed the simple formula given below (Fernandez et al., 2020; Uygan et al., 2021)

$$NM = R\text{-}C \qquad (4)$$

Where, NM is net margin per unit land area (US$ ha^{-1}), R: Revenue or gross income (US$ ha^{-1}), C is total fix and variable costs (US$ ha^{-1})

The Role of Water Productivity on Water Saving

Crop water productivity varies with location, depending on such factors as cropping pattern, agronomy, climatic conditions, irrigation technology, field water management and infrastructure, and on the labour, fertilizer and machinery inputs (Kijne et al., 2003). However, use of drip irrigation systems that provide very high irrigation water savings is much more important than the others. According to the results of many researches, drip irrigation can save between 20-50% of irrigation water compared to surface irrigation (Shah, 2011; Çetin and Akalp, 2019).

According to the results of the study carried out by Cetin and Bilgel (2002), if surface irrigation (furrow) is used for cotton, approximately amount of irrigation water of 950 mm (9500 $m^3\ ha^{-1}$)

is required whereas if surface drip and subsurface drip irrigation is used, irrigation water of 600 mm (6000 m^3 ha^{-1}) and 550 mm (5500 m^3 ha^{-1}) are sufficient for optimum cotton yield, respectively (Çetin et al., 2021). Considering the results of this study, surface and subsurface drip irrigation can save irrigation water of 37% and 42% compared to surface (furrow) irrigation, respectively. In addition, the cotton seed yield increased in drip irrigation systems although the use of irrigation water was decreased significantly lower.

Depending on the developing technologies, it has become important to use surface and subsurface drip irrigation systems, especially in field crops such as cotton and corn planted in rows as well as horticultural crops (Çetin and Bilgel, 2002; Shah, 2011; Uygan et al., 2021). Because, it is possible to reduce the evaporation from the soil using drip irrigation, especially in the early development periods of the plants (the percentage of canopy cover is not yet fully developed) because of the whole land surface is not irrigated (not wetted). This provides the significant irrigation water savings compared to traditional irrigations (surface irrigation).

The irrigation water productivity was higher at lower irrigation water levels and/or deficit irrigation. The increase in WP_I decreases relatively as long as the irrigation water increases, and thus, it decreases considerably in over-irrigation. Accordingly, WP_I decreases on the one hand while the crop yield increases on the other hand. For an effective and sustainable water management, the right side of the intersection of the irrigation water-yield curve and the irrigation water-WP_I curve can be considered as non-beneficial irrigation water applications (Figure 1). However, this approach might not be valid for all circumtances. In this situation, the economic return and water saving conditions should be taken into account together.

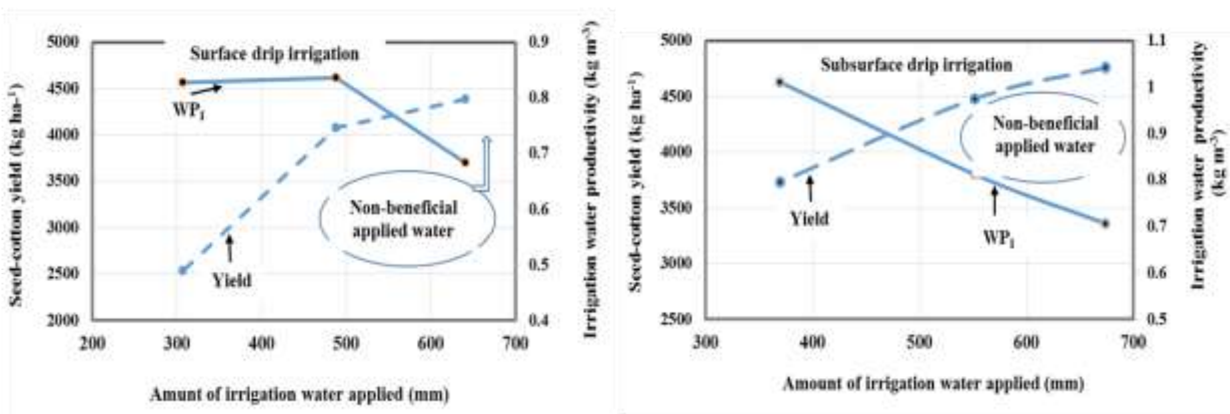

Figure 1. The relationships between irrigation water producrivity and seed cotton yield depending on the amount of irrigation water applied in surface and subsurface irrigtion drip (Cetin and Kara, 2019).

Evaluating drip irrigation systems in terms of irrigation water productivity and net economic water productivity, both surface and subsurface drip irrigation provided significantly higher values than those in surface irrigation. Connecting these results, the values of WP_I were 0.70 and 0.80 kg m^{-3} in surface and subsurface drip irrigation, respectively, while WP_I was 0.37 kg m^{-3} in furrow irrigation (Figure 2). Similarly, it is reported that subsurface drip irrigation increased both cotton yield and IWP compared to the other irrigation methods (Phene et al., 1992; Martinez and Reca, 2014; Jayakumar et al., 2015).

Use of Economic Water Productivity on Irrigation Management

According to the study carried out by Cetin et al. (2021), the net economic water producutivty ($NEWP_I$) using the surface and subsurface drip irrigation systems for cotton was 0.13 and 0.20 US\$ m^{-3}, respectively. These results were also significantly higher than 0.07 US\$ m^{-3} in the surface irrigation as WP_I (Figure 2). From this, it could be considered how important drip irrigation systems were important in terms of both water productivity and economic water productivity. Accordingly, the net income per unit of land, which is especially important for farmers, is higher in drip irrigation systems. All these data and evaluations are important especially in the creation of decision mechanisms in the management and sustainable use of water resources, and in terms of water saving and economic income. On the other hand, the net margin is depended mainly on the irrigation water applied. In other words, the main factor affecting the net income is irrigation. Because the increased level of irrigation water increased the yield (Perry, 2011). As a result, use of subsurface drip irrigation can provide very important advantages in terms of the total irrigation water used, water prodcutivity and total net incomes. The results showed that use of drip irrigation systems (especially subsurface drip) will be very important in terms of possible water shortage, decreasing water resources, farmers, irrigation schemes, regional and national income. However, all the advantages of drip irrigation systems can be realized/operated appropriately with the necessary implementation of correct engineering installation, suitable irrigation management and operation, taking into account the soil, crop and climate characteristics of the irrigated lands. In addition, all these systems need more expensive cost and experienced and trained users.

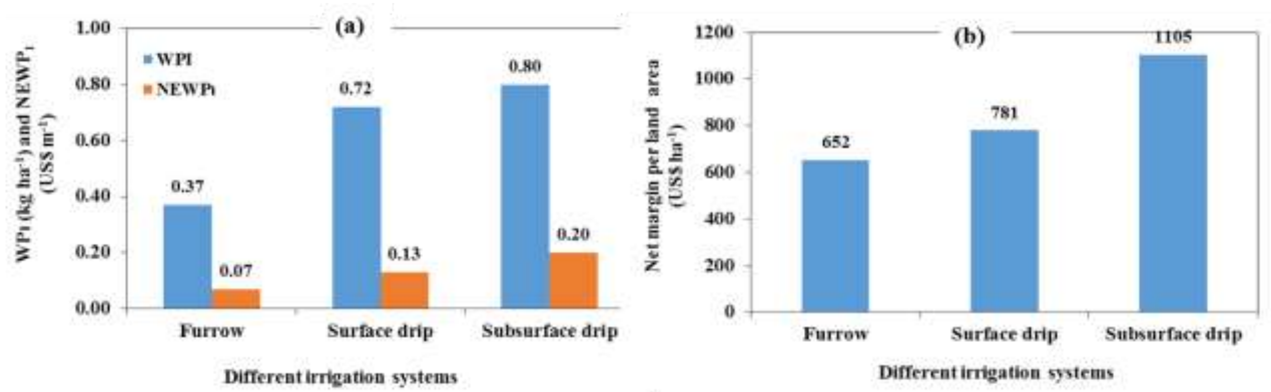

Figure 2. The effects of different irrigation systems on irrigation water productivity (WP_I) , net economic water productivity ($NEWP_I$) (a) and net income per irrigated land (b) (Çetin et al., 2021).

Conclusion

An appropriate irrigation management is extremely important in terms of the efficiency of irrigation investments and providing the necessary economic contribution and the sustainable use of soil and water resources. Water productivity, WP, (kg m^{-3}), net economic water productivity, ($NEWP_I$) (\$ m^{-3}) and land economic return for irrigated agriculture will be important for assessment of irrigation schemes and/or and decision makers. These data and assessments should be, thus, considered by farmers, irrigation operators, irrigation management authorities and decision makers at the regional, national and also international levels considering transboundary water.

Abstract

Overuse and overprescribing of antimicrobial drugs and disinfectants both in veterinary and human medicine have resulted in bacterial resistance leading to the need for new antimicrobial drugs. One of the possible alternatives is the use of essential oils - aromatic liquids of oil consistency, which by different methods are extracted from almost all parts of plants. It has been proven that essential oils, to varying degrees have antibacterial activity, that depends on the type of bacteria and the type and chemical composition of the oil used. The aim of this work is to examine the antibacterial activity of essential oil of St. John's wort, mint, cinnamon, clover, rosemary, thyme, garlic, fennel, lemon and reference antimicrobial drugs to the growth of the bacteria Escherichia coli. Agar diffusion method was used to determine the antibacterial effect of essential oils and different amounts of essential oils were prepared by dissolving with 96% ethanol alcohol (1:1 and 2:1). The largest activity was demonstrated by essential oils of St. John's wort, mint, cinnamon and cloves while essential oils of rosemary, thyme, garlic and fennel showed slightly weaker inhibition depending on whether they were used as pure oils or combined with alcohol. Also, the type of action of essential oils is determined.

Keywords: *antimicrobial drugs, antimicrobial activity, Escherichia coli, essential oils.*

Introduction

Etheric or essential oils are mixtures of highly volatile, lipophilic substances isolated from plants or plant parts. It is estimated that 3000 different essential oils are known, of which about 300 have commercial importance (Van de Braak et al.,1999). Essential oils are used in the food industry as aromas, in the pharmaceutical industry due to their pharmacological properties and in the perfume industry (Bauer et al., 1985, Bakkali et al., 2008.). Essential oils as natural, biologically active substances have insecticidal and antimicrobial activity and they are very important in the food industry for preserving food and preventing the development of pathogenic microorganisms. Spice plants or their essential oils, in addition to food, are used to achieve appropriate sensory characteristics, but which at the same time can provide both the appropriate stability and food safety (Kalaba et al., 2020.). Antimicrobial activity of spicy and medicinal plants has been known since ancient times. More than 1340 plants are known as a potential source of antimicrobial components, but a smaller number have been studied in detail (Wilkins and Board,1989). Flavonoids, saponins, tannins and alkaloids as natural ingredients of plants are known to have certain antimicrobial activity. It is also known that antimicrobial activity of plants such as thyme, rosemary, orange, cloves, etc., comes from essential oils (Radulovic et al., 2013). The amount of essential oils in plants varies widely and in some plants they are present in very small quantities (0.05 -0.1%) while in other plants the amount of essential oil can be up to 20%, like in cloves (Popović and Đurđević Milošević, 2008). In many studies it has been proven that some of the active components present in essential oil (carvacrol) can prevent the spread of *Salmonella spp*. in meat as well as to reduce the number of aerobic bacteria in meat and meat products and to act antibacterial on Escherichia coli, Staphylococcus aureus, Streptococcus pneumonia, Mycoplasma gallisepticum, Clostridium perfingens, Salmonella enterica (Feizi al., 2013). Food products can be carriers of various pathogenic bacteria that enter food through raw materials, during the production process or subsequent contamination. Their presence or toxins can cause poisoning of people, sometimes with a lethal outcome. Escherichia coli is one of the most well-known microorganisms in general. This bacterium is a normal resident in the intestines of humans and many animals, but certain strains can cause urinary and intestinal infections and lead to very severe forms of the disease with a possible fatal outcome (WHO, 2015). Also, Escherichia coli is a very resistant bacterium that easily adapts to different conditions in the external environment. It is very often a contaminant of various foodstuffs, and its presence is an indicator of fecal contamination of food. E. coli infections are most associated with poultry meat, minced meat, milk and dairy products, ready meals, as well as in fresh fruits and vegetables and their products. (Buchanan and Doyle 1997). The most common mode of transmission is from human to food and from food to human because healthy people, but also patients, excrete these bacteria and they are regularly found on the hands and clothes of patients. Diseases caused by Escherichia coli are always associated with poor hygienic living conditions, as well as food preparation (Kalaba, 1999). Due to the resistance of bacteria to many antimicrobial drugs, but also the ability of plants to synthesize biologically active substances, the use of preparations of plant origin in the control and suppression of bacteria has become increasingly important. In the European Union, there are several preservatives based on essential oils that are commercially available and contain the essential oil of rosemary, sage and citrus and glycerol (Mendoza et al.1997.). The aim of this study was to determine the influence of essential oils of different plant species used in the food and pharmaceutical industry as well as the antimicrobial activity of various antimicrobial drugs on the growth of Escherichia coli and to determine the type of action.

Material and methods

Material

Commercially available essential oils were used: St. John's wort, mint, cinnamon, clover, rosemary, thyme, garlic, fennel and lemon.

Test microorganisms

As a test microorganism in this study was Escherichia coli, a clinical isolate from the collection of the Laboratory for Microbiology of Animal Food, Feed and Water. The culture of Escherichia coli is sown in the nutrient broth (N- broth) and incubate for 18 hours at 37^0C. Petri plates with the appropriate base (M-H agar) are inoculated with 0.1 ml bacterial suspension with a concentration of 10^5CFU/ml.

Method

A disk diffusion method was used to examine the effect of essential oils on the growth inhibition of Escherichia coli (Kirby-Bauer., 1996). Sterile cylinders with a diameter of 9 mm were placed on the surface of the prepared petri plate, under sterile conditions. 10 µl of the appropriate essential oil was added dropwise into the cylinders by micropipette and the petri dishes were incubated for 24 h at 37°C. The essential oil was used as pure, mixed with 96% alcohol in a ratio of 1:1 and in a ratio of 2:1. As a control, 10µl of 96% alcohol was added to the cylinder. Three repetitions were performed for each essential oil. After incubation for 24 h the results were read by determining the diameter of the inhibition zone and the mean value for each type of essential oil was calculated.

Antimicrobial drugs

An antibiogram method was used to examine the effect of antibiotics on the inhibition of Escherichia coli growth. Antibiotic susceptibility was researched by the disc diffusion technique according to the Bauer-Kirby method (1996), which is in line with the CLSI laboratory recommendations (Clinical and Laboratory Standards Institute - 2013). In this part of the work disc papers for antibiogram with appropriate antibiotic were used ("Liofilchem" s.r.i Italy): gentamicin 10 µg, ciprofloxacin 5 µg, cefotaxime 30µg, ofloxacin 5 µg, chloramphenicol 30 µg, streptomycin 10 µg, ampicillin 10 µg.

Medium

Nutrient broth and Müeller-Hinton agar (Laboratorios CONDA S.A Spain) were used in this study.

Type of action

Also, the type of action of essential oil was determined. To see if essential oil has a bactericidal or bacteriostatic effect, a small piece of agar was taken from the inhibition zones and added to the nutrient broth. Incubation was performed 24 hours at 37ºC. If after incubation there was a turbidity of broth it is considered that the presence of essential oil of this plant is bacteriostatic. If, after incubation the broth remained clear the origin of the essential oil of that plant was bactericidal.

Results and discussion

The results obtained by examining the influence of different essential oils on the growth of *Escherichia coli* are shown in Table 1.

Table 1. The inhibition zone (mm) of etheric oils for the growth of Escherichia coli

Plant	The inhibition zone (mm) Etheric oil		
	Etheric oil	Etheric oil : Alcohol (1:1)	Etheric oil : Alcohol (2:1)
Hypericum perforatum	38.66±0.94	27.66±2.06	24.00±4.24
Menthe piperita	33.33±2.36	30.33±0.47	30.00±0.00
Cinnamomum Zeylonicum	33.66±2.87	32.33±2.05	30.00± 0.00

There is a notable difference in the activities of pure essential oils and alcoholic solutions of essential oils. Pure oil of St. John's wort, mint, cinnamon, cloves and fennel showed the greatest activity according to E. coli. Rosemary oil applied in proportion to oil: alcohol 1:1 showed greater activity than applied pure rosemary oil. Garlic oil applied in a ratio of 2:1 with alcohol showed a stronger effect than pure oil and of the combination oil: alcohol in a ratio of 1:1. Mint and cinnamon essential oil showed strong action in all combinations. The obtained results are in

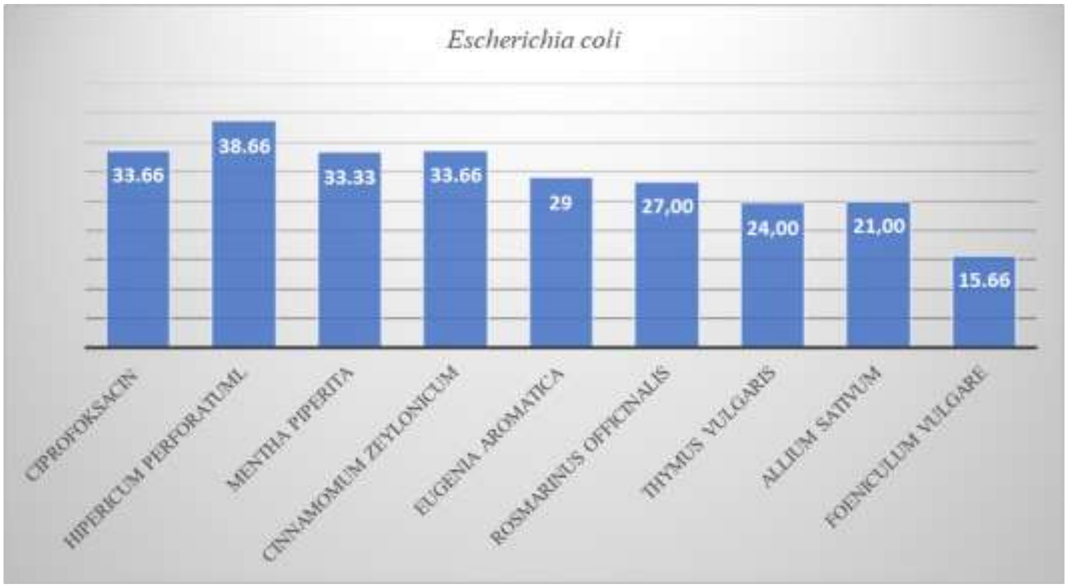
accordance with the works of other authors (Thompson et al. 2013, Burt and Reinders, 2003; Dorman and Deans, 2000; Emiroğlu et al. 2010, Kalaba et al. 2020, Kalaba et al., 2016a Kalaba et al., 2016b, Kalaba et al. 2019, Al-Nabusi I et al.2020, Lopez-Romero et al., 2015).
Lemon essential oils did not show antibacterial activity against E. coli in any combination which is contrary to the research of other researchers (Fisher and Phillips, 2006).
Studies have shown that essential oils in a concentration of 0.1 to 10 µl /g was very effective in preventing food spoilage. Oregano oil at concentrations of 7 to 21 µl/ g has an inhibitory effect on E. coli O157: H7 and leads to a decrease of bacteria in the eggplant compared to untreated control samples (Burt, 2004). Thyme essential oil in a concentration of 0.6% in combination with nisin (500 or 1000 IU / g) has an enhanced antibacterial effect against E. coli O157: H7 in minced beef. In the same study it was found that thyme essential oil in a concentration of 0.9% adversely affects the organoleptic properties of meat (Solomakos et al., 2008). Table 2 shows the zones of E. coli growth inhibition with antimicrobial drugs.

Table 2. Zones of growth inhibition of Escherichia coli achieved with different antibiotics.

Antimicrobial drugs	Zones of inhibition
Gentamicin	24,66±0,48
Ciprofloxacin	33,66±1,25
Cefotaxime	27,33±0,47
Ofloxacin	30,66±1,70
Chloramphenicol	30,00±0,81
Streptomycin	16,33±0,47
Ampicillin	0

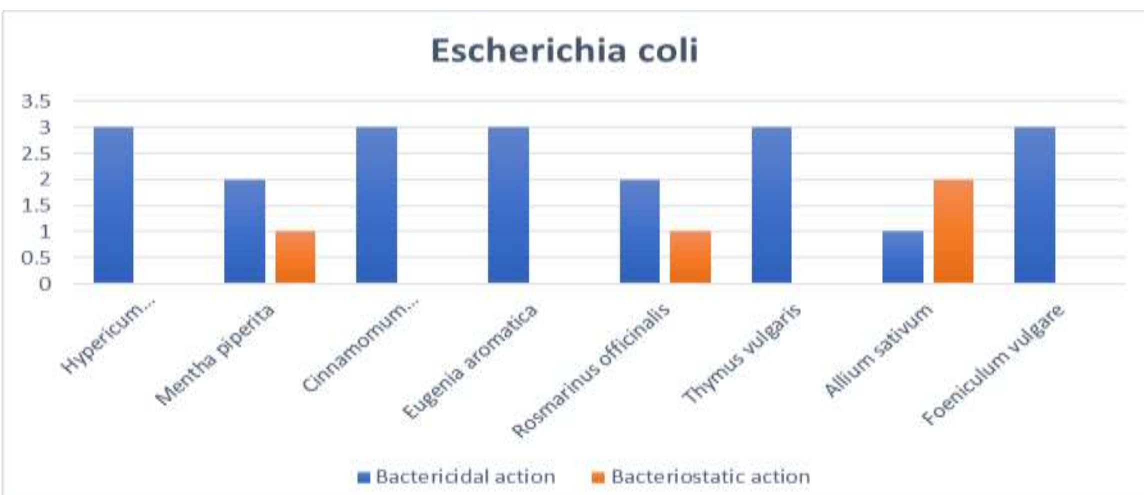
* Displayed values are given in mm and represent the mean value of inhibition zones for three measurements.

If the maximum inhibition zones of individual essential oils are presented in pure form and compared with the inhibition zone of the most effective antibiotic ciprofloxacin then the results are as in Picture 1., St. John's wort has more pronounced antibacterial activity against E. coli than the most effective antibiotic. Equally, it is noticeable that cinnamon has the same effect, and mint has the same effect as ciprofloxacin. Due to such characteristics, the essential oils of St. John's wort, cinnamon and mint stand out in relation to the other tested ones and are recommended for further research. The results agree with the results of other researchers who studied the effects of antimicrobial drugs on the growth of E. coli (Abu-Darwish et al. 2012, Sagdic O et al., 2009; Küçükbay et al., 2014; Behbahani et al., 2013).



Picture 1. Comparison of maximum zones of inhibition of essential oils and antibiotics ciprofloxacin in mm.

The antibacterial activity of essential oils and their components can vary from partial to complete inhibition of bacterial growth, so that essential oils exhibit bacteriostatic or bactericidal activity. (Abhay et al., 2017). When examining the type of effect of essential oils on the inhibition of E. coli growth it was found that all tested oils showed a bactericidal effect, except for mint and rosemary oils in one and garlic in two replicates when these oils had a bacteriostatic effect. Picture 2 shows the type of action of essential oils on Escherichia coli.



Picture 2. Bactericidal and bacteriostatic action of essential oils on Escherichia coli.

As can be seen from the picture all tested oils had a bactericidal effect, except for mint and rosemary oils in one and garlic in two replicates when they had a bacteriostatic effect. Based on the obtained results, essential oils of St. John's wort, mint, cinnamon, cloves, rosemary, thyme, garlic and fennel showed a good inhibitory effect on the growth of Escherichia coli and can be recommended for use in the food industry to prevent the development of Escherichia coli and disease which it can cause. Also, it can be concluded that a careful selection of essential oils in food production is required, which will also correspond to the organoleptic properties of the food and its composition (Gutierrez et al., 2009; Fabian et al. 2007; Beatriz Nunes Silva et al., 2020).

Conclusion

All tested essential oils, except lemon essential oil, show antimicrobial activity against Escherichia coli. A difference in the antimicrobial activity of essential oils was observed depending on the type of plant and the amount of oil. The essential oils of St. John's wort, mint, cinnamon and cloves showed the greatest activity, while the essential oils of rosemary, thyme, garlic and fennel showed slightly weaker inhibition, depending on whether they were used as pure oils or in combination with alcohol.

All tested oils had a bactericidal effect, except for peppermint and rosemary oils in one and garlic in two replicates when they had a bacteriostatic effect.

Individually or by combining vegetable essential oils, an effective mixture for inactivating Escherichia coli can be provided thus achieving adequate storage and preservation of food. Essential oils are a very topical alternative to synthetic antimicrobial drugs. They are increasingly used for industrial purposes as natural preservatives and preservatives in the food, cosmetics industry and as active ingredients in medical preparations. However, both their possible toxicity and safe doses for use in food, cosmetic or pharmaceutical products should be considered and therefore detailed studies on the toxicity, stability and safety of the tested essential oils are required.

GEOGRAPHICAL ORIGIN OF ALIEN INVASIVE FISH SPECIES IN SERBIA

Milan GLIŠIĆ*, Biljana DELIĆ VUJANOVIĆ

Academy of Applied Studies Šabac, Serbia
*Corresponding author: milanglisic88@gmail.com

Abstract

Aquatic ecosystems around the world have been dramatically altered as fish are shifted around, whether for commercial fishing stock or the aquarium trade. Hydroecological conditions in Serbia have caused a high diversity of its ichthyofauna including about 94 permanent or occasional fish species recorded in Serbian watercourses. However, among them are numerous non-native fish species, which often show an invasive character. According to one of the lists of invasive species in Serbia, 29 species of fish are marked as invasive. In order to prevent further introductions of potentially invasive alien fish species, it is of great importance to know the ecology, but also the biogeography of those species that are currently considered invasive in Serbia. In general, among invasive fish species in Serbia, those originating from the Old World are more common than those coming from the New World. Palearctic origin has 14 invasive fish species, of which 8 have a primary geographic range limited to Europe, while 6 of them are known to have a primary geographic range in both Europe and Asia. There are 6 species of Nearctic origin, 5 species of Sino-Tibetan origin and 1 species of Neotropical origin, while the primary range of some species occupies more than one biogeographical region. However, in contrast to these species with very large primary geographic ranges, some of the species that have been marked as invasive in Serbia are even endemic to the Balkan or Apennine Peninsula, while some are classified as vulnerable according to the IUCN categorization.

Keywords: *Geographical origin, Invasive fish species, Serbia.*

Introduction

Freshwater organisms have lower dispersal abilities than terrestrial vertebrates and are geographically isolated in drainage basins that usually flow to the oceans (Leroy, *et al.* 2019). Fishes are subject to several biogeographical constraints that are unique to the aquatic world (Olden *et al.*, 2010). Their ability to move in response to environmental change is constrained by the dendritic arrangement of riverine ecosystems, as well as a variety of physiographic barriers (Fausch *et al.*, 2002). Drainage basins can be observed as "island-like" systems for strictly freshwater organisms (Dias *et al.*, 2014; Hugueny *et al.*, 2010; Rahel, 2007; Tedesco *et al.*, 2012). As a result of this, most freshwater fishes occupy only a fraction of the localities where they might otherwise thrive (Darlington, 1948).
Leroy *et al.* (2019) divided the world of freshwater fishes into two biogeographical supercontinental regions: the New World (America) and the Old World (Eurasia, Africa and Australia). At the second level, they found six major regions (named after Morrone, 2015), that are spatially nested within two supercontinental regions. The Old World supercontitental region include: Ethiopian region (covering the entire African continent and including areas north from the Sahara and a few basins in the Arabic Peninsula), Sino-Oriental region (including south-eastern Asia from India to Borneo, most of China and Mongolia, Korea and Japan), Palearctic

region (covering Europe, Central Asia and Siberia), Australian region (covering Australia, Tasmania and Papua – New Guinea). Madagascan has been identified as a distinct minor cluster of the Old World, due to the large number of endemic species and genera. The New World supercontitental region include: Neotropical region (covering the whole of South America and Mesoamerica up to Southern Mexico) and Nearctic region (covering North America and northern Mexico).

The Balkan Peninsula is considered one of the hotspots of European freshwater fish diversity (Oikonomou *et al.*, 2014). Hydroecological conditions in Serbia have caused a high diversity of its ichthyofauna, including 94 permanent or occasional fish species of 26 families recorded in Serbian watercourses (Lenhardt *et al.*, 2011). Area of Serbia belongs to the Palearctic region (Leroy, *et al.* 2019). The largest part of Serbia belongs to the Pontic province (Black Sea basin), while only a small part of it (western Kosovo and Metohija; Oikonomou *et al.*, 2014).

Increasing colonisation by alien organisms was observed in Serbian waters during the last few decades (Rat *et al.*, 2016). Earlier introductions of allochthonous species into Serbian waters were made primarily in order to increase ichthyoproduction for purposes of weed control and sport fishing, and also incidentally (Maletin *et al.*, 1997). The main route of fish introductions into Serbia was via the Danube and Tisza rivers from Romania and Hungary (Lenhardt *et al.*, 2011). According to ESENIAS country report (Rat *et al.*, 2016), 29 species of fish are marked as invasive in Serbia, while according to Lenhardt *et al.* (2011), there are 22 invasive fish species (IFSs) in Serbia.

Biological invasions are considered to be the second most important cause of species extinction after habitat destruction (Casal, 2006). Fish invasions are so widespread that they are now considered a significant component of global environmental change, and are recognized as a leading threat to native biodiversity (Dudgeon *et al.*, 2006). By dissolving physical barriers to movement and connecting formerly isolated regions of the world, human-mediated species introductions have dramatically reshuffled the present-day biogeography of freshwater fishes (Olden *et al.*, 2008). Data on the negative effect of non-native fish species on native species are reported in many papers dealing with allochthonous species in Serbia, but a detailed study is still lacking (Lenhardt *et al.*, 2011).

In order to prevent further introductions of potentially invasive alien fish species it is of great importance to know their ecology, but also their biogeography. The objective of the present paper is to provide an overview of geographical origin of those species that are currently considered invasive in Serbia.

Material and Methods

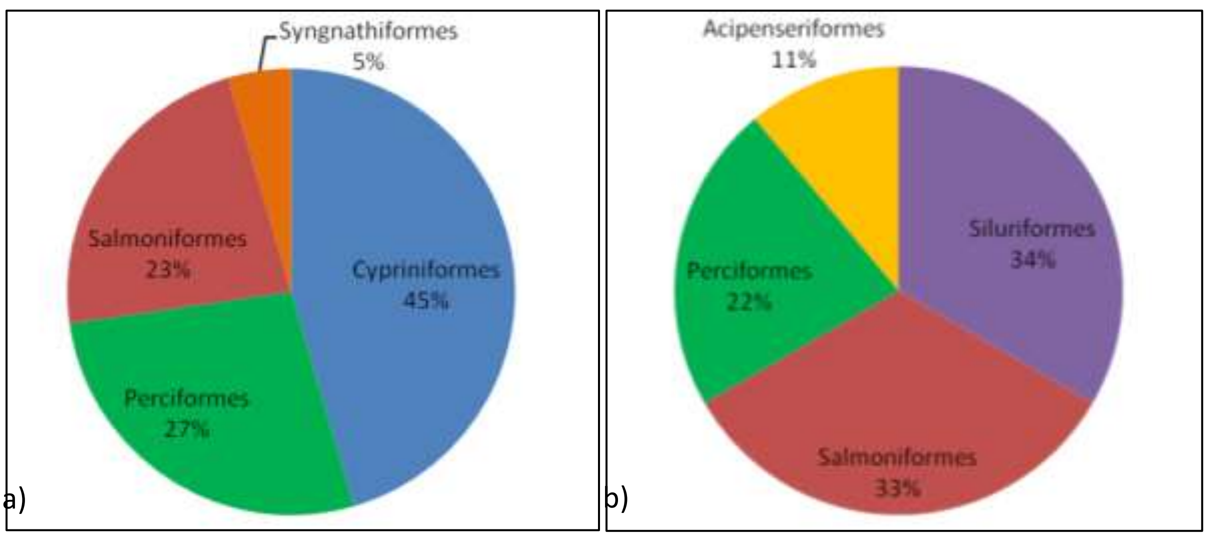
For the purposes of this paper, a list of IFSs according to Rat *et al.* (2016) was used. This list is part of Country report for Serbia, published by East and South European Network for Invasive Alien Species (ESENIAS). According to the report, 29 IFS can be found in Serbia. Rat *et al*. (2016) actually list 30 IFSs in Serbia. However, in addition to the species *Ponticola kessleri* (Gunther, 1861), they also list *Neogobius kessleri* (Gunther, 1861), which is the synonym of *Ponticola kessleri* (Gunther, 1861) according to FishBase (2021). For that reason, for the purposes of this paper, 29 instead of 30 IFSs were taken into account.

IFSs in Serbia are associated with data on their geographical origin, ie. with data on geographical area occupied by their primary range, according to FishBase (2021). Based on these data, it was determined to which biogeographical supercontinental region and to which biogeographical major region (according to Leroy *et al.* 2019) each of the species belongs. In this way, groups of invasive species in Serbia were created based on their geographical origin. For each group, a percentage share in the total number of IFSs was calculated.

Results and Discussion

All IFSs in Serbia can be classified into two large groups: those that come from the Old World (Europe, Asia, Africa) and those that come from the New World (North and South America). As many as 76% of invasive fish in Serbia originate from the Old World, while 31% originate from the New World. The total percentages are greater than 100, because the two species have a primary range that occupies parts of both the Old and New World.

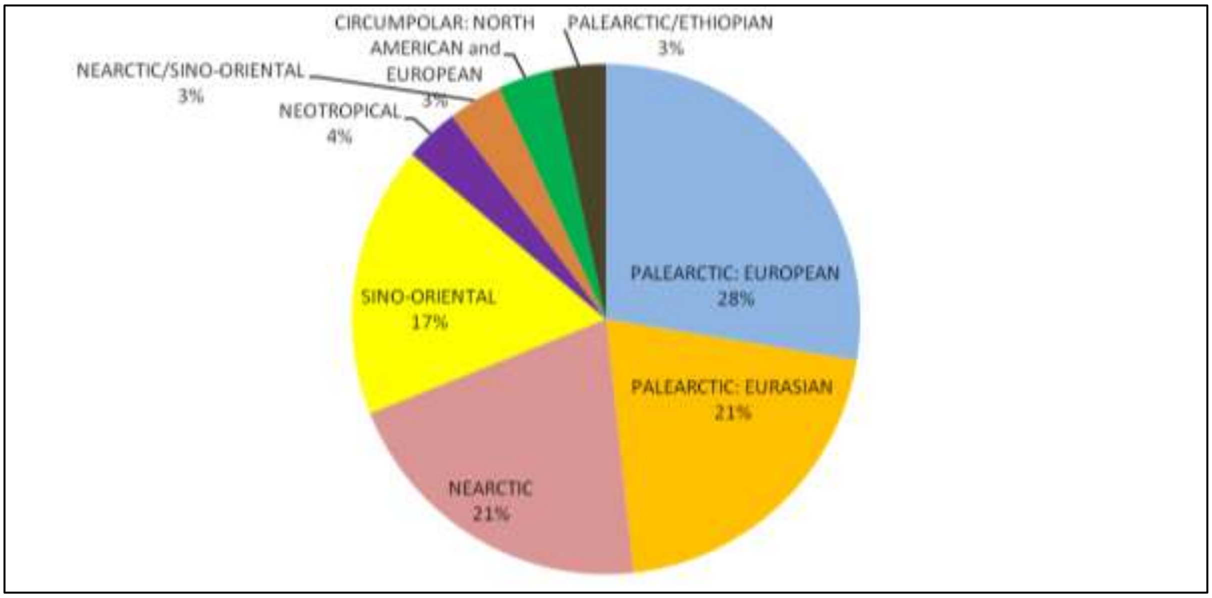
IFSs in Serbia belong to the following orders: Cypriniformes (10 species), Perciformes (8), Salmoniformes (6), Siluriformes (3), Acipenseriformes (1) and Syngnathiformes (1). Fish species from the orders Perciformes and Salmoniformes are represented in both groups – in the group of fish of the Old World, and in the group of fish of the New World. In contrast, IFSs from the orders Cypriniformes and Syngnathiformes are characteristic only for the group of fish from the Old World, while representatives of the orders Siluriformes and Acipenseriformes are characteristic only for the group of fish from the New World (Graphic 1).



Graphic 1. Percentage representation of representatives of different fish orders among IFSs in Serbia: a) fishes originating from the Old World; b) fishes originating from the New World

A large number of species from the order Cypriniformes among invasive fish in Serbia is expected, given the following facts: (1) Cypriniformes is the most diverse order of freshwater fishes (Tan and Ambruster, 2018); (2) cypriniforms occur throughout North America, Africa, Europe and Asia; (3) cypriniforms are dominant members of a range of freshwater habitats (Nelson, 2006); (4) many cypriniforms are important food and recreational fishes and they are popular in the global ornamental pet trade (Tan and Ambruster, 2018). Although members of this order can also be found in North America, all invasive cypriniforms are of Palearctic origin. The reason for this may be the following: (1) a higher degree of deliberate introduction of fish from Asia to Serbia, and/or (2) a greater diversity of Asian cyprinids, given that cypriniforms are

thought to have originated in South-east Asia, where the most diversity of this group is found today (Briggs, 2005).
Depending on the biogeographical region (according to Leroy *et al.* 2019) in which their primary range is located, IFSs in Serbia can be divided into Palearctic, Nearctic, Sino-Oriental and Neotropical. Palearctic species can be further divided into those whose primary range is limited to Europe (European) and those whose primary range occupies both Europe and Asia (Eurasian). Among the IFSs in Serbia are also those whose primary range includes more than one biogeographical region: Nearctic and Sino-Oriental, Nearctic and Palearctic (Circumpolar: North American and Euoropean), Palearctic and Ethiopian (Graphic 2).



Graphic 2. Percentage representation of IFSs in Serbia according to their geographical origin

Palearctic species are predominant among IFSs in Serbia. As many as 14 IFSs in Serbia (49% of total number) have a primary range that is entirely located in the Palearctic biogeographical region. Among them are 8 European (28% of total number) and 6 Eurasian (21 % of total number).
Palearctic European IFSs in Serbia are: *Salmo letnica* (S. Karaman, 1924), *Salmo macedonicus* (S. Karaman, 1924), *Proterorhinus semilunaris* (Heckel, 1837), *Alburnus albidus* (Costa, 1838), *Alburnus scoranza* (Heckel & Kner, 1858), *Pachychilon macedonicum* (Steindachner, 1892), *Rutilus basak* (Heckel, 1843), *Scardinius knezevici* (Biando & Kottelat, 2005). It is interesting that among these species there are as many as 6 whose primary range is limited to the Balkan Peninsula (rivers and lakes of Albania, Croatia, Greece, Montenegro and North Macedonia), and 1 whose primary range is limited to the Apennine Peninsula (FishBase 2021). This species, *Alburnus albidus*, is even on The IUCN Red List of Threatened Species (2021), in the category "Vulnerable" at global level, due to the next reasons: decline in the number of mature individuals, small area of occupancy, ongoing range reduction, severe fragmentation of population and decline in habitat quality.
Palearctic Eurasian IFSs in Serbia are: *Coregonus peled* (Gmelin, 1788), *Neogobius fluviatilis* (Pallas, 1814), *Neogobius gymnotrachelus* (Kessler, 1857), *Neogobius melanostomus* (Pallas, 1814), *Ponticola kessleri* (Gunther, 1861), *Carassius gibelio* (Bloch, 1783). These species

originate mainly from rivers and lakes of Sea of Azov, Black Sea and Caspian basins, whereas *Carassius gibelio* is usually considered as native from central Europe to Siberia (FishBase 2021). Some of these species have expanded their range due to the construction of the Rhine-Main-Danube Canal (Van Kessel *et al.*, 2009).

Nearctic IFSs in Serbia are: *Ameiurus nebulosus* (Le Sueur, 1819), *Ameiurus melas* (Rafinesque, 1820), *Polyodon spathula* (Walbaum, 1792), *Salvelinus fontinalis* (Mitchill, 1815), *Lepomis gibbosus* (Linnaeus, 1758), *Micropterus salmoides* (Lacepede, 1802). These species originate mainly from Great Lakes, Mississippi River basins, Gulf Slope drainages etc. All of the listed species are known as invasive worldwide and at least one country reports adverse ecological impact after their introduction (FishBase 2021). Despite that, *Polyodon spathula* is on The IUCN Red List of Threatened Species (2021), in the category "Vulnerable" at global level, due to exploitation and the effects of introduced taxa, pollutants, competitors or parasites.

Sino-Oriental IFSs in Serbia are: *Ctenopharyngodon idella* (Valenciennes, 1844), *Hypophthalmichthys molitrix* (Valenciennes, 1844), *Hypophthalmichthys nobilis* (Richardson, 1845), *Pseudorasbora parva* (Temminck and Schlegel, 1842). These species originate from the northern part of the Sino-Oriental biogeographical region, mainly from the Amur River system or some other Pacific dainages of East Asia. All of them are known as invasive worldwide and at least one country reports adverse ecological impact after their introduction (FishBase 2021). These species were mostly deliberately introduced into the waters of Serbia, in order to "improve" the fish stock in fishponds.

Neotropical IFS in Serbia is *Pterygoplichthys pardalis* (Castellnnau, 1855). This South American species primarily inhabits rivers of lower, middle and upper Amazon River basin, but it is introduced to countries outside its native range (FishBase 2021). There is evidence that in its introduced range this species disrupt aquatic food chains, decrease the abundance of native aquatic species and degrade aquatic plants or banks of waterbodies through burrowing and tunneling (Hoover *et al.*, 2004).

Nearctic/Sino-Oriental IFS in Serbia is *Oncorhynchus mykiss* (Walbaum, 1792), a marine, brackish and freshwater fish. This species is native for two biogeographical regions, since its primary range includes the Pacific slope of North America (from Alaska to California), but also the eastern Pacific coast (Kamchatka, Commander Islands, Sea of Okhotsk). Several countries reported adverse ecological impact after introduction of this species (FishBase 2021).

Circumpolar (North American and European) IFS in Serbia is *Salvelinus alpinus* (Linnaeus, 1758). This species inhabits sea water, freshwater and brackish water. It is native in Iceland, Scandinavia, northern Russia, but also in Alaska, Canada, Greenland and USA, in Atlantic, Arctic and Pacific coastal areas.

Palearctic/Ethiopian IFS in Serbia is *Syngnathus abaster* (A. Risso, 1826). Range of this marine, brackish and freshwater fish species occupies Eastern Atlantic and the Mediterranean and Black seas, but also the coasts of North Africa.

Conclusions

In order to prevent further introductions of potentially invasive alien fish species it is of great importance to know their ecology, but also their biogeography. IFSs in Serbia originate from all biogeographical regions exept Australian and Madagascan. Despite being considered invasive in some parts of the world, in some others some of these species are considered threatened.

Therefore, it is not enough just to have a list of species that are considered invasive, but it is necessary to investigate the degree of their invasiveness.

Abstract

Sea urchins are important members of benthic communities by impacting algal production and therefore the other members of the communities. A member of these organisms, *Diadema setosum* Leske, 1778, was introduced to Mediterranean Sea in 2006 and it has extended its distribution to various localities. However, previous studies on this invasive species have only focused on its occurrences in different parts of the Mediterranean Sea. Here, we conducted an observational study on the density of this sea urchin at six sites along the Turkish coast of Aegean Sea differing in the habitat types. Additionally, we determined the density of a native sea urchin, *Arbacia lixula* Linnaeus 1758, at the same sites to reveal the potential interactions between these two species. We found that *D. setosum* reached a notable density on the Turkish coast of Aegean Sea and this density was higher at the sites with hard bottoms. We further found an inverse relationship between the densities of *D. setosum* and of *A. lixula*. Overall, this study emphasizes the need of an urgent management/conservation plan since *D. setosum* has already reached the previously reported threshold density at which it is harmful to benthic communities in the Mediterranean Sea.

Keywords: *Arbacia lixula, competition, Diadema setosum, Mediterranean Sea, sea urchin.*

Introduction

Sea urchins are important members of benthic communities by exerting a top-down influence on macroalgae (Aronson & Precht, 2000). Their herbivorous diet with specific grazing preferences (Coppard & Campbell, 2005; Luza & Malay, 2019) directly impacts the macroalgal production and thus the benthic community structure (Qiu *et al*., 2014). These impacts may vary with bioerosion (Qiu *et al*. 2014), competitive exclusion of other benthic organisms (*reviewed in* Muthiga & McClanahan 2007), reductions in algal growth (Ishikawa *et al*., 2016) and the reductions in species composition that depends on algal production. Furthermore, they can favor coastal fish by providing shelter (Bilecenoğlu *et al*., 2019).

Diadema setosum Leske 1778, is an Indo-Pacific sea urchin (Muthiga & McClanahan, 2007) that has introduced to Mediterranean Sea. The first individuals of *D. setosum* were reported in 2006 from Kaş Peninsula (Yokes & Galil, 2006). Since the first introduction of the species, it has extended its distribution to the coasts of Lebanon (Nader & Indary, 2011) and Israel (Bronstein & Kroh, 2018), to Rhodes (Kondylatos & Corsini-Foka, 2015) and Simi (Galanos & Kritikos, 2019) islands, to the southeastern coastline of Turkey (Turan *et al*., 2011; Yapıcı *et al*., 2014), and to the Sea of Marmara (Artüz & Artüz, 2019). *D. setosum* has two genetic clades and a recently published distribution model predicted that these clades have different expected range of expansions due to habitat suitability in the Mediterranean Sea (Bronstein *et al*., 2017). However, *D. setosum* clade b has exceeded its predicted range to the Sea of Marmara (Artüz & Artüz, 2019), suggesting that this species can be harmful for a larger area in the Mediterranean Sea than it has been predicted.

Previous studies conducted on *D. setosum* in the Mediterranean Sea has only reported new localities where this species has spread since its first introduction in 2006. However, understanding the impacts of the introduced species and development of useful conservation and management plans to control for the impacts of introduced species require further knowledge such as density (Yokomizo *et al*., 2009) and the interactions with native species (Sax et al., 2005 and chapters therein). Therefore, here we investigate the abundance of this introduced species and its interaction with the native sea urchin (*Arbacia lixula*); they both utilize similar hard substrate habitats; across sites that differ in substrate type to understand whether *D. setosum* follows similar distribution pattern with its native habitats in the Mediterranean Sea.

Materials and Methods

We examined the density of the invasive, *Diadema setosum* and native, *Arbacia lixula* sea urchins at six coastal sites between 9th and 12th October 2019 on the Turkish Coast (Fig. 1). Similar to this, studies conducted on *D. setosum* in its native range showed its strong hard bottom preference (*reviewed in* Muthiga & McClanahan, 2007). Therefore, we selected our study sites based on differences in the bottom types, which have either soft bottom (sand) or hard bottom (rock) in order to understand if the *D. setosum* follows the same habitat preference in its invasive region (e.g., Mediterranean Sea) with the native one. We conducted our density observations at three sites with soft bottom and three sites with hard bottom. We scanned an area of approximately 100 m^2 at each site. We counted individuals of the native and the invasive sea urchins from coast to 15 m depth by SCUBA diving.

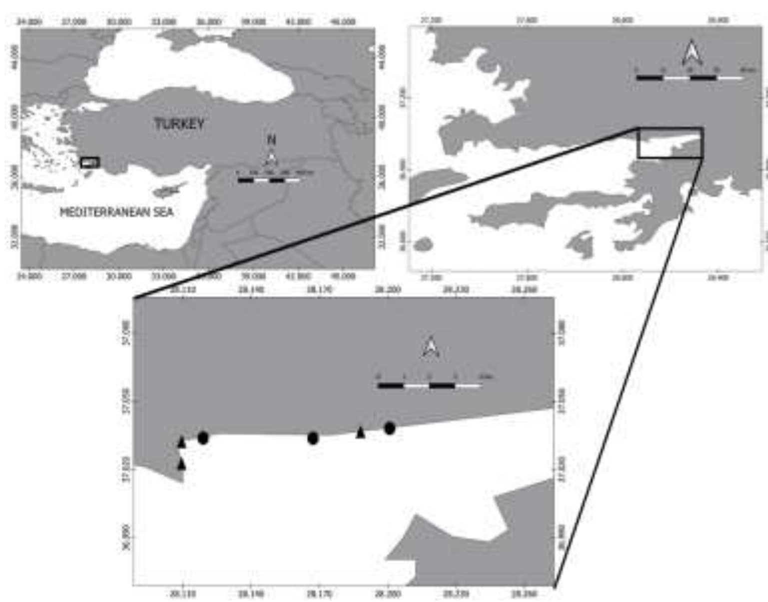

Figure 1. Study sites. In the map, circles indicate the sampling sites with hard bottom and triangles represent the sampling sites with soft bottom. The map was created with QGIS v3.10 software.

To understand if the densities of the invasive and of the native sea urchins varied between sites with different bottom types, we conducted two separate Linear Mixed-Effects Models (GLMMs) with a Poisson distribution. The bottom type (soft vs hard) was treated as categorical fixed factor. To control for spatial differences, site was added as random factor to these analyses. We further applied another GLMM with a Poisson distribution to assess whether the densities of the native sea urchin, *Arbacia lixula*, were related to the densities of the invasive sea urchin, *D. setosum*. We treated the density of *D. setosum* and the bottom types as fixed factors. We, again, treated the site as a random factor to control for the spatial variation between sites. All statistical analyses were conducted using the statistical software R version 3.6.2 (R Core Team, 2020).

Results and Discussion

Density of the invasive sea urchins, *D. setosum*, at the sites with soft bottom (average = 1.053 ind./m^2, range = 0.96- 1.2 ind./m^2) was significantly lower compared to the density at the sites with hard bottom (average = 3.166 ind./m^2, range = 1.5- 4.2 ind./m^2, GLMM, Z = -3.684, p < 0.001, Fig. 1, 2). In contrast, the density of the native sea urchins, *A. lixula*, at the sites with soft bottom (average = 0.053 ind./m^2, range = 0.02 - 0.08 ind./m^2) and density at the sites with hard bottom (average = 0.096 ind./m^2, range = 0.05 - 0.17 ind./m^2) was similar (GLMM, Z = -1.863, p = 0.062, Fig. 2). Further, the density of *D. setosum* was significantly higher compared to native sea urchin, *A. lixula*, at the sites with hard bottoms (GLMM, Z = 18.52, p < 0.001, Fig. 2) and soft bottoms (GLMM, Z = 11.64, p < 0.001, Fig. 2).

The differences in densities of the invasive *D. setosum* between sites with hard and soft bottoms is likely to reflect the natural habitat preference of the species. Similar results for the habitat choices of *D. setosum* have been reported by several authors from both experiments and observations in the wild from the species' native habitats (Dumas et al., 2007; Puspita et al., 2012). This habitat preference with hard substrate may be the result of the food choices of *D. setosum* (Muthiga & McClanahan, 2007). Alternatively, *D. setosum* may prefer hard substrates in order to avoid its potential predators by hiding between rocks and small crevices (Coppard & Campbell, 2005; Dumas et al., 2007; reviewed in Muthiga & McClanahan, 2007); however, no predator for this echinoid species in the Mediterranean Sea has been reported. Furthermore, various feeding preferences of *D. setosum* have previously been reported mostly from its native habitats (Coppard & Campbell, 2005; Luza & Malay, 2019); however, echinoid species can consume a variety of diet items (Coppard & Campbell, 2005), which is a common dietary trait for the successful invasive species (Slatyer et al., 2013; Machovsky-Capuska et al., 2016). Moreover, *Diadema* species consume an important portion of sand in order to obtain biofilm and particulate organic matter accumulate on the sand surface (Muthiga & McClanahan, 2007). These may explain the presence of *D. setosum* with a moderate density on sandy bottoms as shown in this study.

D. setosum can lead to dramatic shifts on the benthic communities by implying grazing pressure on macroalgae (Aronson & Precht, 2000). However, the degree of the pressure applied by this species is density-dependent (Ishikawa et al., 2016). Ishikawa et al. (2016) reported a threshold of 2 ind./m^2 at which the influence by *D. setosum* becomes drastic on the community composition. If a similar threshold also exists in the Mediterranean Sea, the density of *D. setosum* we currently report from the Turkish coasts is expected to have detrimental effects on algal proliferation. We further found that the densities of *D. setosum* in our study sites are close to the 2 ind./m^2 threshold also on soft (e.g., sand) bottom habitats. However, this threshold may

vary based on the habitat characteristics and biodiversity, therefore further studies should focus on the algal production and the community composition of the benthic communities that are under the influence of *D. setosum* in the Mediterranean Sea.
The density of the native sea urchin, *A. lixula*, was inversely related to the density of the invasive sea urchin, *D. setosum* (GLMM, $Z = -2.794$, $p = 0.0052$, Fig. 2); however, this relationship was not influenced by the bottom type (interaction of habitat type:density of invasive sea urchin, GLMM, $Z = 1.371$, $p = 0.17$).
This inverse relationship between the densities of native and invasive sea urchins could be the consequence of potential competitive interaction between *D. setosum* and *A. lixula*. Competitive interactions between *D. setosum* and other sea urchins in the range of their native habitats are common (*reviewed in* Muthiga & McClanahan, 2007). The consequences of these inter-specific interactions are based on the size of individuals with some exceptions (i.e., *Echinometra mathaei* outcompete other sea urchins with larger body sizes) (McClanahan, 1988). However, the magnitude of this potential competitive interaction was not the objective of the current study, therefore future studies should focus on this and other relationships with native species and the potential consequences of the latter for the community structure in the Mediterranean Sea.

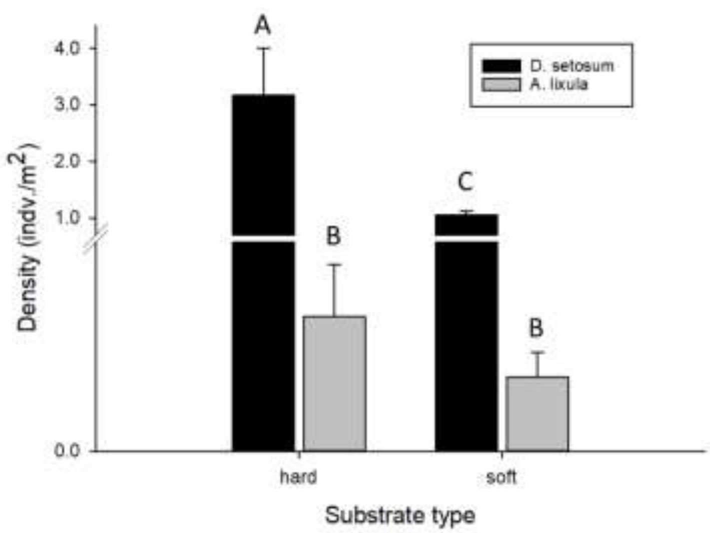

Figure 2. Variations in the density (average/m2 ± S.E.) of invasive, *Diadema setosum*, and native, *Arbacia lixula*, sea urchins between sites with hard and soft bottoms. Letters above bars indicate the significant differences.

Conclusion

Results of this study show that the invasive sea urchin, *D. setosum*, has reached to potential critical densities at several sites in the Mediterranean Sea which can harm benthic communities. Furthermore, their populations are larger compared to the native sea urchins within hard bottom habitats. However, the influence of this density increases on the community structure remains to be tested. Understanding the interactions with the native species will contribute to the management and conservation plans, which are urgently needed in the Mediterranean Sea.

EFFECT OF NITROGEN FERTILIZATION ON TRITICALE GROWN FOR DUAL PURPOSE OF FORAGE PLUS GRAIN IN SEMI-ARID ENVIRONMENT

Sadreddine BEJI

Higher Institute of Agriculture Kef. University of Jendouba, Tunisia
*Corresponding author: beji_sadreddine@yahoo.fr

Abstract

In Tunisia, lack of forage is one of the most important problems of livestock feeding during the autumn and winter seasons. One of the solutions is the practice of dual-purpose cereals; Cereals are grazed or cut at a young stage (tillering) and then allowed to re-grow up to grain production. Effect of application of three Nitrogen fertilization rates (0, 75 and 175 kg/ha) on Triticale variety Tcl 83 grown for grain production only and for the dual purpose of forage plus grain was studied in semi-arid region in Tunisia during 2018-2019 cropping season. Removal of forage for the dual purpose treatment was done at the pseudo stem erect stage (C30). Variance analysis showed that Tillers number/plant, spike number/m^2 and grain yield were significantly ($P<0.01$) influenced by the combined effect N fertilization and cutting at (C30) stage. This experiment has also shown that dual-purpose cultivation affected positively the grain protein content and nitrogen regime has a significant effect on thousand-kernel weight of the triticale produced at maturity stage. As per 2018-2019, when climatic conditions were favourable. The dual-purpose use of triticale could constitute a solution for the winter feed gap in the livestock cycle provided that adaptations of the traditional crop management to dual purpose, such as the sufficient nitrogen fertilization are undertaken.

Keywords: *Triticale, Dual purpose, Nitrogen, Semi-arid.*

Introduction

Under semi-arid conditions, Triticale can be used as forage and as grain during same cropping season. It is grazed or cut in a young stage (tillering) and then allowed to re-growth up to grain production. This will provide forage during winter season which is known as a forage deficit period. Researches about cereals dual-purpose for seeds and forage have given widely varying results according to the climate, to the specie, to the fertilization and to the cut or grazing stage. Under poor weather and fertility conditions, grain yield losses can be expected if cereals are grazed during the vegetative phase (Kilcher, 1982). Reduction in triticale grain yield was between of 9.6 to 50.8% for Nachit (1983) and 22% for Beji (2015). Decreases in grain yield after clipping have been attributed to a reduced number of spikes/m2 at harvest (Royo and al., 1993) and also to a reduced grain number (Bonachela and al., 1995) and kernel weight (Royo and al., 1994). Nevertheless, there have been observations of grain yield increases after forage removal, which were explained by a lower incidence of lodging (Droushiotis, 1984). Other results showed also that a properly managed grazing does not reduce grain yield in the dual-purpose system. It shows that the stocking pressure and number of cuts have been shown as important factors that influence the subsequent grain yield (Arzadun and al., 2003). Epplin and al. (2000) and Hossain and al. (2003) also suggested that an optimal choice of planting date and density is crucial if cereal is to produce high forage and grain yields. In the other hand, Nitrogen

fertilization, appears as one of the most limiting factors in the production of grain and forage. Appropriate fertilization (timing and quantity) is determining factor for a dual purpose use of cereals (Zagonel and al., 2002).
Other studies dealt with the influence of winter defoliation on quality traits but did not find detrimental effects of dual-purpose management on wheat grain protein or on dough strength parameters (Beji, 2016 ; Royo and al., 1994; Royo and Tribo, 1997; Khalil and al., 2002 ; Royo and al., 1997). Given the interest in cereals as dual purpose crop in northwest of Tunisia, this study was conducted to determine the impact of nitrogen fertilization on grain yield and quality for triticale grown for dual purpose.

Material and Methods

The present study was performed in el Kef region, in the experimental field of the Higher Institute of Agriculture Kef (36° 11' 9'' N, Longitude 8° 42' 59'' E; Altitude 652 m) during 2018-2019 cropping season. Trial was carried out in a clay-sandy-loamy soil with organic matter content around 1.54%. The climate is Mediterranean, with rainfall concentrated in in the autumn and winter. The average annual rainfall is 425 mm on the basis of 50 years. Climate temperature and rainfall from sowing to harvest are presented in Table 1.

Table 1. Mean temperature (°C) and rainfall (mm) of experimental field of the higher Institute of Agriculture Kef from sowing to harvest (2019-2019).

	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	Jun
Rainfall (mm)	33	13	18	93	91	123	41	66	5
Temp Max	25	20	17	12	14	18	25	31	41
Temp Min	11	8	3	0	5	10	12	17	18

Triticale Variety used is the Tcl 83, the most known cultivar, used for sillage production and grain production as well. The experimental design was a Split plot one with 4 replications and each plot measured 10 m^2 in which the main factor was the crop use (grain use only or forage + grain use) and the secondary treatment is nitrogen fertilization rate. The two treatments within main factor were: (i) control plots which were only clipped at seeds maturity in order to estimate the grain yield and (ii) dual purposes plots which were clipped first time and harvested as forage at the stem erect stage (C30) and then let regrowth up to seeds maturity. For secondary factor three fertilization rates were tested ; (i) : control plots, unfertilized (N0), (ii) 75 kg/ha N applied (N75) and (iii) 150 kg/ha N applied (N150). Fertilization done with Ammonitrate (33%) and distributed according to cutting regime. For uncut plots (only grain use) 50% of total Nitrogen amount was applied at 3 leaf stage and 50% at end of tillering stage. For dual purpose plots, fertilization was applied 3 leaf three (50% of total amount) and 50% same day of forage cutting. Sowing was carried out early October at a density of 300 viable seeds/m^2. Forage harvest was done on 26 February 2019. Plants were cut about 8 cm above ground level. Grain harvest was made at seeds maturity on 28 June 2019. Weeds and diseases were chemically controlled.
Grain yield (GY), number of spikes/m^2 (SN/ m^2), number of grains per spike (NG/Sp), thousand-kernel weight (TKW) were determined for each plot at seed maturity, tillers number per plant (TN/Pt) measured at end of tillering period and grain crude protein (GCP) content was evaluated by means of the standards micro-kjeldahl procedure.

Analyses of variance (ANOVA) were performed using SAS (1985) and Means were separated using Duncan Test.

Results and Discussion

The results of the analysis of variance for grain yield and its components are shown in Table 2. Cutting at the green stage (C30) did not cause significant reduction of grain yield for dual-purpose use compared to grain use only. However, disparencies were noted and the grain yield reduction was more accentuated (-25%) under Fertilization regime 150N compared to unfertilized plots (-9%). The highest grain yield was obtained under regime 150N and when triticale was used only for grain (4.33 T/ha). Regrowth and capacity to produce high grain yield after defoliation was more important when N fertilization was higher. These results corroborate those of Hastenpflug and al. (2011) Zagonel and al. (2002) who found a positive interaction between nitrogen fertilization level and grain yield for wheat used under dual purpose management.
Analysis of variance has also showed that tillers number per plant (TN/Pt), number of spikes/m^2 (SN/ m^2) and thousand-kernel weight (TKW) were significantly affected by treatments studied. TN/Pt was significantly affected ($P<0.05$) by the interaction between management system and fertilization level. The dual purpose management and augmenting of nitrogen fertilization have increased the component TN/Pt. Higher tiller number (8) was measured on triticale used as forage and grain and fertilized with 150 kg/ha N.
SN/m^2 increased from 218 spikes /m^2 when triticale was not fertilized to 350 spikes /m^2 for triticale which has received 150 kgN/ha. Defoliation at stage (C30) has increased significantly ($P<0.05$) this parameter when fertilization was at (150N) regime and did not has effect for the two other fertilization regimes (0N and 75N). This is explained by the removal of the apical domination during final stage of the tillering period. In fact, with defoliation the predominant apex is eliminated and then tiller production restarts again and could drive to a higher number of productive tillers per plant (Briske and Richards, 1994). Bonachela and al. (1995) have also found that forage use during winter makes the tillering period longer and then capacity to make fertile tiller and spike greater. Compared with cereals species grown in temperate regions, triticale and barley cultivars adapted to Mediterranean climates have relatively short life cycles, especially in the phases before terminal spikelet (Kirby, 1991), Thus, a longer life cycle before the stage of maximum spikes number could increase tillering potential and, thereby, spikes number.
In the other hand, TKW was significantly affected only by fertilization regime ($P<0.05$) the higher TKW was measured on triticale fertilized with 150kg/ha N independently from management system. The decrease grain weight in the clipped treatment can be explained by a reduction of remobilisation of reserves and carbohydrates due to a shorter heading and flowering stages (C50-60) (Beji, 2016).
The third yield component, Number of grains/spike (NG/Sp), was a very stable variable, being similar for both treatments and the three fertilizations regimes.
This experiment has also shown that the fertilization regime has affected positively the grain protein content while the management system did not has effect on this parameter. This result is in agreement with Lestingi and al. (2010) who found a positive correlation between Nitrogen fertilization applied and grain crude protein. The higher grain protein content in this experiment has reached 102.5 g/kg DM which is considered high and similar to level indicated as adequate by Royo and al. (1997).

Table2. Yield components, grain yield and grain crude protein measured in different management system (MS) and different nitrogen regime (NR)

	TN/Pt	GY (T/ha)	SN/m²	NG/Sp	TGW (g)	GCP (G/KgDM)
Dual Purpose Unfertilized (0N)	6ab	1.03 c	207 d	23 a	38.4 b	99.3 b

Manag System x Nitrogen Regime	*	*	*	NS	NS	NS

Distinct letters in the row indicate significant differences according to Duncan test (*$P \leq 0.05$, ** $P \leq 0.01$, NS: not significant).

Conclusion

Combined the two factor (Nitrogen and Dual purpose Management), we conclude that optimum grain yield was produced under grain use only and application of 150 kg N /ha. Capacity of regrowth increases with the quantity of Nitrogen applied.

Triticale could constitute a solution for animal breeders to fill winter deficit period as it provides green forage and could regrowth without a significant reduction of grain yield.

Further research which study the economic impact of dual purpose management of triticale compared to only grain use may aid to make the choice for the dual or single use of triticale

CHARACTERIZATION OF PHOTOSYNTHETIC ACTIVE RADIATION IN BURGOS

Ana GARCIA-RODRIGUEZ*, Sol GARCIA-RODRIGUEZ, Manuel GARCÍA-FUENTE, Diego GRANADOS-LÓPEZ, David GONZÁLEZ-PEÑA

Abstract

Photosynthetically Active Radiation (PAR) is the fraction of the solar radiation spectrum that produces biochemical processes and influences in vegetation growth. PAR wavelength range is between 400 and 700 nm, being part of the visible light spectrum band (400-780 nm). This solar energy can be converted into biomass by photosynthesis in plants. Therefore, vegetation growth is directly related with solar radiation intensity and can be predicted with physical models. Two different models are normally implemented: one is based on photosynthetic photon flux density, Q_p (μmol·s^{-1}·m^{-2}) and the other is based on PAR (W·m^{-2}).
Q_p is not often measured in regular meteorological stations, consequently the main objective of this study is to stablish a methodology to estimate Q_p from solar irradiation measurements, R_s (W/m^2). The experimental. Specifically, the average value of the ratio Q_p/R_s was calculated every 10 minutes, from experimental data measured between April 2019 and January 2020 in Burgos, obtaining a global mean value of 1.93±0.15 μmol· J^{-1} .
The relationship between the ratio Q_p/R_s and the typology of the sky: clear, intermediate and overcast skies, accordingly to the CIE standard, is also analysed in this study. On the one hand, results show that there are statistically significant differences in the values of Q_p/R_s for each CIE standard sky type. On the other hand, aligned with other works in the bibliography, the overcast sky type shows the highest values of the ratio Q_p/R_s, contrary to clear and intermediate skies that show the lowest ratio.

Key words: *photosynthetic active radiation (PAR), vegetation growth, solar energy, sky types.*

Introduction

Photosynthetically Active Radiation (PAR) is the component of solar radiation that has the highest influence in plants growth. Its wavelength is between 400 and 700 nm, including photosynthetic photon flux (Q_p, (μmol·s^{-1}·m^{-2})) and energy (PAR (W·m^{-2})) (McCree, 1973). Q_p is usually measured with photon sensors and then can be converted into energy units through the McCree conversion factor, 4.57 $\mu mol \cdot J^{-1}$ $\pm 3\%$ according to climatic factors (Akitsu et al., 2015).
In most weather stations, PAR sensors are not included, so its value is usually obtained from solar radiation measurements, R_s. Although there is no single value for the ratio Q_p/R_s in bibliography, the differences between the values proposed by the different authors are small: 45-50% (Tsubo and Walker, 2005), 44-45% (Moon, 1940), close to 50% (Monteith and Reifsnyder, 1974). Additionally, authors also concluded that this ratio is not affected by the location, season, or daylight effects (Proutsos, Liakatas, and Alexandris, 2019).

The effect of sky conditions on the Q_p/R_s ratio has been studied in other works, concluding that, under overcast sky condition, Q_p/R_s ratio shows higher values (Blackburn and Proctor, 1983; Stigter and Musabilha, 1982).
The main objective of this study is to establish Q_p/R_s ratio in Burgos (Spain) and to analyse its dependence on the sky type. Available experimental data of horizontal solar global irradiation, R_s, photon photosynthetic flux density, Q_p, and CIE standard classification for homogeneous skies, determined through experimental sky scanner measurements, are used for this work. Figure 1 shows the main characteristics of each CIE standard sky type. The results obtained under different sky conditions are analysed over 10 months of real data.

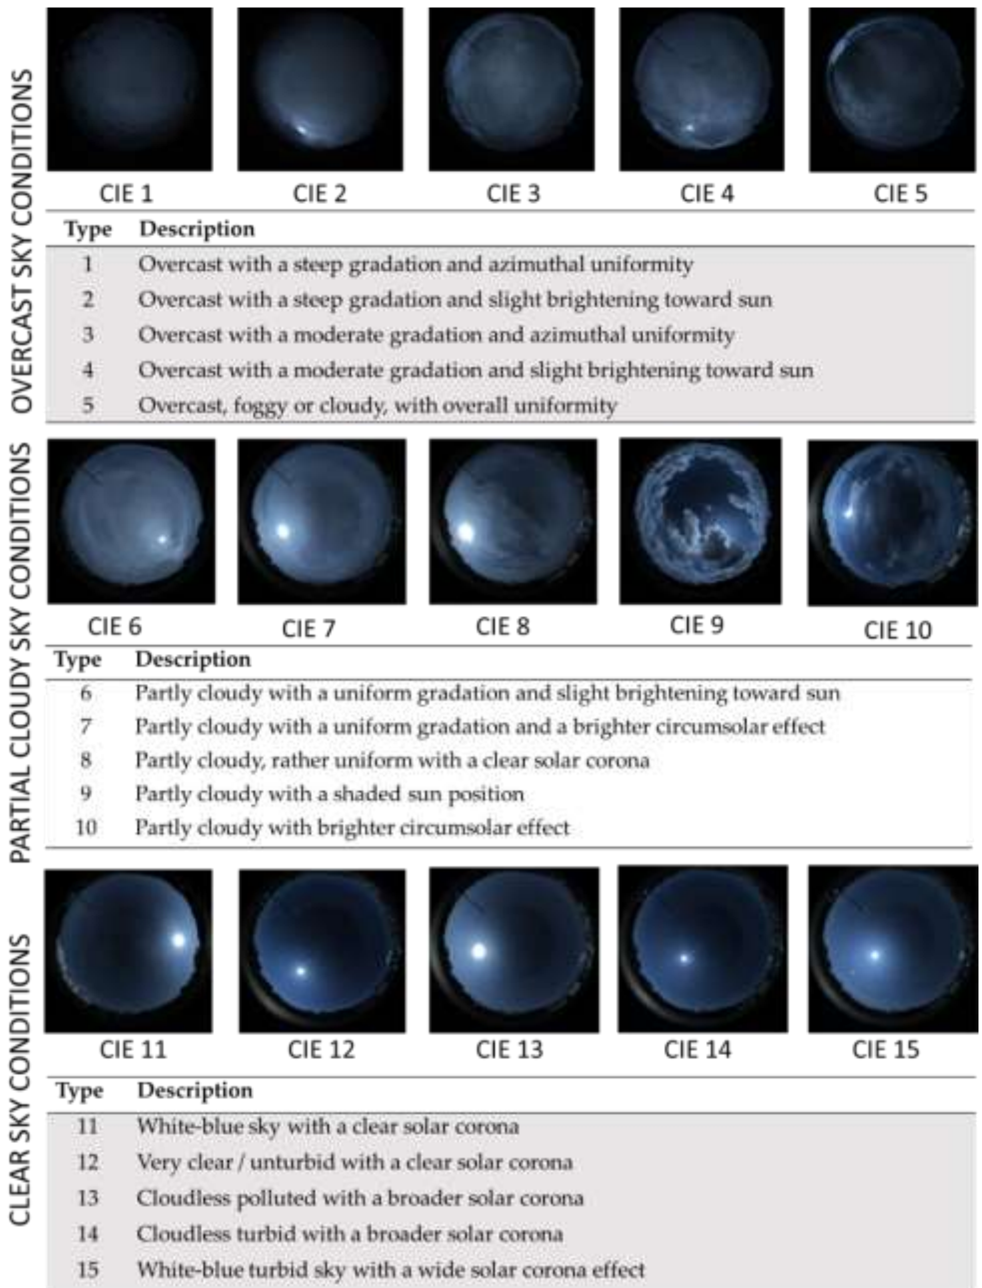

Figure 1. CIE Standard sky conditions in Burgos (Spain). Sky Camera SONA201D.

Material and methods

Global horizontal irradiation, R_s, and photosynthetic photon flux, Q_p, data are measured by a pyranometer (Hulseflux, model SR11) and by a photon meter (EKO instruments, model ML-020P) respectively. Additionally, the Sky luminance/radiance distribution is obtained from a commercial MS-321LR sky scanner from EKO. All parameters are registered every 10 minutes and Q_p and R_s data are filtered accordingly conventional quality criteria (Gueymard and Ruiz-Arias, 2016). When any measure is rejected, all other parameters registered simultaneously are rejects too. The experimental campaign of this study took place from April 1st, 2019 to January 31st, 2020.

Figure 2 shows the location of the weather station, which was described in a previous work (García-Rodríguez et al., 2020). It is placed at University of Burgos on the flat roof of the building, with no external obstructions or reflections from other surfaces.

Figure 2. Location of the experimental equipment on the roof of the Higher Polytechnic School building at University of Burgos, Spain.

Results and discussion

CIE Standard Sky Classification in Burgos from April, 1st, 2019 to January 31st, 2020

The normalization ratio (NR), introduced by Littlefair (Littlefair, 1994) in the original Standard Sky Luminance Distribution method (SSLD), deeply described in a previous work (Proutsos, Liakatas, and Alexandris, 2019), was used to determine the sky type in Burgos through the experimental campaign. Its frequency of occurrence (FOC) is plotted in Figure 3. As it can be seen, sky types 11, 12, and 13, which corresponds to clear sky, was predominant in Burgos, with a FOC value between 10% and 14.5%. On the other hand, sky types 5, 9, and 10 was less frequent with a FOC value of lower than 3%.

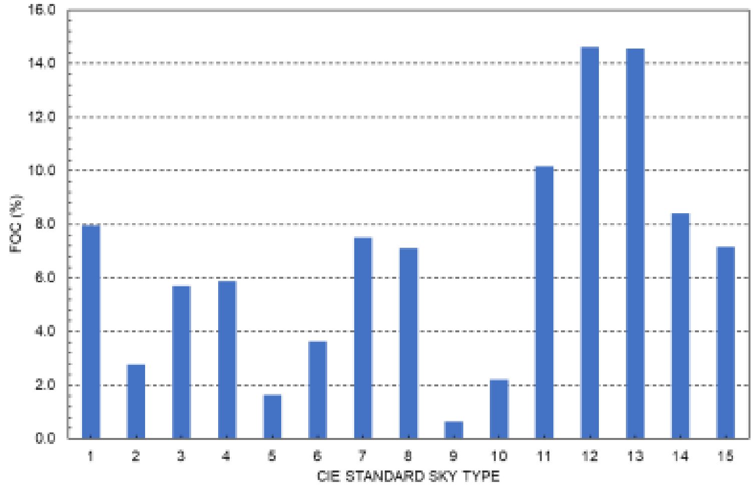

Figure 3: Frequency of occurrence (FOC, %) of CIE standard sky types in Burgos, Spain, between April 2019 and January 2020.

Align with it, when the study include only three categories of the sky (clear, partial, and overcast), as shown in Figure 4, the clear sky is the most frequent, with a FOC value close to 62%. On the other hand, partial and overcast skies have a FOC value of 23.96% and 22.92%, respectively.

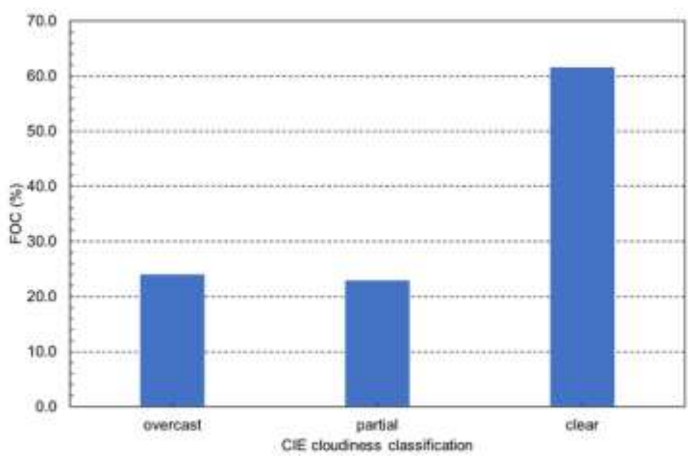

Figure 4: Frequency of occurrence (FOC, %) of CIE Cloudiness classification in Burgos, Spain, between April 2019 and January 2020.

Sensitivity of the ratio Q_p/R_s to the data timing interval

In addition to the Sky classification study, a preliminary study for the seasonal characteristics of the ratio Q_p/R_s was carried out with a data processing interval of ten-minutes, hourly, daily and monthly. Most relevant results are obtained when using ten-minutes data interval, where a strong relation is obtained between both variables (R^2=0.992), as it can be seen in Figure 5. The slope is calculated in 1.893±0.001 μmol·J^{-1} being close to the mean value of 1.93±0.15 μmol·J^{-1} with a standard deviation of ±0.15 μmol·J^{-1}. The results of the Q_p/R_s ratio agreed with those proposed by other authors, which should be in the range of 1.21 and 2.84 μmol·J^{-1} (Foyo-Moreno, Alados, and Alados-Arboledas, 2017)

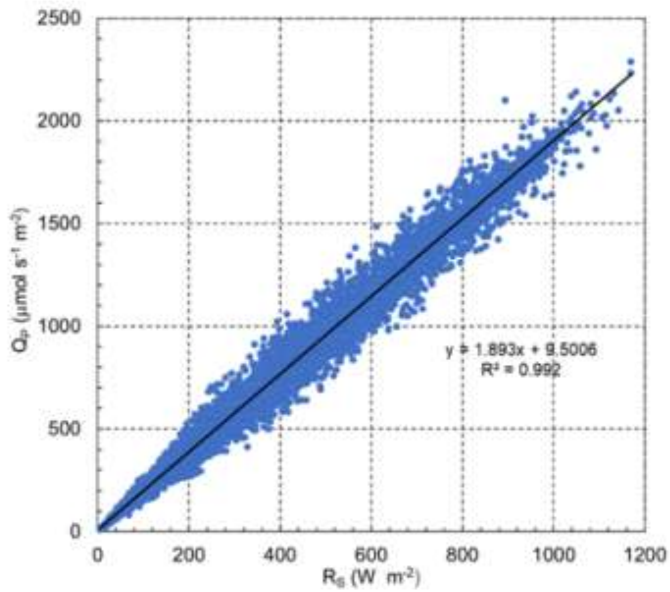

Figure 5. Relationship between the photosynthetic photon flux density, Q_p (μmol·s^{-1}·m^{-2}), and broadband solar irradiance, R_s (W·m^{-2}), measured in Burgos, from April 2019 to January 2020.

Variability of the ratio Q_p/R_s with the CIE Standard Sky types

Last study calculate Q_p/R_s ratio for each sky type when ten-minutes data interval is used. This results are represented in Figure 6. Although many outliers results were showed, the mean value of the Q_p/R_s ratio was obtained for the clear sky types 12,13,14 and 15 which show small standard deviation and interquartile range, between 0.06 to 0.11 μmol·J^{-1} and between 0.05 to 0.09 μmol·J^{-1} respectively. For partial and overcast skies, the dispersion of the data was almost similar. The highest Q_p/R_s ratio is obtained when sky is types 1,2,3 and 4, which belong to the overcast sky category. In addition, when the 15 types of skies are reduced to 3 categories, Q_p/R_s ratio increased while the cloudiness of the sky decreased, as shown in Figure 7.

In both Figures 6 and 7, crosses and horizontal lines inside the box, indicate the mean and the median respectively. The limits of the boxes give the 1st and 3rd quartiles, while the outer whiskers are the minimum and the maximum points. Circles represent outliers.

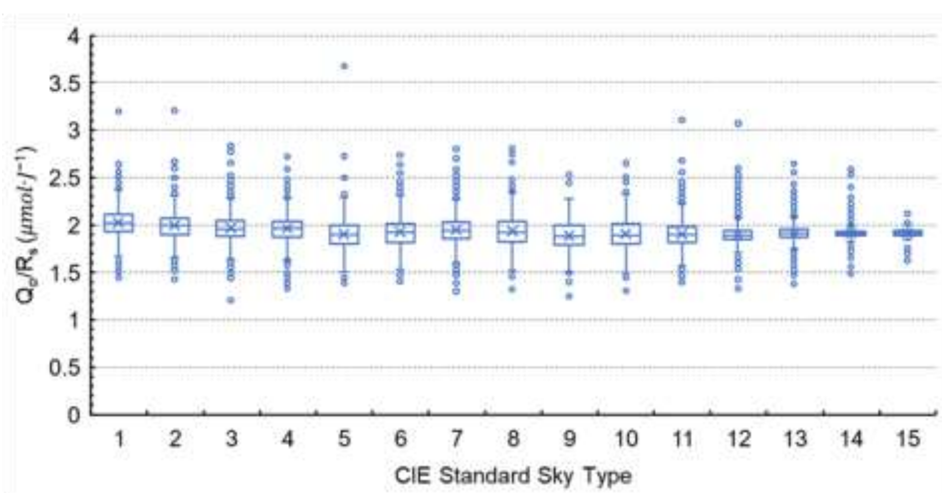

Figure 6. Box-plot ratio of photosynthetic photon flux density to broadband solar irradiance, Q_p/R_s, for each CIE standard sky type.

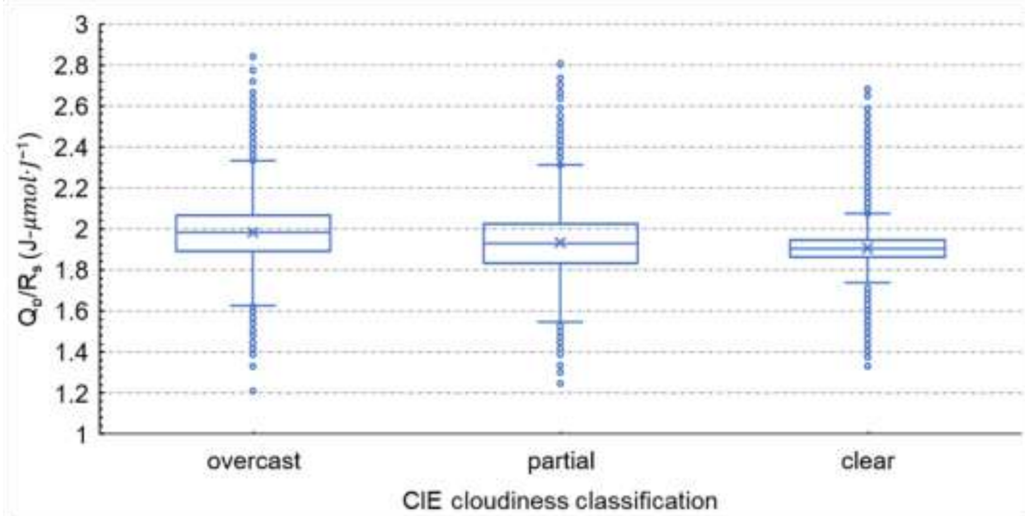

Figure 7: Box-plot of the of the ratio of photosynthetic photon flux density to broadband solar irradiance, Q_p/R_s , for CIE cloudiness sky classification.

Conclusion

The analysis of photosynthetic photon flux density to broadband solar radiation ratios of the data recorded between April 2019 and January 2020 in Burgos at 10-minute intervals, showed a dependence with the type of sky, classified according to the CIE standard,

The highest data of the Q_p/R_s ratio was obtained for overcast skies, while for clear skies, more scattered and smaller values were obtained. The global mean value is 1.93±0.15 $\mu mol \cdot J^{-1}$. In Burgos, the skies with the highest frequency of occurrence are clear skies, with a FOC of 62%, while overcast and partial skies have a FOC of 23.96% and 22.92%, respectively. As has been shown in this and other works, the factor that most influences the Q_p/R_s ratio is the presence of overcast conditions. Although other authors have used different climatological parameters for sky classification, the CIE sky classification provides a good general framework for representing real sky conditions, covering the entire likely spectrum of skies.

THE RELATIONSHIP OF GLOBAL CLIMATE CHANGE WITH AGRICULTURE AND ENVIRONMENT

Aybüke KAYA*

Department of Agricultural Economics, Faculty of Agriculture, Hatay Mustafa Kemal University, Hatay, Turkey
*Corresponding author: aybukekaya@mku.edu.tr

Abstract

The demand for needs increases with the world population. The whole world is affected directly or indirectly while meeting the needs. The composition of atmosphere deteriorates as a result of human activities. This situation is an important problem that confronts us as global climate change. The aim of study is to examine the sectoral relationship of global climate change in Turkey. In addition, it is to reveal the effects on agriculture and environment. Excessive and unconscious use of fossil fuels and industrialization have an impact on climate change. Climate change has serious impacts such as drought, desertification, erosion and disruption of natural balance all over the world. It indirectly threatens sustainability in agriculture. It endangers the production and nutrition necessary for life. People unknowingly cause greater problems. Climate change affects socio-economic sectors and ecological balance. Its effects such as excessive rainfall, depletion of water resources, insufficiency of plant nutrients adversely affect agricultural activities. However, it is thought that the negative effects will be reduced with different methods used in agriculture such as organic farming, drip irrigation, land consolidation and use of renewable energy. Climate change, which is a global problem, can only be reduced by global measures.

Keywords: *Climate change, ecology, agriculture, environment, sustainability.*

Introduction

Global climate change is a mechanism that seriously affects humans, animals and all living things. Due to the nature of each living thing, its sensitivity to environmental and weather conditions is also different. Climate change has increased in recent years. This situation creates direct and indirect effects on human and environmental health. Özdağ (2011) stated in study that environmental destruction and health problems are on the agenda of climate change.

In the last 100 years, the global climate has warmed by about 0.5°C due to greenhouse gas emissions from anthropogenic activities. This warming process continues due to today's intense economic activities and increases in greenhouse gases released into the atmosphere. The British scientist Stern's claim suggested that even if no greenhouse gas emissions are released into the atmosphere from today, the global temperature will increase. He said that it will continue to increase between 0.5°C and 1°C in the coming decades (Stern, 2007). This report, known as the Stern report, includes climate models. It is predicted that the world will warm by 1.4°C to 5.8°C in the next century unless measures are taken to significantly reduce greenhouse gas emissions (Akalın, 2014).

Climate change also has negative effects on water resources. It is one of the important consequences of climate change, perhaps the most important. Water resources are the main source of life in the world (Anonymous, 2020). The first stage of human and environmental relations goes back to hunting and gathering periods. This stage has passed with the recognition of the environment and the effort to adapt to the environment. In the second stage, man began to dominate nature with the use of iron and the help of tools. In this period, people left behind the culture of living in harmony with nature for thousands of years. It has adopted the approach of unlimited exploitation against nature and beings in nature. Nature and the environment are preserved only as long as they are beneficial to humans. On the other hand, it has been used indefinitely. This situation emerged in the second period of the 20th century and started the third phase. Environmental problems, awareness of the environment and the need to take precautions have emerged. Thus, it was possible to take precautions against environmental problems. Afterwards, it has been understood that it is necessary to protect the environment for our own health. In the fourth stage, the environment began to be perceived as a cost problem. However, the inability to price environmental resources (such as the inability to price air, water and land) has emerged as an important problem. It has been suggested that with the last stage of consciousness, human beings are integrated with natural resources and other living things in the environment (Ertan, 2004).

Climate change is increasing its impact due to anthropogenic processes as well as natural processes. These effects of climate change are expected to emerge at global and regional scales. It can directly or indirectly affect agriculture, forest and vegetation, clean water resources, sea level, energy, human health and biodiversity in various ways. In addition, climate change puts pressure on agriculture socially and economically (Akalın, 2014). Therefore, climate change is a serious problem. In this context, there are a number of regulations regarding climate change at the global level. These are the United Nations Framework Convention on Climate Change, the Kyoto Protocol and the Paris Peace Agreement. When the regulations applied in the world are examined in terms of environmental ethics approaches, it is understood that they are anthropocentric. Although the Paris Agreement adopted in 2015 seems to be "more biocentric and ecocentric", it does not contain provisions to support these issues. The emphasis of the Paris Agreement on gender equality is not sufficient to comply with the principles of new ethical approaches (İğci and Çobanoğlu, 2019).

The aim of study is to evaluate the possible effects of climate change on agriculture and environment.

Material and methods

Studies on climate change and the environment were used in the research. It has been prepared by examining national and international studies within the scope of subject. In addition, the data of the Ministry of Agriculture and Forestry were researched.The effects of climate change have been mentioned all over the world. The impact of climate change has been addressed on agriculture, farming and environment.

Results and Discussion

Climate change is an important issue among the sustainable development goals. This issue concerns the whole world. While the priority targets are realized at the national level, global solutions should not be forgotten.

There are different activities according to different regions all over the world. Just as the industrial sector has some effects on climate change, the agricultural sector also has an effect. At the same time, since the agricultural sector is dependent on natural conditions, it is adversely affected by climate change. While agriculture affects climate change, it is also negatively affected by this situation. For this reason, climate change and the environment are intertwined within the scope of sustainability.

1. Climate change and agriculture

As is known, agricultural activities are directly related to the climate. Depending on climate change, changes occur in activities. Agricultural activities also cause climate change. Excessive irrigation, stubble burning, excessive and unconscious use of pesticides and fertilizers are some of them. Climate change also has negative effects on agriculture. Drought due to temperature increase affects crop yield and product quality. It is necessary to provide land management and sustainable agriculture with the awareness of globalization. Good agricultural practices and nature-friendly activities such as organic farming are among the agricultural activities aimed at preventing climate change.

The effects of climate change on agricultural activities and farm are examined in Table 1. Although these effects are considered directly on agriculture, they are also important in economic terms. Therefore, climate change also affects the development and development levels of countries. In addition, it is thought that the world's increasing food need and the problem of hunger will continue to increase.

Table 1. Effects of climate change

Agricultural effects	**Problems caused by farm**
Warmer and less rainy climatic conditions	Planting
Increase in extreme meteorological events	Harvest-threshing
Reduction in water resources	Tillage
Increase in drought severity	Fertilization
Deterioration of water and soil quality	Spraying
Degradation of the ecosystem and reduction of biodiversity	Cultural operations (hoeing, pruning, etc.)
Change in ecological fields	Yield
Decrease in agricultural production and quality	Quality
Increase in pests and diseases	Supply of water and irrigation water
Fertilizing and struggle problems	Plant diversity problems
Sustainable food security issues	Increasing CO_2 concentrations increase plant growth

Source: Anonymous, 2020 (www.tarimorman.gov.tr)

Due to climate change, soil and water regimes are changing. For this reason, agricultural production is decreasing and food security is in danger. Climate change in the long term; puts stress on water and other resources. It is also expected to degrade soils, cause desertification, increase pests and diseases, and destroy coastal ecosystems by raising the sea level (Akalın, 2014).

Climate change primarily makes the living conditions of people who live off the land more difficult. Then, it can threaten the health of all people by putting food safety at risk. Food security is defined by the World Agriculture Organization as the physical and economic access of all people to healthy, safe and nutritious food so that they can lead an active and healthy life. A possible food crisis and the endangerment of food security will cause bigger problems in the economic, social and political fields on a global scale. Coping with these situations is possible by reducing the negative effects of climate change on agriculture. In addition, it will be possible to

adapt to these negative situations (Kurukulasuriya and Rosenthal, 2003). Climate change is transforming the forms of agricultural production. Also, it causes stress on the amount of world food supply by reducing the productivity of agricultural products (Bindi and Olesen, 2000; McMicmael and Githeko, 2007).
Agricultural activities are responsible for about 20% of the increasing greenhouse gases in the World (Pathak and Wassmann, 2007). As a result of agricultural activities (energy consumption, production, animal breeding, fertilization, medicine, etc.), greenhouse gases such as CO_2, CH_4 and N_2O are released. Therefore, agricultural production is among the causes of climate change (Houghton, 2003).

2. Climate change and environment

The climate crisis has important effects on the environment, as in all areas. It causes many negative effects on the environment such as floods, strong winds, and reduction of biodiversity. Climate change has a direct impact on natural disasters and environment. Environmental problems arise with the consumption-oriented of individuals and urbanization. It is very costly to restore the broken system. Sometimes it is not even possible.
Climate change is a concern all over the world. It is a problem independent of the political and socioeconomic conditions of society. Environmental pollution should not be tolerated in the world. It also draws attention to climate change within the scope of economic development. In addition, it is necessary to invest in agriculture and renewable energy against climate change. Clean energies such as solar and wind are cheaper. With the increasing environmental awareness in recent years, the number of people who demand a cleaner country is increasing. There are 85% of people who think that the environment cannot be polluted even at the expense of economic development. This is an indication that the dirty investments to be made in the country from now on may attract more reactions (Doğru et al., 2020).
There are also some chain effects of global climate change in social and economic life (Doğan and Tüzer, 2011). Human-induced climate change is not appropriate and sufficient on its own in terms of directing thoughts about global environmental problems. In this context, higher moral standards and norms are required to solve a serious problem such as intergenerational justice in climate change (İğci ve Çobanoğlu, 2019). In this framework, ecological problems are seen as a policy problem to the extent of the negativities, threats and dangers they create for human beings. With the increasing environmental problems, the anthropocentric approach falls short of explaining the human-animal-nature relations (İğci ve Çobanoğlu, 2019).
The place of environmental problem on the agenda of humanity is not very old. Environmental problems are not only a problem that threatens non-human creatures, but also threatens the existence of human beings (Eren, 2015).

Conclusion and Recommendations

Agriculture and the environment cannot be separated from each other. All individuals have a duty to combat climate change. In this context, individuals should be educated on environmental and future awareness. Control of our needs and wants is important for the whole world. Individuals need to understand the importance of environmental problems. It is important to be conscious of taking measures to eliminate these problems. Recently, national solutions have started to be created on climate change with the renewable energy and recycling practices of local governments. The search for solutions by countries has accelerated as a result of environmental, economic and social pressures. In terms of climate change, it is important to prefer new technologies in agriculture. The support given to economical irrigation methods should be increased. In addition, it is necessary to focus on practices that reduce the risk situation. For this reason, agricultural insurance is important. Environmental health can also be protected by disseminating renewable energy in agriculture. In addition, high energy costs are reduced. Today, in order to eliminate these negativities due to climate change, first of all, it is necessary to determine the situation with climate change scenarios. Afterwards, these effects should be minimized by implementing adaptation and mitigation strategies effectively. National and international projects on sustainable agriculture and environmental studies should be supported. As a result; We must change ourselves, not the climate.

Abstract

Among the dairy cattle production problems, mastitis and lameness rank first in terms of socio-economic impact. Our aim is assessment of the state of well-being of the udder and the foot in dairy cows and its relationship with milk production. A sample of 42 Prim Holstein and Montbeliard dairy cows in second lactation was used for milk analysis by pH paper test and for locomotion index determination. The results obtained show that the average quantity of milk produced by healthy cows is greater than that produced by cows infected at the rate of (14.90; 10.5) L/d respectively with $p < 0.05$. The rate of lame cows observed was 21.42%, being above the recommended alert threshold (it must be less than 15%). Lame cows presented a greater score for hoof growth and angle plumb than non-lame cows to a value of (1.11; 0.22) and (1.61; 0.83), respectively with $p < 0.05$. A mastitis prevalence of 47.61% was observed. The teat lesion score was higher in cows with mastitis than in healthy cows to a value of (0.81, 0) with $p \leq 0.05$ and the score 5 of the line mammary was determined as the best position score of the mammary gland to avoid the appearance of teat lesions. The score for the hygienic condition of the udder was higher in sick cows than in healthy cows to a value of (3.11, 2) with $p \leq 0.05$. In conclusion, the evaluation of the well-being of the foot and the udder reveals that the conditions for raising dairy cows are not satisfactory and there is no respect of the animal's welfare.

Keywords: *Animal welfare, dairy cattle, audit, lameness, mastitis.*

Introduction

Milk occupies an important place in the diet of the Algerian population. According to Srairi *et al.*, 2019, the milk crisis in Algeria is caused by a lack of production, associated with an increase in annual consumption. Several support programs have been adopted since independence to encourage the dairy sector and despite these efforts, powdered milk is still imported to fill a production deficit estimated at over 60% (Kaouche-Adjlane, 2019; Kebbal *et al.*, 2020). Many factors affect milk production, including the health of cows. Mastitis is considered to be the most important and costly pathologies affecting the dairy sector, as it results in a significant decrease in milk production (Davies *et al.*, 2009; Vikou and Gbangboche, 2019). The problems of mastitis in dairy cattle farms outground remain difficult to control in the Algerian context. Usually mammary gland dysfunction is due to the conditions of breeding and milking (Haj Mbarek *et al.*, 2013). The environment of the milking parlor (air, food used during milking, teats, quality of the litter and its degree of soiling) (Haj Mbarek *et al.*, 2013), contamination of the milk during its passage through the milking machine by the biofilm developed on its surface (Mtaallah *et al.*, 2002), the cleaning practices of the milking machine associated with other practices at the level of general hygiene and teats (Michel et al., 2006), the composition and the degree of maintenance of the litter can be one of the major points of the variability of the microbial load (Haj Mbarek *et al.*, 2013), the cleanliness of the cows as well as the lesional state of the udder have consequences on the one hand on the well-being of animals and on the other hand on milk quality (Ruegg, 2006; Kaouche-Adjlane, 2019). In dairy cattle breeding, lameness is also an important pathological dominant after parturition. she is the third disease behind mastitis and reproductive disorders. In addition to their economic repercussions, lameness is considered to be an impairment of well-being through the pain and discomfort caused (Endres, 2017). In order to participate effectively in improving the productivity of dairy cattle and the quality of the milk produced, we have deemed it necessary to assess the state of well-being of the udder and foot in dairy cows because this will allow us to:

- assess the quantitative losses of milk linked to mastitis and lameness.
- research the relationship between certain practices in breeding, mastitis and lameness.

Material and Methods

Our study was carried out from June until November 2020 at a dairy farm located in the region of sidi Mhamed Benali wilaya of Relizane (Algeria) on a sample of 42 cows of Montbéliarde and Prim_Holstein breeds in 2nd lactation and after the parturition. The herd is maintained, in the majority of cases, in zero grazing with a diet based mainly on oat hay, corn silage and concentrate. The building is designed of bricks, the floor is made of concrete, damaged and not mulched. Milking is carried out twice a day, in the morning and in the evening, mechanically in the barn using a milking cart. During milking, teat cleaning is carried out with water rarely with disinfectant. In general, the hygienic practices of milking and equipment were poorly applied. Experimental monitoring is based on recording the following parameters:

- Individual measurement of the quantity of milk produced during morning and evening milking. This measurement was calculated using a very resistant and light food-grade plastic container, with a capacity of 20L.
- The locomotion index assessment widely used scoring system is that described by Sprecher *et al*., 1997.
- The evaluation of the degree of cleanliness of the foot, is based on the grid described by Guatteo *et al.*, 2013.
- Assensment of plumb angle and of the growths is based on the diagnosis the hind limbs, because foot lesions most often concern the hind legs according to Solano *et al*., 2016, it is based on the observation of the animal in a resting situation based on a rating scale established by Bareille *et al*., 2014.
- A hygienic and sanitary score of udder were carried out jointly before milking, based on a scoring grid for lesion of the teat established by Gourreau *et al.*, 1995 and the scoring grid for udder hygiene according to the model of Lensink et Leruste, 2012, Regarding the location of the udder, we based ourselves on scale established by Lajudi *et al*., 2014.
- Analysis of the milk was determined at the time of milking with pH indicator paper (bromothymol paper). This test consists of placing a few drops of milk on the indicator paper, after removing the first jets. After 15 to 20 seconds of contact, the color change from yellow to green, or blue was considered to be from an infected udder (positive sample).

Statistical analysis was carried out by Statistica software using the Student test comparison of two means.

Results and Discussion

Total milk production is estimated at 253L / d with an average of 12.7 L / d, maximum and minimum production per cow is estimated at (19, 10) L / d respectively. This result is insufficient according to Kadi *et al.* 2007, for farms which breed the two breeds Prim Holstein and Montbéliarde.

1. The Lameness

According to statistical analysis of data of degree of cleanliness of foot of healthy and lame cows, we have found that the average of degree of cleanliness of two types of cow was identical to a value of (2 - 1.69) respectively, while we noted a significant difference in the outgrowth of hoof and plumb angle between non-lame cows and lame cows to a value of (0.22, 1.11) and (0.83, 1.61) with p = (0.0025, 0.001) respectively. We have also observed that the average quantity of milk produced by healthy cows is greater than that produced by lame cows to a value of (14.90; 10.5) L / d respectively with p = 0, 0001 (table 1).

Table 1. Comparison of outgrowth, angle, the cleanliness of the foot and the amount of milk between lame and non-lame cows

Cows	lame	Non-lame	
Outgrowth	X= 1.11 Std= 0.33	X= 0.22 Std= 0.66	*P*= 0.0025
Angle	X= 1.61 Std= 0.50	X= 0.83 Std= 0.57	*P*= 0.001
Cleanliness	X= 1.69 Std= 0.63	X=2 Std= 0.42	*P*= 0.16
Amount of milk (l/d)	X= 10.5 Std= 0.68	X= 14.90 Std= 2.72	*P*=0.0001

p<0,05, M=mean, Std= standard deviation

A loss of 31.49% of average milk production was noted . This coincides with the results found by Bouraoui *et al.,* (2014 a) who report that a cow with severe foot and limb problems can lose up to 35% of her milk production. This can be explained by Stress harmful reactions threaten animal welfare and production, because they consume energy and weaken the body at several levels. Environmental and hygrometric faults, the type of sleeping arrangements, as well as unfavorable social interactions (such as, for example, overdensity) (Wang, 2016 ; Solano *et al.*, 2016 ; Ito *et al.*, 2014 ; Endres, 2017) can place cows under repeated stress, with a potential impact on the quality of immune defenses, thus leading to pathologies. The rate of lame cows observed is 21.42%, which is above the recommended alert threshold which must be less than 15%. This hight frequency is due to the quality of housing, indeed the lack of litter associated with damaged concrete floors allowed the water to stagnate causing very high humidity. According to Borderas *et al.,* (2004), the tissues that make up the hoofs of cows absorb water quickly thus reducing their hardness which makes the foot vulnerable to bacterial attack. the hoof growths associated with a lack of plumbness can be explained by the fact that animals uncomfortable on their hind feet or who present in pain will tend to spread their limbs, that is to say modify its plumbs to rest the affected foot from any pressure (Bareille *et al.*, 2014) , An excess of growth of hooves makes it possible to highlight a disruption of balance between (push / wear) of horn which is linked to a lack of abrasiveness of soil, therefore the absence of grooving of surface concrete is a risk factor for the appearance of growths thus leading to problems with locomotion. (Fox *et al.*, 1991).

2. Mastitis

A mastitis prevalence of 47.61% was observed. The physical condition of teats is an indicator of quality of environment, milking procedures and the milking system used. It also helps define the risk of intra-mammary infections. We have noted in Table 2 that the teat lesion score is higher for udders with subclinical and clinical mastitis by repport to the healthy udder to a value of (0.77, 0.81, 0) respectively with p = (0.000032, 0.00040), The evaluation of cleanliness of udder is also important because it has consequences on the one hand on the comfort of the animal and on the other hand in hygienic quality of milk. We observe in Table 2 that the score of degree of cleanliness of udder affected by clinical and subclinical mastitis is greater than that of healthy udder to a value of (3.11, 2.72, 2) respectively, with p = (0.000097, 0.0014).

Table 2. Comparison of udder cleanliness and teat lesions between healthy cows and cows with mastitis

<table>
<tr><td>udder</td><td>Subclinical mastitis</td><td>healthy udder</td><td>Clinical mastitis</td></tr>
<tr><td rowspan="3">Teat lesion</td><td>M=0.77
Std=0.44</td><td>M=0
Std=0.19</td><td>M=0.81
Std=0.60</td></tr>
<tr><td colspan="2">P= 0.000032</td><td></td></tr>
<tr><td></td><td colspan="2">P =0.00040</td></tr>
<tr><td rowspan="3">Udder cleanliness</td><td>M=2.72
Std=0.92</td><td>M=2
Std=0.27</td><td>M=3.11
Std=0.68</td></tr>
<tr><td colspan="2">P= 0.0014</td><td></td></tr>
<tr><td></td><td colspan="2">P =0.000097</td></tr>
</table>

It is observed in Table 3 that the best position for having a teat without lesion is the rating 5 of mammary line with p = (0.003, 0.00005) for a high and low position of the udder respectively.

Table 3. Comparison of teat lesions between different positions of the mammary gland

<table>

<tr><td></td><td colspan="2">P= 0.00005</td></tr>
</table>

So the risk factors for the appearance of mastitis are linked to the method of breeding and anatomical position of udder by report to the hock. The total absence of litter within the breeding is considered a risk factor, essential for mastitis. The work carried out by Brouillet, have shown that the incidence of mastitis is strongly linked to the quality and quantity of litter (Brouillet, 1990), because a failure of litter will promote the accumulation of dirt and increase the proliferation of germs in the environment, indeed the udder cleanliness results showed that the infected udders were very dirty moreover presence of teat lesion is considered one factor predisposing colonization of germ and thus leading to the appearance of mastitis, the work of Fox LK *et al.*,(1991), have showed than The appearance of teat lesion are due either to an incorrect adjustment of the milking machine or because lack of flexibility of the teat sleeves (Federici, 2004) or to defects in the conception of housing or of its use, thus exposing cows to various udder trauma (Bouraoui *et al.,* 21014b ; Kebbal *et al*., 2020). We noticed in the field that breeders did not change the sleeves every year, according to Federic-Mathieu *et al.,* (2002). Changing the sleeves every year prevents the appearance of mastitis. (Bouraoui *et al*., 21014b) Scoring the mammary line by report to the hock is important in order to avoid teat injury, 33.33% of cows with a mammary line score of 5 did not show any injury. Neijenhuis *et al*., (2002), believe that a defective anatomical location of udder and its teats exposes it to trauma during: difficult lifting, an lying on rough ground, an trampling, slipping, pushing and scratching this increasing the risk of subclinical mastitis (Ficher *et al*., 2003). Indeed 66.66% of cows with mastitis (subclinical and clinical) presented lesions at the level of the teats because their udders were in an inadequate position.

Conclusion

According to the results of this study we found that the problem of lameness and mastitis is linked to the animal's environment (the quantity of litter, the quality of the soil, the maintenance of the milking machine, the building hygiene , ………), thus significantly influencing milk production. It is possible to consider the use of animal welfare assessment technique on the farm to identify cows affected earlyer in order to ensure good prevention. These techniques are within the reach of breeders, including those with low technical skills, because, in addition to their low cost, they are easy to perform, read and interpret.

Abstract

The alder grove is a characteristic environment of the wetland of El Tarf. This ecosystem is now exposed mainly to free grazing by local cattle. The aim of this work is the determination of the diurnal behavior of cows of local breed "Brown Atlas" at the level in the alder grove of Ain Khiar. For this purpose, 5 cows were daily followed for 10 days to determine their feeding activities and their behavior during the summer. During the summer, the animals are locked up at night in the sheepfold and go out to the pasture at dawn. They roam all the plots chosen by the shepherd for a total of 14 hours per day. However, their feeding activities are restricted to 8 hours of feeding (57% of total time). In addition, during the hottest hours, the animals are parked in a make shift pen in the middle of the forest, and the rest of the time, the animals spend resting, which is 37% of the total time. As for the choice of food, the animals are restricted to single species of *Typha latifolia* (L, 1753). The body condition score of the animals decreases considerably during the summer and can go down to 2 or 1,5.

Introduction

FAO analytical study on livestock in Africa highlights the insufficient productivity of pastoral systems and their negative environmental impacts on soil and atmosphere (Steinfeld *et al*., 2006). Yet extensive livestock farming remains a keystone of rural populations' activities in Africa due to its economic, ecological and social functions (Chirat *et al*., 2008). However, because of their considerable impact on the structure and dynamics of plant communities, herbivores play a key role in the maintenance and enhancement of grasslands, and conversely, the abundance, distribution and nutritional value of these plant resources largely affect the acquisition of nutrients by these mammals, and consequently their performance (Van Langeveld and Prins, 2008). Therefore, understanding the interaction between herbivores and plant resources remains a major challenge for ecosystem management. The Aïn Khiar alder grove is a characteristic environment of the National Park of El-Kala, particularly rare in Algeria. Indeed, Eastern Numidia is the only African area with alder groves. Such ecosystems probably have high biological and scientific value in the Maghreb. Junqua (1954) already stated that "it is only in the circle of the Calle that we find the known North African stands of the glutinous alder (Alnus glutinosa)". It is therefore a sensitive site which fully justifies its Ramsar classification, although the area is not supposed to be accessible to livestock.

which is characterised by a marked seasonality in which the value of the food supply fluctuates with the season. Forage availability peaks in spring, decreases rapidly in summer, then picks up again in autumn depending on the rainfall regime before decreasing again in winter (Mebirouk-Boudechiche *et al.,* 2011), The objective of this study is to gain a better understanding of the activities and feeding behaviour of local cows of the "Brune de l'Atlas" breed in the Ain Khiar alder grove, one of the rangelands of northeastern Algeria, and determine its impact on this fragile area.

Material and Methods

The Ain Khiar alder grove is located between the coastal dunes and the agricultural plain of El Tarf in the extreme North East of Algeria (36°48'09"N 8°19'04"E). It covers an area of 170 ha and enjoys a Mediterranean climate with hot, dry summers and mild, wet winters, where average annual rainfall is around 800 to 1200 mm (Chaker-Houd *et al*., 2017). The monitoring of the activity rhythm of four-year-old non-pregnant adult cows of the local breed "Brune de l'Atlas" with an average BCS of 2.5 was carried out daily in the morning and in the afternoon by means of 8-minute visual observations at 40-minute intervals for the duration of a 10-day trial, during the summer season of 2019. The amount of dry matter consumed was evaluated by taking samples simulating the bite of the animals, i.e. the "hand plucking" method. The breed studied is known for its hardiness, its resistance to cold and humidity, and its adaptation to the food resources of wooded and well-watered mountains (Chellig, 1992). In addition to its resistance to certain diseases (Yakhlef, 1989), the breed has good walking abilities on difficult, even rugged terrain. Samples of the vegetation consumed by our females were also taken, dried in an oven set at 50°C for 48 hours and then ground. For the analysis of primary chemical according to AOAC (1990) procedures.

Results and Discussion

During this summer season and following the survey carried out with the farmers and the daily follow-up of the cows selected on the alder grove, we were able to determine a single free grazing station, totally open herbaceous composed exclusively of *Typha latifolia* (L, 1753), a species that grows on waterlogged or even flooded ground. During the hottest hours of the day, the females are parked with the rest of the herd in shaded fenced areas on bare ground.

Chemical composition of the single species ration of the cows during the summer season

The food bowl of our females during the summer season is composed exclusively of *Typha Latifolia* leaves, an herbaceous vegetation in the form of a cattail belonging to the Typhaceae family, the rate of coverage of which is 100% due to the availability of water in the alder grove itself. Table 1 reports the chemical composition of *Typha latifolia*. Our species can be qualified as a mineral-rich species with a good total nitrogen content, the dry matter content is around 21%, while the fibre content is over 34%. The fact that the animals are only interested in one plant species reassures us about their impact on the tree layer.

Table 1: Chemical composition of the simulated ration (*Typha latifolia*) during the summer season

Designation	*Typha latifolia*
Dry matter (%)	20.3
Mineral matter (% DM)	16.69
Carbohydrates (%DM)	83.3
Crude protein (%DM)	10.2
Crude fibre (%DM)	34.4

Circadian rhythm and feeding activities of cows on the alder grove

During the summer, cows leave the barn at dawn and spend an average of 14 hours on the alder grove. The daily monitoring shows that grazing is the main daily activity, with local cows spending 480 min or 57% of the total grazing time. While 330 minutes are spent resting and just 30 minutes moving, which represents 37% and 4% of the total grazing time respectively, 10 minutes are spent on average for watering per day. Observations made in the Sahelian environment show that grazing occupies 59% of the animal's activity at pasture (Sanon *et al.*, 2006). These activities would be linked to the season effect where the time spent grazing can increase from 54% in the rainy season to 84% in the dry season (Ouedraogo-Koné *et al.*, 2006). The diurnal ingestion times, rest and movement that we observed are much higher than the results obtained on cattle grazing on natural grassland (Mebirouk-Boudechiche *et al.,* 2011) and Borgou bulls grazing fallow land (Babatounde' *et al.*, 2009). Moreover, according to Balent and Gibon (1986), the duration of grazing is strongly linked to the length of the day and to weather conditions, which can greatly reduce it by delaying the animals' exit time (frost) or by disturbing their activity rhythm.

Table 2. Different activities of cows on the range during the summer season

Activity	FT	RT	TT	WT
Time (mn)	480	330	30	10
%	57	37	4	2

FT: feeding time, RT: resting time, TT: travel time, WT: watering time

Feeding behaviour parameters

The circuit and the time in free grazing of the local breed cows during the heat season seem to be determined by the temperatures and the orientations of the shepherds,These results confirm the work of CHIRAT, 2008 in the hot season due to the high level of insolation. Resting times are significantly longer in the hot season ($p < 0.001$). They also noted that there was no ruminating during the day of divagation. This suggests that the consistent tethering time (at least 12 hours per day) and the importance of movement to ensure a certain level of intake limits the time spent on rumination. As it is not possible to dissociate grazing from movement, we describe this system as 'walking'. The amount of dry matter ingested by our cows during this summer period is 7548 g of DM/animal/day with a total number of tines of 296 NTS/observation, and a tine weight of 3.4 g of DM. While at the end of spring and the beginning of summer the cows still seem to be in good health due to the availability of fodder, as the summer progresses their BCS decreases considerably from 2.5 ±0.78 to 2 ±0.57. This can be explained by the high heat which causes stress and probably leads to a decrease in appetite in addition to the decrease in feed availability. Mebirouk-Boudechiche *et al*. (2011) reported an NTS of 41 Bite/min but the TSW was lower than ours, i.e. 2.5 g DM, for local breed cows grazing on natural grassland dominated by legumes. Thus, animals try to compensate for the low amount taken per mouthful by increasing the frequency of mouthfuls and/or grazing time in order to maintain their feed intake rate (Penning, 1986; Allden and Whittaker, 1970).

Table 3. Main parameters assessed during observation of cows on pasture

Parameter	CT	TSF	NTS	TSW	IQ	BCS	
value	48	37	296	3.4	7548	beginning	end
						2.5 ±0.78	2 ±0.57

CT: Counting time in minutes, TSF: Teeth strike frequency NTS: Total number of teeth strikes on the vegetation during the 8 minute teeth strike counting period, TSW: Average teeth strike weight (in g DM), IQ: Intake quantity (in g DM/animal/day), BCS: Body condition score,

Conclusion

At the end of this study, we can conclude that the Ain Khiar alder grove, in spite of its floristic richness, turns into a hostile terrain with limited food availability during the hot season. The monitoring of local cows of the breed "Brune de l'Atlas" on the alder grove of Ain Khiar shows that grazing is the main daily activity compared to moving and resting. The movements are determined firstly by the position of the obligatory crossing points (pens and water points). Secondly, it is as if the intake is determined by the vegetation units crossed, and finally by the herder. The cows graze in the morning and afternoon and rest at midday, spending more than 14 hours on the grove. The composition of the feed bowl, the estimation of the ingested quantities and the weights of the teeth strokes give a picture on the adaptive and selective behaviour of our cows during the summer season.

EFFECT OF INCORPORATION OF THE PLANT EXTRACTS IN NATURAL CASING ON CONTENT OF FATTY ACIDS IN FERMENTED SAUSAGES

Ana VELEMIR*, Snježana MANDIĆ, Danica SAVANOVIĆ

University of Banja Luka, Faculty of Technology Banja Luka, Republic of Srpska, Bosnia and Herzegovina
*Corresponding author: ana.velemir@tf.unibl.org

Abstract

In this study, the effect of natural casing treated with ethanol extract of *Aronia melanocarpa* and *Cornus mas* on the fatty acid content in fermented sausages "sucuk" type was evaluated. The sausages were produced in industrial conditions, stuffed into the pretreated natural casings, vacuum packaged, and stored at 4°C for six months. Five groups of sausages were tested, C1 (natural casing without treatment), C2 (treated with 6% (v/v) ethanol), C3 (treated with ascorbic acid), A (treated with ethanol extract of *A. melanocarpa*), and D (treated with ethanol extract of *C. mas*). The qualitative and quantitative composition of fatty acids in the tested samples was determined by the GC-FID analytical technique. Palmitic (C16:0) and stearic (C18:0) acids were predominant of the saturated fatty acids (SFA) and their quantity ranged from 15.93% to 27.50%, and 13.81% to 24.74%, respectively. Oleic acid (C18:1) in the range from 19.02% to 31.87% was the most represented unsaturated fatty acid (USFA). Based on the obtained results, it can be concluded that treated casings had a statistically significant effect ($p<0.05$) on the content of the identified fatty acids in tested samples. During six months of storage, it was noticed a decrease in SFA content and an increase in USFA content, especially C22:1, C24:1, and C22:6. The ratio SFA/USFA ranged from 1.04% to 1.50% after production and from 0.53% to 0.69% after six months of storage. The ratio of polyunsaturated fatty acids (PUFA) n-6/n-3 ranged from 0.27% to 5.14% after production and from 0.23% to 1.65% at the end of the testing period.

Keywords: *fermented sausage, extract, natural casing, fatty acids.*

Introduction

Consumers, especially in developed countries, are increasingly interested in the elements of nutrition food values and the impact of food ingredients on health. The content of fatty acids in food is of great importance for a healthy human diet. All around the world, meat traditionally occupies a central position. The fat content and fatty acid composition of meat are significant properties that affect the quality of meat and meat products. Special importance is attached to the use of fats in human nutrition, especially omega 3 and omega 6 fatty acids and their mutual relationship (Pleadin *et al*., 2016; Ahmad *et al*., 2018).

The production of dry fermented sausages has a very long tradition. Fermented sausages are made of minced meat and fatty tissue of various animals, with the addition of salt, nitrates/ nitrites, sugar, ascorbic acid and different spices. The mixture is filled into natural and/or artificial permeable casings of various diameters and then subjected to fermentation and ripening in ambient or controlled conditions for several weeks or months (Stajić *et al*., 2012).

Sucuk is a fermented sausage originating from Turkey, popular in most the Middle East and European countries. Manufacturing of sucuk varies regionally, but in general, recipes consist of

beef and beef fat and/or sheep tail fat. The mixture is filled into a beef small intestine and tied with rope (Yıldız-Turp and Serdaroglu, 2008).
The use of edible coatings and films as a barrier to the transit of oxygen and water to preserve food quality has intensified recently (Hromiš *et al*., 2013; Ozvural *et al*., 2016). These coatings act, thereby slowing oxidation reactions and retaining moisture (Tyburcy *et al*., 2010; Shon *et al*., 2011). This is the main mechanism by which coatings enhance quality and prolong storage life. Furthermore, adding plant extracts and some natural bio preservatives gives the coatings antimicrobial and antioxidant properties (Raesi *et al*., 2016; Król *et al*., 2017). Plant extracts are generally added to prevent oxidation of fats and proteins, and/or inhibit the growth and development of bacteria, yeasts and molds, or prevent spoilage of the product (Botsaris *et al*., 2015). In recent decades, many researchers have tested plants and plant extracts, such as oregano, sage, rosemary, grape seed (Man and Jaswir, 2000), thyme, white, red and mountain peony, angelica, sedge, marjoram, wild marjoram, cumin, ginger, plum, aloe vera (Nuñez *et al*., 2008). This study aimed to investigate the effect of submerging natural casing in plant extracts (*A. melanocarpa* and *C. mas*) on the fatty acid content in fermented sausages.

Materials and methods

For the preparation of extracts, fruits were washed and the petioles and the seeds removed. For ethanol extract, 40g of fruits were homogenized with 160 mL 80% (v/v) ethanol, first on a Polytron PT 3100 homogenizer, 10 minutes at 8000 rpm, then in an ultrasonic bath for 30 minutes, and 30 minutes on a magnetic stirrer. The mixture was filtered and the obtained filtrate was evaporated to a dry residue, first on a vacuum evaporator and then in a dry sterilizer at 50°C. The dry extracts prepared in this way were stored in a dark place until the moment of use. The prepared dry extract of *A. melanocarpa* was diluted to 45 mg/mL and extract of *C. mas* was diluted to 22.5 mg/mL in 6% (v/v) ethanol and used for casing treatment. Duration of submersion was 24h for all casings.
Domestic fermented sausages, sucuk, were produced traditionally under industrial conditions. The emulsion consisted of beef meat 80%, beef fat 16%, nitrite salt 2.5%, spices: black pepper 0.3%, white pepper 0.15%, garlic granules 0.35%, additive (mixture of dextrose, salt, sucrose, ascorbic acid, preservative E252 (2.5%) 0.6%, starter culture 0.01%. After grinding and mixing in the cutter, the sausage emulsion was filled into natural beef casings with the addition of all components. For this study, five samples of domestic fermented sausages: C1-the control (natural casing without treatment); C2 (natural casing treated with 6% (v/v) ethanol), C3 (natural casing treated with ascorbic acid), A (natural casing treated with ethanol extract of *A. melanocarpa*), and D (natural casing treated with ethanol extract of *C. mas*) were made.
The sausages were first tempered (18-20°C) for 8h, then smoked (beech wood) for three days (20-23°C, 92-95% RH), and finally left for fermentation (ripening) at 16-18°C for eight days.
After production, sausages were vacuum-packed and stored in a cooling chamber at 4°C until sampling (usual storage conditions for this kind of product). Analyses of sausages were carried out after production and after six months of storage.
The total fat extraction was performed by the reference method BAS ISO 1443:2007, the principle of determination is based on the hydrolysis of the sample with dilute hydrochloric acid.
Fatty acid methyl esters of the tested samples were prepared by dissolving samples in hexane and direct esterification with saturated KOH/methanol solution (David *et al*., 2005). The equipment used to determine fatty acids was Clarus 680 Perkin Elmer gas chromatograph with FID detector,

Elite-wax L 60 m column, ID 0.32, DF 0.5, with the standard: Sigma Aldrich Supelco 37 components FAME MIX. Injector and detector temperature 250ºC, sample volume 1µL, temperature regime: 60ºC for 2 min, 10ºC/min up to 200ºC, 5ºC/min up to 240ºC, and 30 min at 240ºC, flow 1.5 mL/min, nitrogen gas (carrier). The total duration of analysis was 54 min. The composition of fatty acids is shown as a percentage of individual fatty acids in the total amount of identified fatty acids (g/100 g of total fatty acids).
Statistical processing of the obtained results was performed using the Microsoft Excel 2013 software package and the IBM SPSS Statistics 22.0 (Armonk, NY, United States). Results were presented as mean values of three individual measurements ± standard deviations. The significance of differences between arithmetic means was determined and expressed with 95% probability (Tukey's test).

Results and discussion

The fatty acid composition of analyzed fermented sausages is given in Table 1. The most common SFA presented in fermented sausages were palmitic acid (C16:0) ranged 20.96-27.50% after production (samples D and C2, respectively) and 15.93-18.07% (samples C3 and C1 respectively) after storage, stearic (C18:0) ranged from 22.98-24.74% after production (samples A and C3, respectively) and 13.81-16.00% after storage (samples A and C1, respectively) and myristic (C14:0) ranged from 3.22-5.72% after production (samples D and C3, respectively) and 2.09-2.74% after storage (samples C3 and C2 respectively). Literature data confirm results from this study (Wójciak *et al*., 2015; Pleadin *et al*., 2016). Other identified SFA were found in much smaller amounts in the analyzed samples.
Oleic acid (C18:1c+t) with content from 25.58% (sample D) to 31.87% (sample A) after production, and from 19.02% (sample C3) to 25.37% (sample C1) after storage, was predominant among MUFAs, which coincides with the literature data for similar products (Barbir *et al*., 2014; Lešić *et al*., 2017). Oleic fatty acid is the most important fatty acid of all kinds of meat, and in beef, it makes up 33% of total fatty acids (Barbir *et al*., 2014). It was an evident increase of MUFA n-9 (C22:1) and C24:1+C22:6 in all samples during storage, especially in sample C3.
Linoleic acid (C18:2c+t) was the dominating PUFA with values around 3.34-6.65% after production, which is in accordance with literature data (Liguori *et al*., 2015, Alabiso *et al*., 2021). During storage, content of the linoleic acid decrease (1.72-2.70%). It can be noticed that statistically significant differences ($p<0.05$) exist between analyzed samples.
Changes that occur in fats and fatty acids in meat can be controlled using various strategies, such as animal dietary supplements, the addition of antioxidants, processing, and the use of special packaging (Amaral *et. al*., 2018).
The results of the total content of SFA and USFA as well as their mutual ratio in the tested samples are given in Table 2. Based on the obtained results, it can be noticed that the total content of SFA was the highest after ripening (from 51.08% in sample D, to 60.04% in sample C1), and decreases during storage (from 34.83% in sample A, to 40.80% in sample C1). In the case of MUFA, the situation is reversed, content increases during storage. The content of PUFA slightly increased during storage. For most traditional cured meat products from Croatia and Slovenia, the proportion of fatty acids was MUFA>SFA>PUFA, except 'budjola' and technologically similar products, for which the order was SFA>MUFA>PUFA (Pleadin *et al*., 2016).

The PUFA/SFA ratio could be a good indicator of the nutritional quality of sausages (Wójciak *et al*., 2015). WHO/FAO experts have reported guidelines for a "balanced diet" in which the suggested ratio of PUFA/SFA is above 0.4, but a recommendation by the British Department of Health for PUFA/SFA is more than 0.45 (Teixeira *et al*., 2020), to prevent an excess of SFA and PUFA with a negative effect human health (Parunović *et al*., 2017). The PUFA/SFA was within the recommended value, ranged from 0.11 to 0.34 for all samples, except sample A after storage (0.56). Another indicator of the quality is n6/n3 PUFA ratio, and according to Teixeira *et al*. (2020), this ratio should be less than 4. Samples C3 and A after production had higher values (4.07 and 5.14, respectively) than recommended. Based on results, MUFA n-9 and PUFA n-3 content in samples treated with vitamin C and both fruit extracts were rather high compared to control C1 and sample C2. On the protection of unsaturated fatty acids from oxidation greatly affect substances with strong antioxidant activity (Hromiš, 2015).

SFA- saturated fatty acids; MUFA-monounsaturated fatty acids; PUFA- polyunsaturated fatty acids; USFA- unsaturated fatty acids.

Conclusion

Palmitic (C16:0) and stearic (C18:0) acids were predominant of the saturated fatty acids (SFA) and oleic acid (C18:1) was the most represented unsaturated fatty acid (USFA) in all analyzed sample sausages. During six months of storage, it was noticed a decrease in SFA content and an increase in USFA content. The PUFA/SFA was within the recommended value, except in sample A after storage. Ratio n6/n3 PUFA also was within the recommended value after storage. Based on the obtained results, it can be concluded that incorporation of the plant extracts in natural casing had a statistically significant effect ($p<0.05$) on the content of the identified fatty acids in tested samples.

Abstract

Freezing meat, as a method of canning, aims to maximize the storage period, while preserving the quality and nutritional value of the product after thawing. The aim of this paper was to examine the effect of thawing methods on the physico-chemical properties of turkey meat. Freezing of the meat samples was performed at a temperature of -20ºC. Prior to analysis, the samples were thawed in one of the following ways: 10 hours at 4°C (in a refrigerator), 2 hours at 20°C (at room temperature) and in a microwave oven (2450 MHz, 700 W), until a temperature of 4°C in the center of a meat piece. The following analyzes were performed: determination of weight loss, determination of moisture, ash, fats and proteins content, measurement of water binding capacity, instrumental measurement of color and texture, measurement of a_w value and pH value. Based on the results obtained in this paper, it can be concluded that thawing methods have a statistically significant effect ($p<0.05$) on the physico-chemical properties of turkey meat. The samples of turkey meat thawed in the refrigerator had the lowest weight loss (1.79%), the highest water content (75.34%) and the highest water binding capacity (2.65 cm^2), compared to the samples thawed in the microwave and at room temperature. It can be concluded that by slow thawing of turkey meat (at the refrigerator temperature), water has enough time to rebind to proteins, and in that case there will be less separated liquids.

Keywords: *Turkey meat, Thawing, Physico-chemical properties.*

Introduction

Freezing is frequently used for preserving food products in the food industry. Freezing is the process of canning food products at low temperatures. Due to heat dissipation, the temperature of the product drops below the freezing point (cryoscopic point), and water in the food is converted into a solid state (ice) (Nesvadba, 2008). That, practically, leads to the termination of chemical, biochemical and microbiological processes in food. The transition of water from a liquid state to ice, with a simultaneous increase in the concentration of dissolved substances, affects the reduction of water activity in food (Delgado and Sun, 2007). By reducing the activity of water below 0.7, the metabolic activity of most microorganisms is significantly decreased or completely stopped (Nesvadba, 2008). The more solid water becomes, the greater the stability of the frozen product (Nesvadba, 2008; Sablani *et al*., 2010). Freezing is an anabiotic canning procedure. That does not mean that the microorganisms are destroyed during the freezing of food. Instead, there are no conditions for their further activity in the frozen product (Pham, 2008; Sánchez-Alonso *et al*., 2012; Espinoza Rodezno *et al*., 2013; Sman, 2013). When the food is thawed, the microorganisms are reactivated. Refrigerated and frozen storage is widely used to

increase the shelf life of meat and meat products (Custódio *et al*., 2018; Rajkumar *et al*., 2020). However, the formation of ice during freezing causes physical and chemical changes in the product (Berry *et al*., 2008; Sučić *et al*., 2010; Gambuteanu *et al*., 2014; Li *et al.*, 2018). These changes are the result of ice formation and lead to changes in product quality after thawing. The intensity of the changes depends mainly on the freezing rate, storage conditions and thawing method (Fellows, 2000; Muela *et al*., 2012; Zequan *et al*., 2019).
After freezing and storage in the frozen state, most foods must be thawed before use. Thawing is the process opposite to freezing (Nesvadba, 2008). To melt the ice crystals, energy is brought into the food. In addition to the freezing rate and storage conditions, the quality of thawed food is also affected by the thawing rate. Frozen meat can be thawed in different ways. The most frequently used conventional methods are thawing in a refrigerator, in cold water, in a microwave oven, and at room temperature. New ways of thawing include high-pressure thawing, ohmic thawing, and acoustic thawing (Akhtar *et al*., 2013).
This paper aims to examine the influence of different thawing procedures (in the refrigerator at 4°C, at room temperature i.e., 20°C and in the microwave oven) on the physico-chemical properties of turkey meat (*Pectoralis major*).

Materials and methods

Analyses were performed on a sample of fresh turkey meat from the slaughterhouse. The pieces were cut into 2.0 cm thick slices, packed in polythene bags and, after marking, frozen at a temperature of -20ºC. After freezing the samples were kept at -20 °C for 24 h, until the analysis. All analyses were performed on fresh unfrozen samples after freezing and after certain defrosting treatments of the samples. This allowed a comparison of the measured parameters before freezing and after thawing. Before the analysis, the samples were thawed in one of the following ways: 10 hours at 4°C (in a refrigerator), 2 hours at 20°C (at room temperature) and thawing in a microwave oven (2450 MHz, 700 W) to the temperature of 4°C in the centre of the piece of meat.
The freezing/thawing weight loss was determined by measuring the weight of fresh meat samples before freezing and after thawing. Differences in weight were expressed as a percentage of the mass of fresh meat measured immediately before freezing.
The moisture content in the meat samples was determined using the drying method (BAS ISO 1442:2007).The total content of ash was determined gravimetrically after incineration at 550°C (BAS ISO 936:2007). Determining the content of fat in meat samples was performed by the extraction method (BAS ISO 1443:2007). The protein content was determined based on the total nitrogen content measured using the Kjeldahl method and multiplying by a 6.25 factor (BAS ISO 937:2007).
The compression method was used to measure the binding capacity of the turkey meat. Determining the water-binding capacity (the squeezed meat juice) was based on measuring the released water (juice) when pressure was exerted onto muscle tissue (Grau and Hamm, 1953). The difference between the surface, determined by the digital planimeter (Placom KP-92N, Koizumi, JAPAN), below the meat films and the total surface area (juice-moistened surface filter) was taken as a measure of the squeezed juice (cm^2).
Water activity (a_w) was measured by direct readings in Aw Meter (Novasina LabMaster-AW 1119971). The pH value was measured by inserting a pH meter (Hanna instruments, HI 2211)

into aqueous meat extract. The calibration of the pH meter was performed using standard buffer solutions before and during the reading of the values obtained.

Instrumental colour measurement was performed using a spectrophotometer CM-2600d (Konica Minolta Sensing Inc., Japan), with 8 mm port size, illuminant D65 and a 10° standard observer and after the standardization of the instrument concerning the white calibration plate. Colour parameters, expressed as CIE L*, a* and b* values, were determined as respective indicators of lightness, redness, and yellowness.

Texture was determined mechanically, using a Texture Analyzer TA.XT plus (Stable Micro Systems), which measures the shear force needed to cut the sample. Warner-Blatzler shear force was used with the HDP/BSK knife cutting blade. The load cell was 25 kg, the rate was 4.00 mm s^{-1}, and the distance was 20.00 mm. The test samples were prepared by cutting rectangular shapes of the meat (1×1 cm, length 5 cm) on which the measurement was performed. The instrument measured the force (kg) needed to move the knife cell a certain distance (mm) into the meat sample. Prior to measurement, the meat samples were heat-treated (in an airtight bag, in a water bath) until a temperature of 75°C was reached in the center of the product (Mandić et al., 2013).

All analyses were performed with three repetitions except for instrumental colour and texture measurement, which was performed with 10 repetitions.

Statistical processing of the obtained results was performed using the Microsoft Excel 2013 software package and the IBM SPSS Statistics 22.0 computer program for Windows (Armonk, NY, United States). The results obtained in this paper are presented as mean values ± standard deviation (SD). The significance of differences between arithmetic means was determined by analysing the variance with one independent variable (One way ANOVA) and multiple interval tests (Dankan Post-hoc test) and expressed with 95% probability ($p<0.05$).

Results and discussion

As can be seen from the results presented in Table 1, the thawing method has a statistically significant influence ($p<0.05$) on the weight loss and chemical composition of turkey meat. The analysis showed that significant weight loss was observed in the meat thawed in the microwave (4.04%). This result differs significantly from the results obtained for meat thawed at room temperature (2.59%) and refrigerator temperature (1.79%). The formation of ice in the product during freezing causes physical and chemical modifications of the product. The main physical changes in frozen products are mechanical damage, water migration, ice recrystallization and water release during thawing (Sučić *et al.*, 2010; Savanović *et al.*, 2017). Since the specific volume of ice is higher than the specific volume of water, freezing can cause mechanical damage inside the product. The spread of ice crystals in the product causes tissue damage, and therefore food releases a certain amount of water after thawing.

The chemical composition of meat depends on the type of animal, race, sex, age, breeding and feeding method, nutritional status, and the part of the carcass from which the meat is taken. According to the share in the overall volume, water may be considered the basic meat component (Rede and Petrović, 1997). During thawing a part of the water comes out of the food after the transition from the solid to the liquid state. Fluid leakage is the result of the crystals formed by freezing and the inability of muscles to absorb the fluid during thawing (Delgado and Sun, 2007; Sučić *et al*., 2010; Savanović *et al*., 2019).

In addition to the freezing rate and storage conditions, the quality of thawed food can be partially affected by the thawing rate. Slow thawing (especially in meat) is believed to allow water more time to re-bind to proteins, which reduces the release of liquid. If the food is slowly thawed, the ambient temperature is not high, which has a somewhat inhibitory effect on microorganisms. Accordingly, slow thawing has a less detrimental impact on food quality (Vereš, 2004). Fresh samples of turkey meat had an average water content of 75.61% before freezing. After thawing, the highest water content was in those thawed in the refrigerator (75.34%). That was followed by the samples thawed at room temperature (74.78%), while the lowest water content was found in the samples thawed in the microwave oven (73.84%). An analysis of the basic chemical composition of the tested samples showed that, in parallel with the decrease in the water content of the thawed turkey meat, there was a statistically significant ($p<0.05$) increase in the content of other ingredients (proteins, fats, ashes). That is shown in Table 1.

Table 1. Weight loss and chemical composition of tested turkey meat samples

Parameter	Fresh meat	Thawing method		
		In refrigerator	At room temperature	In microwave oven
Weight loss (%)		1.79±0.09[a]	2.59±0.08[b]	4.04±0.20[c]
Water content (%)	75.61±0.13[c]	75.34±0.26[c]	74.78±0.18[b]	73.84±0.07[a]
Protein content (%)	22.30±0.18[a]	22.33±0.06[a]	23.13±0.07[b]	23.44±0.10[c]
Fat content (%)	0.52±0.04[a]	1.09±0.06[b,c]	0.82±0.04[b]	1.35±0.03[c]

[a-c] Mean values with a different letter in the same row are statistically significantly different from 95% probability ($p<0.05$)

The property of meat to retain water and water added under certain conditions, even when exposed to an external force such as pressure or heating, is known as the water-binding capacity (WBC) or water-holding capacity. The major water-binding carrier in muscles is myofibrillar proteins; this is due to their specific chemical structure (Rede and Petrović, 1997). Freezing of meat mainly results in a reduced water-binding capacity and an increased amount of liquid phase released during thawing. That is explained by changes in the protein state caused by the formation of ice crystals (Savanović and Grujić, 2017; Li *et al*., 2018). The fluid released during meat defrosting is affected by various changes taking place during the storage and freezing of meat. These changes can be freezing-related tissue damage (Li *et al*., 2018), protein oxidation (Estévez, 2011; Utrera *et al*., 2014) or changes in the isoelectric point of the protein (Estévez, 2011). The water-binding capacity is an indirect measure of protein denaturation (Savanović and Grujić, 2017). As can be seen from the results presented in this study, the thawing methods had a statistically significant influence ($p<0.05$) on the water-binding capacity of turkey meat after thawing (Table 2). The compression method showed statistically significantly higher ($p<0.05$) amounts of fluid released from meat samples thawed at room temperature (3.41 cm^2) and in a microwave oven (4.74 cm^2) compared with those thawed in refrigerator (2.65 cm^2) and with unfrozen (fresh) meat (2.31 cm^2). Therefore, the meat thawed using slower thawing methods had a greater water-retaining capacity and released less fluid during compression than meat thawed using faster thawing methods. In the released cellular fluid, water-soluble substances, minerals, vitamins and proteins are lost during defrosting of the product, which reduces its nutritional value (Liu *et al*., 2013). Dehydration of frozen products is a significant factor as it causes a decrease in weight and quality of the product, like changes in colour, appearance, texture etc. (Li *et al.*, 2018).The obtained results showed that thawing methods had no statistically significant effect ($p>0.05$) on the change in a_w and pH value of turkey meat (Table 2).

Table 2. Influence of thawing methods on water-binding capacity (WBC), aw and pH value of turkey meat

Parameter	Fresh meat	Thawing method		
		In refrigerator	At room temperature	In microwave oven
WBC (cm^2)	2.31 ± 0.23^a	2.65 ± 0.12^a	3.41 ± 0.36^b	4.74 ± 0.18^b
a_w	0.966±0.00	0.965±0.00	0.967±0.00	0.966±0.00
pH value	5.73±0.06	5.81±0.06	5.77±0.10	5.77±0.09

$^{a\text{-}b}$ Mean values with a different letter in the same row are statistically significantly different from 95% probability ($p<0.05$)

Table 3. shows the values of the instrumentally measured colour and texture parameters of the tested samples of turkey meat. From the obtained results, it was observed that thawing procedures had a statistically significant effect ($p<0.05$) on the colour and texture of turkey meat. On the surface of meat samples thawed in the refrigerator and those thawed at room temperature, a statistically significantly higher ($p<0.05$) value for illuminance (L* value) was measured than on fresh meat. The L* value on the surface of the samples thawed in the microwave oven was statistically significantly lower ($p<0.05$). In all three thawing methods, there was an increase ($p<0.05$) in the share of red colour (a* value) and yellow colour (b* value) compared to those measured on fresh meat.

Due to structural changes in the tissues, the texture of thawed meat is softer (as shown by the analysis results presented in Table 3). Fresh meat had the highest hardness (1.57 kg), and the meat thawed using other methods had lower hardness (it was softer).

Table 3. Instrumentally measured color and texture parameters of fresh and thawed turkey meat

Parameter	Fresh meat	Thawing method		
		In refrigerator	At room temperature	In microwave oven
L*	56.40 ± 1.80^b	58.41 ± 1.69^c	59.95 ± 1.65^c	53.21 ± 2.03^a
a*	-0.33 ± 0.23^a	1.24 ± 0.20^c	0.49 ± 0.13^b	1.10 ± 0.33^c
b*	7.79 ± 0.78^a	10.28 ± 0.87^c	9.96 ± 0.68^c	9.14 ± 0.88^b
Texture (kg)	1.57 ± 0.16^c	$1.08\pm0.14^{a,b}$	0.99 ± 0.07^a	1.13 ± 0.17^b

a-c Mean values with a different letter in the same row are statistically significantly different from 95% probability ($p<0.05$)

Conclusion

The results in this paper indicate that the thawing procedures affect ($p<0.05$) the physic-chemical properties of turkey meat. Turkey meat samples thawed in the refrigerator had the highest water content and the highest water-binding capacity compared to those thawed in the microwave and at room temperature. Based on the obtained results, it can be concluded that slow thawing of turkey meat (at the refrigerator temperature) allows water to re-bind to proteins, which results in a lower amount of separated liquids. If the food is slowly thawed, the ambient temperature is not high, which could have an inhibitory effect on microorganisms. In addition to changes in the basic chemical composition, different thawing procedures result in the change in colour and texture of thawed turkey meat.

Abstract

The sensory properties of food product have an influence on overall quality and consumers' product acceptance. Different factors during processing have an impact on quality characteristics of the final product. As a very important foodstuff in human nutrition, cheese can be produced in different ways and have different composition and sensory properties. The aim of this study was to examine the influence of coagulation conditions (type of coagulant and coagulation temperature) on the sensory properties of six produced cheese samples. Milk coagulation was performed at 85°C (samples 1,3,5) and 95°C (samples 2,4,6), and citric acid (samples 1 and 2), tartaric acid (samples 3 and 4) and acetic acid (samples 5 and 6)were used as coagulants. A team of 10 trained evaluators has performed sensory analysis of tested cheese samples by ranking samples according to acceptability and using a 5-point scoring system (1=very considerable deviation from expected quality to 5=no deviation from expected quality) to assess appearance (external and cross-sectional), odour, flavour and consistency. Based on the obtained results, it can be concluded that coagulation conditions have a statistically significant effect ($p<0.05$) on the appearance, flavour and consistency of produced cheeses. Sample five had the highest score (5.00) for external appearance, and the cross-sectional appearance was the best in sample four (score 4.80). The odour of all samples was excellent (score 5.00), while the samples five and six had slightly lower scores for flavour and consistency. Sample four was most acceptable by ranking according to overall acceptability.

Keywords: *Milk, cheese, sensory properties.*

Introduction

The organisation and implementation of product and process quality control are prerequisites for a successful business. In addition to specific instrumental and analytical methods, the modern food industry uses the results of the sensory analysis as a set of additional information on the quality of tested products. The sensory properties of the products are of great importance for the overall acceptability of food products (Radovanović and Popov-Raljić, 2000; Jimenez-Maroto *et al*., 2016; Lipkowitz *et al*., 2018; Kandasamy *et al*., 2020). For a product to become competitive on the market and be able to meet consumer expectations, special attention should be paid to sensory properties during the development and improvement of product quality.

Sensory assessment of food quality includes techniques that can be used to accurately measure food sensations while controlling and eliminating the impact of data on product origin and the trademark impact of a well-known competing producer and the impact of other factors on the acquired impressions about the product quality (Lawless and Heymann, 1999; Budimir *et al*., 2004). To be offered on the market, food products must meet the prescribed minimum quality

and safety requirements. Different sensory analyses of selected quality indicators are performed to examine the impact of various factors on dairy products quality (Papetti and Carelli, 2013; Lipkowitz *et al*., 2018; Vanbergue *et al*., 2018; Brighenti et al., 2020; Manzocchi *et al*., 2021).
The sensory properties of milk and dairy products are specific to each type or group of products if they are of appropriate quality, designed and shaped to be attractive and pleasant to consume. Cheese is the crown of dairy production, which is the oldest and safest form of concentrating and preserving the nutritional value of milk. Cheese is not only a valuable dairy product but has recently become a favourite food to enjoy, especially in countries with a high standard of living, where its consumption is also growing (Popović-Vranješ, 2015). A very important foodstuff in human nutrition, cheese can be produced in different ways, which results in different composition and sensory properties.
This study aimed to examine the influence of coagulation conditions (type of coagulant and coagulation temperature) on the sensory properties of cheeses obtained by heat-acid coagulation of milk.

Material and Methods

Cheese production was carried out at the milk processing plant (mini cheese factory) of the Secondary Agricultural School in Banja Luka. Six models of cheese samples were produced for this experiment. Pasteurized cow's milk containing 3.2% fat (produced by Pađeni Dairy, Bileća, Republika Srpska, Bosnia and Herzegovina) bought in a local supermarket was used to make cheese. The milk was stored in a refrigerator at +4°C before it was processed into cheese. Fresh pasteurized milk was heated to the appropriate temperature (85°C and 95°C), and citric, tartaric, and acetic acids were used to coagulate the milk (Table 1). After the addition of acid, the mixture was blended well and rested for 10 minutes to obtain curd. The resulting curd was filtered through gauze into a strainer. The hot drained curd was weighed and 1.5% of salt was added to it. After salting and mixing, the curd was placed in a mould for pressing. The pressing took one hour, and the load was 2 kg per one kilo of cheese. The finished cheese was cooled in a refrigerator to +4°C and stored at the same temperature until the analysis. The analysis was performed 24 hours after production at the Faculty of Technology, University of Banja Luka.

Table 1. Type of coagulant and coagulation temperature used for production of cheeses

Sample	1	2	3	4	5	6
Type of coagulant	Citric acid	Citric acid	Tartaric acid	Tartaric acid	Acetic acid (9%)	Acetic acid (9%)
Amount of coagulant (%)	0.30	0.30	0.30	0.30	1.50	1.50
Coagulation temperature (°C)	85	95	85	95	85	95

Sensory evaluation of the selected cheese quality indicators was performed by a group of ten trained evaluators. The assessed sensory properties were the external appearance, cross-sectional appearance, odour, flavour, and consistency. The assessment was performed using a 5-point scoring system (from 1 = very considerable deviation from expected quality to 5 = no deviation at all) (BAS ISO 22935-2:2011; BAS ISO 22935-3:2011), with an explanation of the given assessment.

To compare the overall sensory quality of the tested cheeses, the samples were ranked according to overall acceptability – from the most acceptable one (1st place) to the least acceptable one (6th place). The evaluators entered the sample codes in appropriate sections of the evaluation sheet. A sum of ranks was determined for each sample. The value of the sum of ranks was compared with the range of tabular values corresponding to the number of repetitions (n=10) and the number of treatments (6 ranked samples), which for the level of statistical significance $p<0.05$ was 25-45 (Radovanović and Popov-Raljić, 2000). If the sum of the ranks is less than the minimum numerical value of the table range, such product is designated as "superior". If the sum is higher than the maximum numerical value of the table range, the product is marked as "inferior". If the sum of the ranks is equal to the limit numerical values of the corresponding table range or is within it, the product is of "standard" quality.
Statistical processing of the results obtained by scoring method was performed using the Microsoft Excel 2013 software package and the IBM SPSS Statistics 22.0 computer program for Windows (Armonk, NY, United States). The results obtained by scoring method are presented as mean values of the individual results ± standard deviation (SD). The significance of differences between arithmetic means was determined by analysing the variance with one independent variable (One way ANOVA) and multiple interval test (Dankan Post-hoc test) and expressed with 95% probability ($p<0.05$).

Results and discussion

The results of sensory analysis obtained by the scoring method are shown in Table 2. Following the results, it was found that coagulation conditions (type of coagulant and coagulation temperature) had a statistically significant effect ($p<0.05$) on external appearance, cross-sectional appearance, flavour, and consistency of produced cheeses. On the other hand, the statistically significant influence of coagulant type and temperature coagulation on cheese odour was not established ($p>0.05$). The sensory analysis showed that all cheese samples produced by heat-acid coagulation of milk were of high sensory quality.

Table 2. Results of sensory analysis obtained by scoring method

Sensory property	Sample 1	Sample 2	Sample 3	Sample 4	Sample 5	Sample 6
External appearance	4.50 ± 0.33^{b}	4.00 ± 0.24^{a}	4.00 ± 0.24^{a}	4.50 ± 0.33^{b}	5.00 ± 0.00^{c}	4.50 ± 0.24^{b}
Cross-sectional appearance	4.50 ± 0.33^{b}	4.00 ± 0.24^{a}	4.50 ± 0.24^{b}	4.80 ± 0.26^{c}	4.50 ± 0.33^{b}	4.00 ± 0.00^{a}
Odour	5.00 ± 0.00	5.00 ± 0.00	5.00 ± 0.00	5.00 ± 0.00	5.00 ± 0.00	5.00 ± 0.00
Flavour	5.00 ± 0.00^{b}	5.00 ± 0.00^{b}	5.00 ± 0.00^{b}	5.00 ± 0.00^{b}	4.50 ± 0.33^{a}	4.40 ± 0.21^{a}
Consistency	5.00 ± 0.00^{d}	5.00 ± 0.00^{d}	4.50 ± 0.24^{c}	5.00 ± 0.00^{d}	4.20 ± 0.26^{b}	4.00 ± 0.41^{a}

$^{a\text{-}d}$ mean values with different letters in the same row differ statically significantly with 95% probability ($p<0.05$)

The appearance of the cheese is assessed visually, usually before the cheese is consumed or when the cheese is prepared for consumption by cutting or spreading. The visual properties include the colour, presence of large lumps and visual texture. These create sensory expectations of what the cheese should taste. Since the appearance may prevail over other modalities, the visual aspects of cheese can often have a considerable impact on the experience of the other characteristics (Budimir *et al*., 2004). The colour of the cheese is another important indicator of quality. During the sensory analysis of the cheese appearance, the colour (that should be white and uniform, in correspondence to the quality of the given product) was evaluated. During the technological process, some ingredients may react with an undesirable substance that accidentally gets into the product, which shows deviations or problems during the process. In extreme cases, this can lead to errors that make the product unsuitable for use (Mandić and Perl, 2006).

In examined samples, the scores for the external appearance ranged from 4.00 (samples 2 and 3) to 5.00 (sample 5). Sample 5 had a smooth surface, shiny, uniform colour on the surface, while the other samples were slightly rough and uneven with noticeable yellowish transitions, which was scored 4.50 (samples 1, 4 and 6) and 4.00 (samples 2 and 3).

Sample 1, which was produced with citric acid at 85°C, had a yellowish, slightly uneven surface. Sample 2, which was produced with citric acid at 95°C, also had a yellowish colour and a somewhat rougher surface than sample 1. Sample 3, which was produced with tartaric acid at 85°C, had a noticeable uneven surface colour but the surface itself was smoother than in samples 1 and 2. Sample 4, which was produced with tartaric acid at 95°C, had a rough surface and uneven colour. Sample 5, which was produced with acetic acid at 85°C, had a uniform white colour and a smooth surface. Sample 6, which was produced with acetic acid at 95°C, had noticeable surface roughness.

The cross-section appearance of examined samples was evaluated with average scores from 4.00 to 4.80. The samples 2 and 6 had a mean value for the cross-section appearance of 4.00 because slight inhomogeneities, irregularities, and depressions were observed in the cross-section. The mean value of the cross-section appearance of samples 1, 3 and 5 was slightly higher and amounted to 4.50, while sample 4 earned the statistically highest ($p<0.05$) mean score of the cross-section appearance (4.80).

The odour of food products should provide intense pleasure, and it is analysed retro nasally – by inhaling and identifying volatile ingredients released in the mouth by evaporation during chewing, chopping, heating, and mixing with saliva. A smell uncharacteristic of the product may be a result of a mistake during production, which may render the product unusable for human consumption. The odour of the cheese depends on its type. Fresh, unripened cheese should have a pleasant odour, neither too strong nor too weak, characteristic of milk, discreet and without unpleasant odours. According to statistically processed evaluation data of the tested samples odour, it is noticeable that there is no statistically significant difference between the samples ($p>0.05$). This is because all tested samples received the maximum score for the odour (5.00).

The flavour analysis of the produced cheese and the palate impression examine the properties like salinity and acidity. The acidity should be slightly pronounced to create a refreshing sensation during chewing. Otherwise, the experience of flavour begins before consumption, when the consumer smells the cheese, but the main experience is gained during consumption (Budimir *et al*., 2004). The flavour of cheese depends on its type. Like the odour, the flavour of unripened cheese is also mild. The flavour should be clearly expressed, characteristic of the product and without uncharacteristic flavours. It should have a moderate flavour and salinity. The mean flavour scores of the tested cheeses are shown in Table 2. Based on the processed data, it can be stated that the mean values of the flavour scores of samples 1, 2, 3 and 4 did not differ statistically significantly ($p>0.05$). The mean flavour score of these samples was 5.00. Samples 5 and 6, produced with acetic acid, had lower ($p<0.05$) flavour scores (score 4.50 for sample 5 and score 4.40 for sample 6) than other samples.

Texture or consistency can be defined as a property of cheese that results from a combination of physical properties, including size, shape, number, nature, and conformation of structural elements experienced through a combination of the sense of touch (tactile texture), appearance (visual texture) and hearing (auditory texture). For example, the softness of fresh cheese can be assessed after cutting. Cheese texture characteristics often include elasticity, firmness, crumbliness, graininess, cohesiveness, and adhesion in the description (Mandić and Perl, 2006). The consistency of cheese depends on its water content. Based on that, cheese was classified into types, with each type having its characteristic consistency parameters. Table 2. shows the mean values of the consistency scores of the tested samples. The consistency of samples 1, 2 and 4 did not differ significantly ($p>0.05$); the samples had optimal hardness (neither too hard nor too soft) and were compact. The cheese was not sticky, and the consistency of the samples was scored 5.00. For sample 3, the consistency score was 4.50 because sample 3 was slightly softer than other samples. The consistency of sample 5 earned the mean score of 4.20 because the sample crumbled in the mouth and was slightly drier than other samples. Similar was sample 6, with the consistency score of 4.00 because it crumbled in the mouth and was noticeably drier than other samples.

Table 3. shows the results obtained by ranking the samples according to the overall acceptability of product quality. Based on the performed ranking, i.e., the sum of the ranks, sample 4 stood out compared to other cheese samples. Sample 4, produced with tartaric acid at 95°C, had a minimum sum of ranks (24), which was less than the minimum tabular value of 25. Therefore, this sample can be described as a "superior quality product". Other samples had sums of ranks within the tabular range (25-45). They were classified as "standard quality products".

Table 3. Ranking results according to the overall acceptability of product quality

Sample	Number of repetitions						Sum of ranks*	Cheese quality
	Place 1	Place 2	Place 3	Place 4	Place 5	Place 6		
1	3	1	2	2	2	0	29	Standard
2	2	0	2	2	2	2	38	Standard
3	0	2	2	2	2	2	40	Standard
4	2	4	2	2	0	0	24	Superior
5	2	1	2	0	2	3	38	Standard
6	1	2	0	2	2	3	41	Standard

*The range of tabular values corresponding to the number of repetitions (n=10) and the number of treatments (6 ranked samples), for the level of statistical significance $p<0.05$ is 25-45 (Radovanović and Popov-Raljić, 2000).

Conclusions

In food quality control procedures, sensory analysis methods play an indispensable role. Quality control and precise definition of different types of cheese can be performed by applying sensory methods of analysis. Based on the results obtained in this paper, it can be concluded that heat-acid coagulation of milk can produce cheeses of high sensory quality. The appearance, flavour and consistency of the produced cheeses depend on the type of coagulant and coagulation temperature. By ranking the samples according to the total acceptability, sample 4, produced with tartaric acid at a coagulation temperature of 95°C, was the most acceptable.

Abstract

The objective of this paper is to present research findings, obtained for nutritional values of Trappist cheese, produced by the monks of the Banja Luka "Maria Zvijezda" monastery, in cooperation with Agricultural Cooperative Livac. Cheese is an important food and is a part of people's daily nutrition. New trends that are promoting a balanced diet are also setting new requirements for the familiarity with nutritional value of cheeses. Until now there has been no opportunity to analyse nutritional value of Trappist cheese due to the specificity of its production. Some analyses might have existed, but the library was destroyed back in 1945, and possibly written traces if there had been any. Some of the characteristics of Trappist cheese are that it is in the shape of a ring, it weighs between 1,6 kg and 2.0 kg, and it has a natural rind, which is yellowish, thin and smooth. The conditions for its ripening and the manner of its ripening are specific and they give this cheese a special aroma. The ripening period is minimum 90 days, under specific air humidity and temperature conditions. The cheese matures on wooden shelves, being regularly turned around and wiped by hand. The consistency of cheese body is soft, elastic, tender and it is easy to cut. The cut is smooth, without or with just a few holes, while the colour of cheese body is yellowish. It is characterized by clean, milk-specific aroma, and is moderately salty with quite meltable texture. The milk fat content is 34,5 grams, saturated fatty acids 24,7 grams, carbohydrates 0.8 grams, proteins 27.5 grams and the content of NaCl amounts to 2,05 g/100 grams of cheese. The energy value of Trappist cheese is 424 kcal or 1758 kJ, Water content is 41.6 g/100 grams, while the dry matter amounts to 56,8 g/100 g.

Key words: *nutritional values, monastery Maria Zvijezda, cheese Trappist.*

Introduction

At the present time, as a result of fast-paced lifestyle and stress, people are aware of the need to pay more attention to proper nutrition. A balanced diet has become an integral part of our lives and is an unavoidable aspect of finished products' labelling.

Milk and dairy products have always been a part of the diet, having a beneficial effect on humans. Nowadays we are striving for newly set goals, which is to prevent certain diseases, in other words to protect our health by means of food (German et al. 2003). We may find on the market a wide choice of milk and dairy products, which base their functional properties on their natural, high-value nutritional composition (Tudor and Havranek, 2009).

Cheese is a type of food having high nutritional value and it takes a significant place in a healthy and well-balanced diet (Gregurek, 2015). The nutritional value of cheese is affected by numerous parameters, of which the most important one is milk, used for the cheese production, followed by the cheese making technological process and finally the cheese ripening period. As such, cheese represents a very good source of proteins and milk fat. On the other hand, it is a good source of fat, which is vitamin-meltable, and in case of mature cheeses (with longer aging time) there is a slightly lower lactose content, which makes them suitable for the diet of consumers who are lactose-intolerant.

Table 1. Composition of some types of cheese (Thomas et al. 2000)

Type of cheese	Water g/100g	Protein g/100 g	Fat g/100g	Carbohydrates g/100g	Cholesterol mg/100g	Energy value	
						kcal	kJ
Brie	48,6	19,2	26,9	Traces	100	319	1323
Camembert	50,7	20,9	23,7	Traces	75	297	1232
Cheddar	36,0	25,5	34,4	0,1	100	412	1708
Cheddar with less fat	47,1	31,5	15,0	Traces	43	261	1091
Cottage sir	79,1	13,8	3,9	2,1	13	98	413
Edam	79,1	13,8	3,9	2,1	80	338	1382
Emmentaler	35,7	28,7	29,7	Traces	90	382	1587
Feta	56,5	15,6	20,2	1,5	70	250	1037
Gauda	40,1	24,0	31,0	Traces	100	375	1555
Gryère	35,0	27,2	33,3	Traces	100	409	1695
Mozzarela	49,8	25,1	21,0	Traces	65	289	1204
Parmesan	18,4	39,4	32,7	Traces	100	452	1880
Ricotta	72,1	9,4	11,0	2,0	50	144	599
Roquefort	41,3	19,7	32,9	Traces	90	375	1552

Milk fat in cheese affects its firmness, cohesiveness of cheese body, fullness of taste and cheese aroma. It directly influences nutritional values of cheese, and as we can see in the Table 1, some cheeses contain large amount of fat (Cheddar, Gryère). Given that the total fat intake is being limited nowadays, while a large number of consumers are trying to endorse recommendations of nutritionists, the modern food industry is producing more and more cheeses with a lower proportion of milk fat. The cholesterol content in cheese varies from 13 -100 mg/100g of cheese, depending on the type of cheese. A good number of people display certain changes in the blood cholesterol if their intake of cholesterol through food is 250-800 mg/day (McNamara, 1987).

The protein percentage in cheese ranges from 3-40% depending on the type of cheese. Of the proteins in cheese, the most represented one is casein, given that the largest quantity of whey protein is separated from curd into whey (Gregurek, 2015).

Salt (NaCl) plays an important role in the cheese production process, while its concentration in cheese depends on the technology itself. The increased intake of salt can be the cause of hypertension, which is a risk factor for coronary and heart diseases (Gregurek, 2015).

In Bosnia and Herzegovina, there are several high-value cheeses with the long production tradition. They are of different qualitative properties and energy values (Dozet et al. 1979). All this represents a significant heritage of this region.

Table 2. Qualitative and energy values of autochthonous cheeses in BiH (Dozet et al. 1979).

Type	Fat %	Protein %	Energy value	
			kcal	kJ
Travnik cheese	25,39	19,807	326,44	1366,5
The Travnik cheese type	24,1	20,414	307,83	1288,42
Feta	21,0	22,634	288,1	1205,84
Livno cheese	32,03	27,357	410,01	1716,22
Sirac	29,3	29,612	393,9	1648,6
Low-fat cheese	9,25	33,354	222,78	932,44
Fat cheese	20,67	15,875	256,67	1074,3
Low-fat cheese	4,27	21,696	128,42	537,48
Dry cheese	39,5	31,172	495,2	2072,48

Table 2. depicts qualitative and energy value of some autochthonous cheeses, being produced in Bosnia and Herzegovina either traditionally or industrially (Dozet et al. 1979).

History of Trappist cheese

The very start of cheese production in the Maria Zvijezda monastery was in 1872, in a small cheese factory built by Abbot Franz, who named his cheese "Swiss cheese". However, the operation of this cheese factory did not last for too long due to a cattle disease which caused a lack of milk. The production of "real" Trappist cheese began in 1882, when brother Ignatius, from the French monastery „Port-du-Salut", came to the Banja Luka monastery. He spent half a year training brother Luka in cheese making. Initially, the cheese was being made only for the monastery community, but later on it was produced for the market of Austria and Hungary, but also for the entire Europe. There was a very high demand for it, while this cheese won numerous awards at different European fairs. At first, the monks were processing milk from their own property, but later on they started purchasing it from the local farmers (Bozinovic 2009).

Maria Zvijezda monastery kept the auxiliary cheese-making facility, but the real cheese factory was built in Josipovac (nowadays Bosanski Aleksandrovac), where a branch of the Maria Zvijezda monastery was opened in 1887.

However, not everything went smoothly there either, especially in the first year. Basically, due to a lack of experienced cheese makers, they initially faced problems with the cheese quality. That is why Abbot Bonaventure I sent brother Dositej to France in 1888, where he spent one year in the French monasteries and finally in Port-du-Salut learning how to make cheese. Upon his return, he started training his brothers on cheese making process, who had to take an oath to keep the cheese production process a secret. This secret was passed down from one brother to another, or they would take a secret with them to the grave. Kirin wrote about this: Although Trappist cheese was predominantly represented in the cheese making activities for an entire century, there is very little information about the cheese making technological procedure in the professional literature. Due to its secrecy, there is no official description of the production process and there is no original Trappist cheese, therefore we can only assume what it was like (Budimir and Bagaric 2015).

A conclusion may be drawn from this secrecy: "The quality of cheese and the art of its making rested for the most part in the method of its production. Basically, a dozen of specialists partook in the cheese production. Each operation was exclusively performed by one of the cheese makers. Each cheese maker mastered his task to the perfection, while the work of others remained a secret to him." A success of the Josipovac branch prompted Abbot Bonaventura I to found another branch. The colonists were marking a significant economic development in the Windthrst colony (nowadays Nova Topola). The Trappist monks purchased the land from one of the colonists in 1893. and founded Marienburg branch – Marijin Dvor (Nova Topola) there. The cornerstone was laid on 18 March 1893. Apart from other economy-oriented facilities, they also opened a cheese factory. The locals would bring them milk which they processed to make cheese and butter (Bozinovic, 2009).

Cheese production in both branches was successful. Everyday they would buy 2000-3000 litres of milk. With the expansion of this cheese factory, the purchase of milk reached as much as 8000 litres. There was 100-200 tons of cheese produced every year. The surplus of purchased milk was pasteurized and transported to Banja Luka, where it was offered for sale. The milk was appreciated both for its quality and its price. It was cheaper than the milk from other retailers. The cheese was packed in 4.8 kg package and was mailed, i.e. it was shipped by rail to the customers throughout the Monarchy, but also beyond its borders. The monks were also official supplier of cheese for the Royal Palace in Belgrade (Bozinovic, 2009).

So far, there have been no reliable data on the organoleptic properties of the original Trappist cheese, while the secrecy of its making does not allow us to get an insight into the production technology. Various authors assume that the technology was identical to today's Saint Paulin cheese, which is a successor to Port-du Salut i Port-Salut (Kirin 2003). It was mainly chemical composition, quality and organoleptic properties of semi-hard cheeses, produced in the former communist dairies that were analysed, (Budimir and Bagaric, 2015).

The cheese production was revived again in 2008 when Father Tomislav went to France in the monastery of Mont-des-Cats and learned the technique of cheese making and brought back the recipe for cheese production (Budimir, 2012).

Materials and methods

The analysis and sampling was carried out at the ZZ Livac farm, located in Aleksandrovac, the municipality of Laktasi, Bosnia and Herzegovina. This agricultural cooperative is engaged in raw milk production. Since 2008, the Maria Zvijezda Trappist cheese has been produced in cooperation with the Trappist monks in the newly built cheese-making plant, according to the recipe owned by the Maria Zvijezda monastery. Currently, about 2.5 tons of Trappist cheese is being produced on a monthly basis. The cheese factory has HACCP and ISO 2008:2009 certificates and is a subject to regular veterinary inspection control. The cheese factory has an export license for the European Union, and as such it abides by all applicable hygiene and health regulations.

The sampling was performed in 2020, where 5 cheese samples were taken in accordance with the Republic of Srpska regulations for food analysis, currently in force.

Physicochemical analysis was conducted by the Public Health Institute, the Republic of Srpska Public Health Institute, the Department for Sanitary Chemistry, Food Testing Laboratory, being an accredited laboratory for food analysis in Bosnia and Herzegovina.

The tests were performed in order to establish: the content of milk fat according to UMH 158 method; of saturated fatty acids content, UMH 466: of carbohydrates as per UMH 356; and of sugar, UMH 159. As for the protein content, the tests were carried out based on the Bosnia and Herzegovina Official Gazette, No. 82/13, Annex II, Section V and UMH 076 method was applied in order to determine NaCl content.

Results and discussion

Trappist cheese belongs to a group of semi-hard cheeses, easy to cut. It differs from other products present on the market under the same name which are either too soft or too hard to cut. Unfortunately, given that in the past there were no restrictions in using this original cheese name, different variants of Trappist cheese can be found on the market.

The softness and easy cutting are a result of the special method of preparation and definitely come from special conditions under which it matures. It is important to highlight here that the original Trappist cheese ripens under specific conditions, where adequate everyday procedures of turning it around and wiping it are being applied. In Bosnia and Herzegovina, the technological production of Trappist cheese takes place in the facilities where the cheese is "dried" for fifteen days and is then delivered to stores. For the original Trappist cheese to mature it takes between 75 and 90 days, which ensures its special consistency and taste.

It is in a shape of a ring, with 980 cm diameter and the size of 7-9 cm (Budimir D. 2012).

Table 3. Analysis of the composition of the Marie Zvijezda Trappist cheese

Parameter	g/100 g
Fat	34,5
Saturated fatty acids	24,7
Carbohydrates	0,8
Sugar	0,0
Protein	27,5
NaCl	2,05
Energy value in 100 g: 424 kcal o 1758 kJ	

As mentioned earlier, no previous analysis of the Trappist cheese exists, therefore in the further discussion we will compare it with some of the above listed cheeses.

Table 3 shows that there is 34,5 grams of fat in Maria Zvijezda Trappist cheese. Given that this cheese is made from full-fat milk, and has somewhat longer ripening time, we are to expect such a slightly higher fat content. The fat content is approximate, i.e. it is a bit higher than in Cheddar or Gryère. If we are to compare it with the BaH cheeses, the fat content is somewhat higher than in the local Livno cheese/Livanjski sir (made from sheep milk) but lower than in the autochthonous "dry" cheese from Bosnia and Herzegovina.

The content of saturated fatty acids in Trappist cheese amounts to 24.7 grams in 100 grams of cheese. The obtained result is relatively high, but due to an increased fat content such a result is in correlation with the previous parameter. In the tested samples, the content of carbohydrates was 0.8 grams in 100 grams of cheese. This result represents a mean value in comparison with earlier analysed cheeses. It is somewhat lower when compared with Ricotta, Edam or Feta, but is higher than in Cheddar, Gryère. The protein content observed in the analysis was 27.5 grams. This is similar to Gryère and Emmentaler, and Livno cheese, but is slightly lower than is the case with Sirac. On the other hand, it is much lower than the protein content in the cheese in a sac or Parmesan.

The salt content is 2.05 grams in 100 grams of cheese, and no sugar was found in the samples.

The energy value of 100g of Maria Stern Trappist cheese is 424 kcal, or 1758 kJ. These values are close to the energy content of Cheddar or Gryère, and when compared with autochthonous Bosnian cheeses, it is identical to Livno cheese, but slightly lower than in dry cheeses.

All of the above results indicate that it is a full-fat, high-energy product.

Conclusion

It was the 160th anniversary of the Trappists' arrival to Banja Luka in 2019. With their arrival they contributed to the improvement of both economic and cultural development of this region, but unfortunately very little is known about this. What the Cooperative is trying to achieve is to bring the activities of the monks, or at least a part of their craft history, closer to the public. This community was affected by difficult moments several times in the past, especially in the end of the II World War. Just like their community was striving to retain the population in this area and provide them with the employment opportunities, we are trying to achieve the same in the present time. We hope that we will manage to employ an additional number of people and pursue the production of the Maria Zvijezda Trappist cheese, as well as the manufacturing of other products nourishing the tradition of the monks' community. The original Trappist cheese belongs to a group of semi-hard, full-fat cheeses with high energy value, and it can be consumed on a daily basis, either as a side dish or an ingredient in the meal preparation. This paper provides the grounds for the further analysis of Trappist cheese and the possibility for the growth of small cheese producers on the territory of Bosnia and Herzegovina, through their adequate protection.

Abstract

The aim of this paper is to examine the egg production of commercial flock of light line hybrids Lohmann Brown, as well as the influence of laying hen age on egg production intensity of different egg weight groups, housed in conventional cage system. The examinations were performed in the production conditions on the farm "Agrovet" in Foca, Bosnia and Herzegovina. Since it is established that commercial flocks in egg production are kept until the end of 72nd week of age (WA) as the final instance in production, the aim of this paper is to examine what happens to production performance, ie laying intensity, after the established 72nd week of laying hen age. In this paper, it is the period of seven weeks, until the 79th week of age of the laying hen of the Lohmann Brown hybrid, where the production period lasted for 61 weeks, ie 427 days.
Based on the results of examination, it was concluded that egg production, as well as laying intensity gradually increase to 27th week of age, when the maximum laying intensity was reached, followed by gradual decline in egg production until the end of the flock exploitation period, with occasional variations.
Analized by the weight groups, during 61 weeks of production, the class M was the most represented with a laying intensity of 47.47%, followed by the class L (31.64%), class XL (3.12%) and then class S with 1.79%.
A positive coefficient of phenotypic correlation was determined between the age of laying hen and laying intensity in all egg weight groups. It was statistically very highly significant ($p<0.001$) until 36th week of age, highly significant between 36th and 42nd week of age ($p<0.01$), and significant from 42nd to 52nd week of age ($p<0.05$).

Key words: *Lohmann Brown, Age, Egg production intensity, Egg weight groups.*

Introduction

Today, intensive egg production is based on exploiting of light-line hybrids of lying hen, which are characterized by great production opportunities (Mahmutovic, 2011). The hybrids for egg production are divided in hybrids for production of eggs with coloured shell and eggs with white shell. The hybrids for production of eggs with coloured (brown) shell are larger, heavier, with stronger constitution, calmer temperament, and more resistant to deseases than hybrids for production of eggs with white shell. The most famous hybrids in our country are Isa Brown

(SSL), Hisex Brown, Lohmann Brown, Tetra SL, Harco (Bogosavljevic-Boskovic and Mitrovic, 2005). Line hybrids for the production of coloured eggs, due to higher demand, are more represented in the world, and in our country as well. Our research is conducted on coloured eggs hybrid Lohmann Brown. Laying intensity is the most important feature of laying hen, representing the number of eggs laid in a certain period of time per one laying hen, expressed as a percentage. Rakonjac (2016) believes that the success in the production of eggs for consumption largely depends on the choice of the most productive and most suitable hybrid of laying hen, which would give the best results in appropriate farm conditions. Neglecting any of these factors will have a negative impact on the health of laying hen, consequently on the production and cost-effectiveness of keeping the flock. Based of the results of research by Rakonjac (2016) conducted on light-line hybrid Isa Brown, the average laying intensity was 77.88%, and the maximum intensity was achieved at 28^{th} week of age. Also, in the last week of the experiment, the Isa Brown hybrid achieve the laying intensity of 72.40%.

Examining the production performance of laying hen hybrid for brown egg shell Hy-Line Brown, Vukic-Vranjes et al. (2009) found the maximum laying intensity of 92.10% at 28^{th} week of age. Based on the examination of production characteristics of the Lohmann Brown hybrid laying hen, in the period from 20^{th} to 72^{nd} week of age, Pandurevic (2011) came to the following conclusions: The laying intensity in the 20^{th} week of age was 18.29%; the maximum laying intensity was reached in 28^{th} week of age and was 95.71%; in the middle of production cycle (48^{th} week of age) the laying intensity was 89.57%, while at the end of production cycle (72^{nd} week of age) 4.91 eggs were produced, ie intensity of laying was 70.14%.

Viewed by classes, the class L has the largest share in total number of eggs (49.09%), followed by class M with 38.57%, while classes XL and S has significantly less share with 7.68% and 4.66% respectively.

Examining the production of eggs for consumption of hybrid Isa Brown, Pandurevic et al. (2015) found that the highest average egg production was in third month of production, at 93.60%. After that, the intensity of producing eggs decrease to 69.90% when the flock was excluded of production cycle. Examining the egg production of Hisex Brown hybrid, Gjorgovska et al. (2016) found the average intensity of egg production was around 82%.

The average intensity of producing eggs of Lohmann Brown hybrid, kept in conventional cage from 20^{th} to 60^{th} week of age, obtained in research by Dikmen et al. (2017) amounted 87.10%.

Since it is established that commercial flocks in egg production are kept until the end of 72^{nd} week of age (WA) as the final instance in production, the aim of this paper is to examine what happens to production performance, ie egg laying intensity, after the established 72^{nd} week of laying hen age. In this paper, it is the period of seven weeks, until the 79^{th} week of age of the laying hen of the Lohmann Brown hybrid, where the production period lasted for 61 weeks, ie 427 days.

Material and Methods

As the initial material for the research, we have used hens of light line hybrids Lohmann Brown, housed on the farm "Agrovet" Foča, with at least 18 weeks of age, i.e. the experiment started in the 19^{th} week of age of laying hens. Production cycle lasted for 61 weeks (79 weeks old hens).

In the course of raising (exploitation) of the commercial flocks, a technology proposed by the selector of laying hens hybrid was used. All technological phases (feeding, power, temperature, lighting, ventilation, drainage system and collecting the eggs) are automatically regulated.

The eggs were sorted daily, into four weight groups, according to EU standards adopted in 2012, as follows: XL – very large (egg weight >73 g), L – large (63-73 g), M – medium (53-63 g), S – small (egg weight <53 g).

According to technological norms, the commercial flock of light line hybrid starts delivering eggs in the 19th week of age (production intensity around 5.50%), maximum intensity reaches between 26th and 28th week of age (around 94%), then gradually decreases until the end of flock exploitation in 72nd week of age, when the intensity was around 72%. On average, for 53 weeks of egg production, the laying intensity is about 85% and about 316 eggs per settled laying hen.

Based on everyday records of egg production during the experiment, the intensity of egg production was defined by weight groups (S, M, L, XL), by weeks of production (%) and for the entire production cycle (61 weeks, from 19th to 79th week of age), for all egs and by different weight groups. The average laying intensity within production week was calculated by dividing the total number of delivered eggs during the week by the number of hens and then dividing by seven. The obtained results are expressed as a percentage for each week of production and in total for the entire period of production.

Based on the obtained results, a phenotypic correlation was determined between the age of commercial flock and the intensity of producing eggs (from the 14th week of exploitation to the end of the production cycle).

The coefficient of phenotypic correlation is calculated according to pattern (Latinovic, 1996):

$$r_{xy}=\frac{\sum xy-\frac{\left(\sum x\right)\left(\sum y\right)}{n}}{\sqrt{\left[\sum x^2-\frac{\left(\sum x\right)^2}{n}\right]\left[\sum y^2-\frac{\left(\sum y\right)^2}{n}\right]}}$$

The strength of phenotypic correlation coherence is discussed on the basis of the Roemer-Orphal classification (Latinovic, 1996). The testing of significance of differences between various ages of laying hens, in terms of monitored characteristics, was performed using an appropriate t-test model with the same number of repetitions according to the following pattern:

$$t=\frac{\bar{x}_1-\bar{x}_2}{Sp\sqrt{1/n_1+1/n_2}}$$

$$S_p=\sqrt{\frac{(n_1-1)S_1^2+(n_2-1)S_2^2}{n_1+n_2-2}}$$

The software package SPSS - Statistical Package for Social Sciences was used for statistical analysis. As statistically significant were taken differences $p<0.05$.

Results and Discussion

Egg production is the most important feature of laying hen and it is important to produce as many eggs as possible during the production cycle, as the success of the production primarily depends on this parameter. At the same time, the intensity of production should be in accordance with biological and physiological abilities of the laying hen at a given age, as well as to achieve optimal share of various weight groups of eggs for a certain period of exploitation.

It should be noted that relatively small number of authors examined the production characteristics of laying hen after the usual 72 weeks of age.

The eggs on the farm "Agrovet" were collected daily and, according to EU standards, classified by weight into four groups: S (<53 g), M (53-63 g), L (63-73 g) and XL (>73 g).

Table 1 shows the values of egg laying intensity by weight groups (%).

Table 1. Egg laying intensity according to the weight groups (%)

Weeks of age/production	S (<53 g)	M (53-63 g)	L (63-73 g)	XL (>73 g)	All eggs

Average	**1.79**	**47.47**	**31.64**	**3.12**	**84.02**

As it can be seen from the table 1, during 61 weeks of production, the class M has the highest intensity of 47.47%, followed by class L (31.64%), class XL (3.12%) and class S with 1.79%.
The mass of eggs increases along with the age of laying hen, so does the share of certain weight groups during the production cycle, which shows certain phenotypic correlation with the age of laying hen. The table 2 shows the correlation, significance of differences and the strength of correlation for two weight classes M and L, which combined make the largest part of all eggs produced during the entire production cycle.

***p<0.001; **p<0.01; *p<0.05; ^{ns}p>0.05

The results in table 2 show that the eggs of class M during 14th, 15th and 16th weeks of production show a statistically significant (p<0.05), strong and medium strong positive correlation between the age of hen and the weight of eggs. From $WA_{35/17}$ to $WA_{53/35,}$ no statistically significant phenotypic correlation was noticed between the age of hen and the weight of eggs (p>0.05). From $WA_{54/36}$ to the end of the production cycle ($WA_{79/61}$), a statistically significant negative correlation was noticed between the age of hen and the weight of eggs, and from $WA_{66/48}$ to the end of production cycle, the phenotypic correlation was very highly significant (p<0.001), except for $WA_{68/50}$ and $WA_{71/53}$ when it was highly significant. The coefficient of phenotypic correlation at the end of production cycle was (r_{xy} = -0,731***).
Unlike the class M, the strength of correlation for eggs of class L was complete, ie very strong, positive in direction, and statistically very highly significant (p<0.001) until 76th week of age, and statistically highly significant from the 76th week of age (p<0.01). The coefficient of phenotypic correlation at the end of production cycle was (r_{xy} = 0,757**).
With the age of laying hens, the intensity of producing eggs gradually decreased, and positive coefficients of phenotypic correlations were determined between the age of hens and laying intensity of all weight groups, and it was statistically very highly significant until the 36th week of age. The coefficient of correlation was statistically very significant (p<0.01) between the 36th and 42nd week of age, while it was statistically significant (p<0.05) between 42nd and 52nd week of age. From $WA_{52/34}$ to the end of exploitation, the correlation coefficients were not statistically significant (p>0.05), with a coefficient of phenotypic correlation being negative from $WA_{65/47}$ to $WA_{79/61}$, and the correlation was weak, very weak or none (r_{xy} = -0.361^{ns}).
Similar results for correlation, significance of differences and strength of correlation between the age of hens and laying intensity (%) of various weigth groups of eggs during entire production cycle, in the same examined hybrid, were obtained by Pandurevic (2011). The coefficients of phenotypic correlations at the age of 72nd weeks were (r_{xy}= -0,718***) for class M, (r_{xy}=0,802***) for class L, and for class XL (r_{xy}= $-0,178^{ns}$).

Conclusion

Based on the examination of production performances of light-line hybrid Lohmann Brown, during experiment that lasted for 61 production week, the following conclusions can be drawn:
The egg production, as well as intensity of laying, gradually increased until the 27th week of age, when the maximum laying intensity was reached, followed by gradual decline in egg production until the end of flock exploitation, with occasional variations. At the age of 27th weeks, the egg laying intensity reached the maximum of 94.76%. The average egg laying intenstity for the entire production cycle (from WA_{19} to WA_{79}) was 84.02%.

The examined flock records slightly higher values of egg laying intensity by examined periods, as well as for stated period of expoitation in comparison to the technological norms.
Sorted by weight groups during 61 weeks of production, the class M has the highest intensity of 47.47%, followed by class L (31.64%), class XL (3.12%) and class S with 1.79%.

Abstract

Honey bee colony swarming event is a good example of an animal group performing a synchronised action with aim to leave the original hive and depart for a new location. Swarming has always been seen by the beekeepers as an extremely important event, which requires an immediate response. During the swarming majority of the bees leave the hive and this dramatically reduces the productivity potential of the colony and profitability of the beekeeper. Thus, remote detection of this event should be done by application of the bee colony monitoring system within the precision beekeeping approach. Remote monitoring of bee colonies helps to reduce the stress and unnecessary activities of bee colonies by minimising the number of visual inspections. There are several technological possibilities for remote detection of swarming. During the swarming event temperature in the colony increases, overall hive weight decreases and there is a specific sound emitted by the colony. Within this article various parameter dynamics are summarised and demonstrated for the successful identification of the swarming event. We summarised findings from various literature sources and also provide our own experimental results conducted for the swarming detection.

Keywords: *Precision beekeeping, Precision apiculture, bee colony swarming, remote swarming detection, bee colony monitoring.*

Introduction

Bees are very important pollinators - around 85% of flowers are pollinated by bees (Warnke, 2009), helping to preserve the wild biodiversity, as well. Besides this, honey bees (Apis mellifera) are the most economically important managed insects (Moritz & Southwick, 1992; Aizen & Harder, 2009).

To help the beekeepers to improve the understanding of the processes in the bee colony without looking inside the hive many sensing technologies are introduced. The technological inventions and their implementation for honey bee colony monitoring are summarized under the term precision beekeeping or precision apiculture.

Precision Beekeeping (PB) is a sub-branch of Precision Agriculture and is an apiary management strategy based on the remote monitoring of individual bee colonies with aim to minimise resource consumption and maximise the productivity of bees (Zacepins et al., 2015).

As well in recent years multiple stress factors have led to a decline of honey bee colonies (Klein et al., 2007) and this event has emphasized the significance of a continuous and remote monitoring to investigate factors that may negatively affect the life cycle of bees (Nolasco et al., 2019).

Remote monitoring of bee colonies minimizes the number of visual inspections, therefore helps to reduce the stress of the bee colonies and can increase the colony health (Stalidzans et al., 2017). The impact of physical inspections (e.g., manual weighing) is also stated by (Komasilovs et al., 2019). Currently the most feasible colony parameters available for constant monitoring are temperature, humidity, weight, acoustics and vibration. By measuring those parameters different states of the bee colony can be detected, like brood rearing, death, swarming, absconding etc. Inside hive temperature and humidity are the most commonly used metrics, when applying precision beekeeping (Zacepins & Karasha, 2013; Meikle & Holst, 2015; Zacepins et al., 2015; Meikle et al., 2017). Hive weight is also a useful metric for monitoring the productivity of a colony (Fitzgerald et al., 2015; Lecocq et al., 2015; Meikle et al., 2017). Several studies have underlined that some behaviors of the honey bees are strictly related to variation in produced sound (Hunt & Richard, 2013; Robles-Guerrero et al., 2017).

Focus of this paper lays at the bee colony swarming detection, as swarming has always been seen by beekeepers as an extremely important event, which requires an immediate response. We aim to review the knowledge related to the bee colony remote swarming detection and summarise the parameter values, which correspond to the swarming event. Basically, beekeeper's notification of a swarming event should be a default functionality for any precision beekeeping system.

Bee colony swarming is a natural way of proliferation of the bee colony. During the swarming the queen leaves the colony with a group of worker bees to establish a new colony in a different place. As a result, the original colony reproduces two or more colonies (Michener, 1974; Heinrich, 1981; Seeley, 1982; Winston, 1987). The main disadvantage of natural swarming for commercial beekeeping is its spontaneous character, as in some years there could be more swarms than in others (Simpson, 1958).

It is known that beekeepers can apply different bee colony management techniques to minimise the risk of potential swarming events. However, it is almost impossible to fully exclude swarming by beekeeping practice, especially with a large number of colonies kept on different apiaries in different geographical locations. Swarms can be detected on-site, as usually swarmed bee colony finds a tree near the apiary to prepare for a longer journey to a new colony place (Seeley & Buhrman, 1999). But the problem resides in the fact that bee colonies are placed far away from the beekeepers' living place and usually swarming is identified only post factum, when the swarm is already gone.

The automatic remote detection of swarming events would have a large impact on beekeeping, as when part of the bee colony leaves the hive, this dramatically reduces the productivity potential of the colony. But if the beekeeper is notified about the colony swarming he/ she still has the opportunity to catch the swarm and place it back into the old hive or a new one (Seeley, 2010).

Swarming detection by temperature

Bee colony temperature monitoring can be characterised by:

- the low cost of data collection as sensors are relatively cheap,
- the low volume of data, even if the measurements are very frequent,
- the easy processing of the data.

It has been discovered that swarming can be detected by temperature monitoring (Seeley et al., 2003; Ferrari et al., 2008; Kridi, de Carvalho & Gomes, 2014; Kviesis & Zacepins, 2016; Zacepins et al., 2016; Kviesis et al., 2020). In the period of warm-up for the final take-off, the temperature above the upper hive body rises by 1.5-3.4 C from normal brood rearing temperature 34-35°C to 37-38°C (Zacepins et al., 2016). A schematic representation of temperature dynamics during the bee colony swarming event is shown below (see Fig. 1):

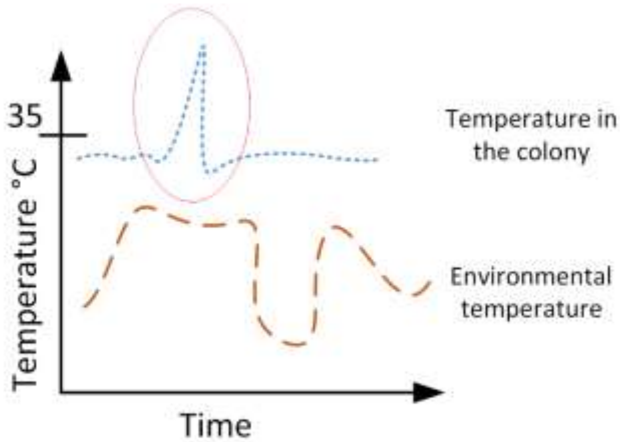

Figure 6. Temperature dynamics in general during swarming event

The chart below (see Fig. 2) clearly demonstrates the swarming moment, when the colony is leaving the original hive. This event is one example of bee colony swarming that was recorded in June 2015 in Jelgava, Latvia, when multiple Appis Mellifera colonies were constantly monitored. It is worth mentioning that detection of such an event is highly dependent on the temperature measurement interval - frequent measurements (with intervals in a range from one to five minutes) are required. It was observed that the spike in temperature only lasts for 20-30 minutes, therefore with less frequent measurement intervals (e.g., every 10-20 minutes) swarming cannot even be detected.

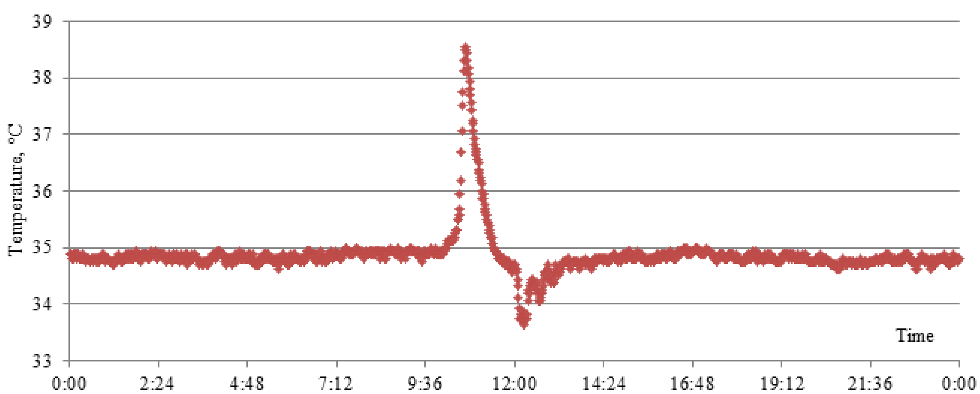

Figure 7. Temperature curve during swarming event in June 2015 in Jelgava, Latvia

To automatically detect swarming events from the temperature measurements several approaches can be used. It is possible to apply fuzzy logic for early abnormality detection in temperature patterns (Kviesis et al., 2020), k-means clustering (Kridi, 2014), simple condition-based mathematical algorithms (Zacepins et al., 2016) or other artificial intelligence methods (Kviesis & Zacepins, 2016).

Swarming detection by sound

Swarming bees generate a specific audio signal (Zgank, 2019), but the earliest electronic swarming detection system based on the sound analysis was "Apidictor," which was "in regular use" by Woods (Woods, 1959), indicating the age of the automatic swarming detection idea.

There are studies that demonstrate correlation between the amplitudes and frequencies of the bee colony sound and identify swarming (Dietlein, 1985; Ferrari et al., 2008; Qandour et al., 2014).

Most of the sounds produced by the bee colony have been characterised by a low fundamental frequency between 300 and 600Hz and their corresponding harmonics. Quandour et al., states that frequencies from 100 till 2000Hz with a single pulse sent by scout bees are triggering colony hissing and preparing for swarming.

Ferrari (Ferrari et al., 2008) proposed a method for predicting the swarming period, based on the labelling of sounds. Swarming is indicated by an increase in the power spectral density at approximately 110Hz. When the bees are beginning to swarm, the sound is augmented in amplitude and frequency to 300Hz and, occasionally, a rapid change occurs from 150Hz to 500Hz (Ferrari et al., 2008).

Bencsik (Bencsik et al., 2011) has identified patterns of vibration signals in colonies during swarming with specific sensors for detecting the frequency of vibrations.

Swarming detection by weight dynamics

During the swarming event part of the bees are leaving the hive within a short period of time. By knowing the size of the colony, it could be possible to evaluate the size and the weight of the swarm itself.

Usually during the swarming around 75% of worker bees are leaving the hive (Seeley & Rangel, 2012), so it can be concluded that the bigger the colony, the bigger the swarm itself. It is also possible to evaluate the potential weight of the swarm. The weight of one bee is approximately one tenth of a gram (https://www.reference.com/pets-animals/much-bee-weigh-2e57426f63f44979), so 10000 bees will weigh 1 kg. Even when the swarm is relatively small, a decrease in weight should be sufficient to be detected by a monitoring system.

In literature only few authors have mentioned the application of weight monitoring for swarming detection (Meikle et al., 2008; Linton, 2012).

A schematic representation of weight dynamics during the bee colony swarming is shown below (see Fig. 3.):

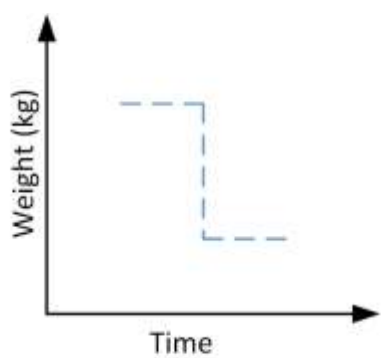

Figure 8. Weight dynamics in general during a swarming event

Figure 4 demonstrates a bee colony swarming event, detected by the temperature and weight measurements during a real-time bee colony monitoring in June 2020, in Witzenhausen, Germany. It can be observed that during the swarming, weight of the colony significantly decreases and is a good indicator for the beekeeper to react immediately. The weight drops as a large number of bees leave the hive in a short time.

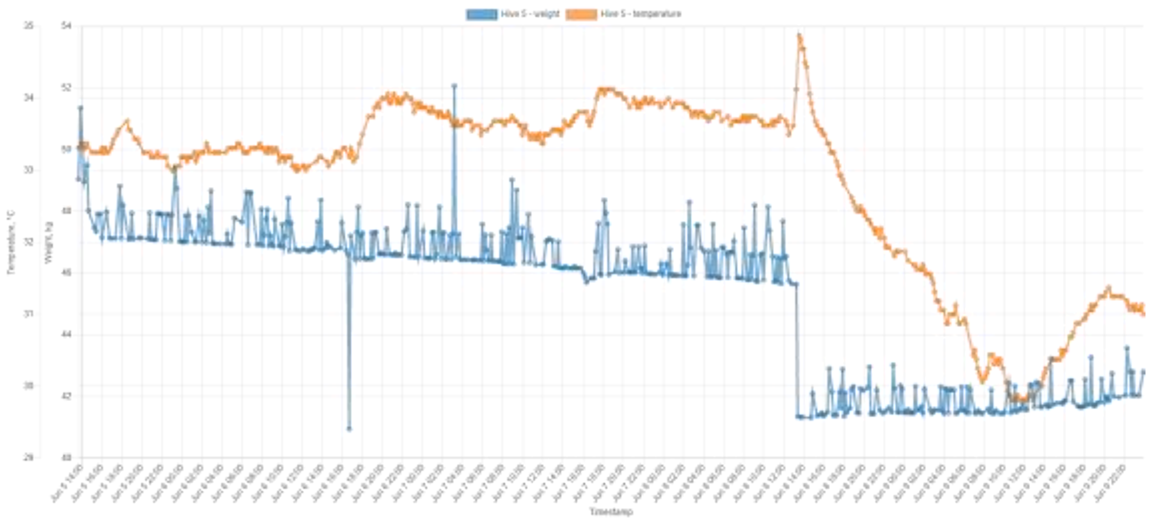

Figure 9. Changes in temperature (orange line) and weight (blue line) during a swarming event in June, 2020 in Witzenhausen, Germany. Image from the SAMS project (Wakjira et al., 2021) public report D4.4 (https://sams-project.eu/wp-content/uploads/2020/12/GA_780755_D4.4_Concept-of-the-DSS.pdf)

Available commercial solutions/products for swarming detection

Nowadays there are many precision beekeeping systems available which are focused on bee colony remote monitoring. Some of the solutions provide the functionality only to record the parameters without any deep data analysis and notification for beekeepers. But there are some commercial products which states that beekeepers will be informed if swarming of the colony will be predicted and/ or detected. For example, BuzzBox monitoring system from osbeehives.com states that artificial intelligence is applied to inspect hive's health and report updates to mobile app continually throughout the day. System can detect swarming, missing queen, healthy, sick, or collapsed hives in real-time. Another monitoring system from solutionbee (https://solutionbee.com/) reports alarms for intrusion, swarming or other colony issues.

Conclusions

Swarming is one of the bee states that, if not controlled, can significantly affect beekeepers' finances. Swarming is one of the events in the precision beekeeping that can be detected by individual parameter monitoring or can be combined with other parameters to increase the reliability. The most common parameters used for the swarming detection are temperature, sound and weight. If the temperature can be measured by relatively cheap sensors and data can be analysed with computationally light methods in order to detect swarming, sound monitoring, on the other hand, is more complex to analyze, but can provide more information, even predict the swarming event." The usage of weight data for swarming detection can be considered as an additional benefit (increases the reliability to correctly detect such an event), as weight primary is used for the foraging activity monitoring.

RESEARCH ON THE MANAGEMENT OF DAIRY BREEDING IN A FARM IN THE DORNELOR BASIN IN ROMANIA

Maria CIOCAN-ALUPII*, Vasile MACIUC

University of Agricultural Sciences and Veterinary Medicine-Iași, 3 Mihail Sadoveanu Alley, Iaşi 700490, Romania

Abstract

The paper aims to highlight the management of dairy cattle breeding on a farm in the Dornelor Basin, Suceava County, with the strengths and problems encountered in this farm. The farm is located in Panaci commune, Coverca village, with 60 head of cattle for milk, comprised of the following breeds: Bălțată Românească, Brună, Bălțată cu Negru Românească and Pinzgau. The paper is based on data taken from the National Register of Holdings on 23.10.2020. Data were statistically processed in the following indicators: dairy cow heads, heifer heads, female and male youth heads, daily milk/cow head production, total/lactation production, percentage of milk fat and protein, number of mountain products benefiting from the optional status of "mountain product". From the processed data it appears that the problems of this farm are represented by the insurance of the feed base, the lack of qualified personnel and the main advantage is represented by the fact that the farmer capitalizes the milk production obtained from cattle on the farm.

Keywords: *cattle, farm, milk, mountain product, dairy products.*

Introduction

The area under study is represented by the Dornelor Basin, Romania, also called "Ţara Dornelor". The Dornelor Basin (figure 1) or "Ţara Dornelor", located on the territory of Suceava county is a tectono-erosive depression, which together with the Câmpulung depression delimits between the northern group and the central group of the Eastern Carpathians. Given the geographical position of Dornelor Country (Dornelor Basin), it can be attributed the definition of mountainous rural space. The Dornelor Basin (figure 1.1), a mountainous area, attracts the attention of specialists, researchers for studies and analyzes with a tourist, agrotourism potential, high through the varied gastronomy specific to the Bucovina area, the traditions, culture and hospitality of its inhabitants. The significant share in the economy of the localities in the Dornelor Basin is held by agriculture and especially the raising of cattle for milk and meat. This animal husbandry activity has its advantages and disadvantages for mountain farmers. The strategic guidelines present the main directions to be followed to ensure the increase of attractiveness and sustainable development of the disadvantaged mountain area, by valuing resources, stabilizing the population, maintaining cultural identity, increasing economic power at local level, while maintaining ecological balance and protecting the environment (Ciocan-Alupii and Maciuc, 2021, *Considerations regarding the activity of animal breeding in the mountain area in relation to the distribution of milk processing centers and units in the mountain area of Romania).*

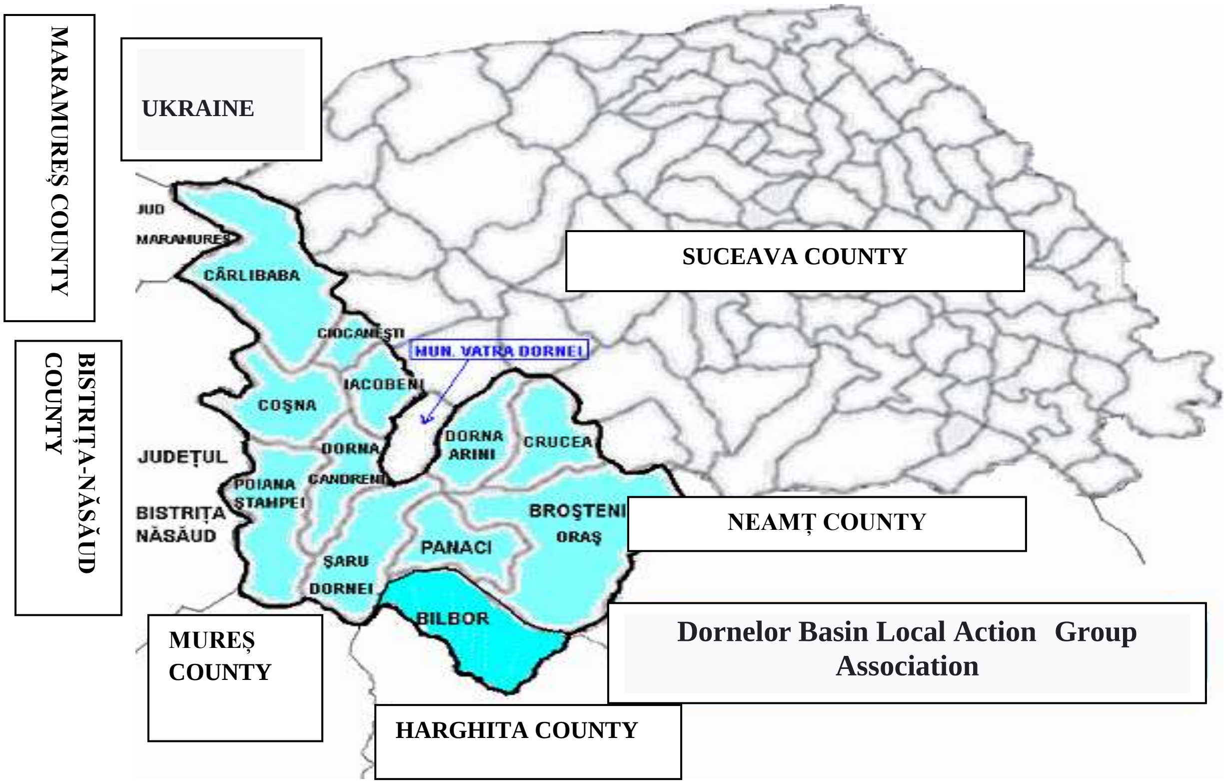

Figure 1. Map of the Dornelor Basin (http://galbazinuldornelor.ro, accessed on 14.01.2021)

Material and method

The research was carried out in the conditions of the household system of exploitation of dairy cows, in a farm from Dornelor Basin, Panaci commune, Coverca village. Dairy cows (60 heads) were studied, belonging to the Romanian Bălțată, Brună, Bălțată cu Negru Românească and Pinzgau breeds. The farmer owns a company whose object of activity is milk processing but also an agro-tourist boarding house. The primary data came from the National Register of Holdings on 23.10.2020. Several aspects were analyzed: dairy cow heads, heifer heads, female and male youth heads, daily milk / cow head production, total production / lactation, percentage of milk fat and protein, number of mountain products benefiting the statement of optional quality "mountain product". Once systematized, the data were processed and interpreted by methods specific to such research - arithmetic mean (), arithmetic mean error (± s) standard deviation (s), coefficient of variability (V%) and significance test p, using the program of statistics, analysis of variance and covariance (SAVC). The complexity of the aspects followed required the use of a diversified work methodology depending on the aspects pursued, using and respecting the investigation methodology recommended by the literature.

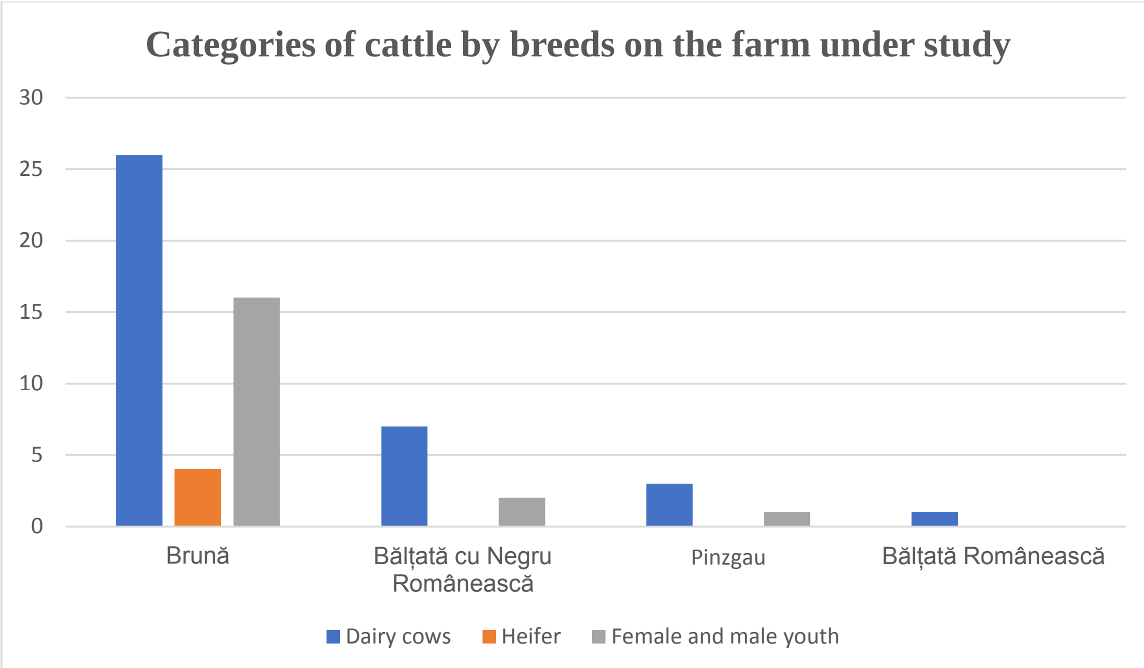
Results and discussions

The intensification of animal husbandry, the traditional occupation and the need for fast milk processing imposed the construction of the milk industrialization factory from Vatra Dornei (Dorna Lactate). Together with the Dorna Candrenilor section, the factory produced numerous varieties of cheese and butter. Unfortunately, at the moment this milk processing unit no longer works, being an opportunity for small producers to open milk processing points in the localities in the Dornelor Basin. In this sense, the farmer whose farm we are analyzing, owns a commercial company (S.C DANY LYLY SRL) that processes milk from the locality and from the surrounding localities. Along with the harmony of the typical mountain landscape, dominated by spruce forests that descend to the hearth of the depression, where they intertwine with rich meadows, these elements of anthropic capitalization of a generous potential, give Ţara Dornelor a strong personality, a particularly favorable brand image. for the development of agro-tourism (Ciocan-Alupii M, Maciuc V., 2021, *Considerations regarding the activity of animal breeding in the mountain area in relation to the distribution of milk processing centers and units in the mountain area of Romania*). The study undertaken in the Dornelor Basin was intended to be an x-ray of the situation of cattle breeding and the impact it has on the specific environment of mountain areas. The rather rational use of permanent meadows, with natural fertilization, without pesticides and with a good floristic composition, attributes special qualities to dairy products and meat. Operating technologies have remained largely traditional, but with the frequent use of livestock effluent storage facilities, so that greenhouse gases from these sources have not exceeded the permitted limits. Of course, there are still emissions from natural processes with a significant share (Toma C., Ciocan-Alupii M., Bocănici M., 2021, *Dairy Cattle Breeding Farm - trumps and restrictions on environmental impact*). The number of cattle on the holding under study is shown in Table 1.

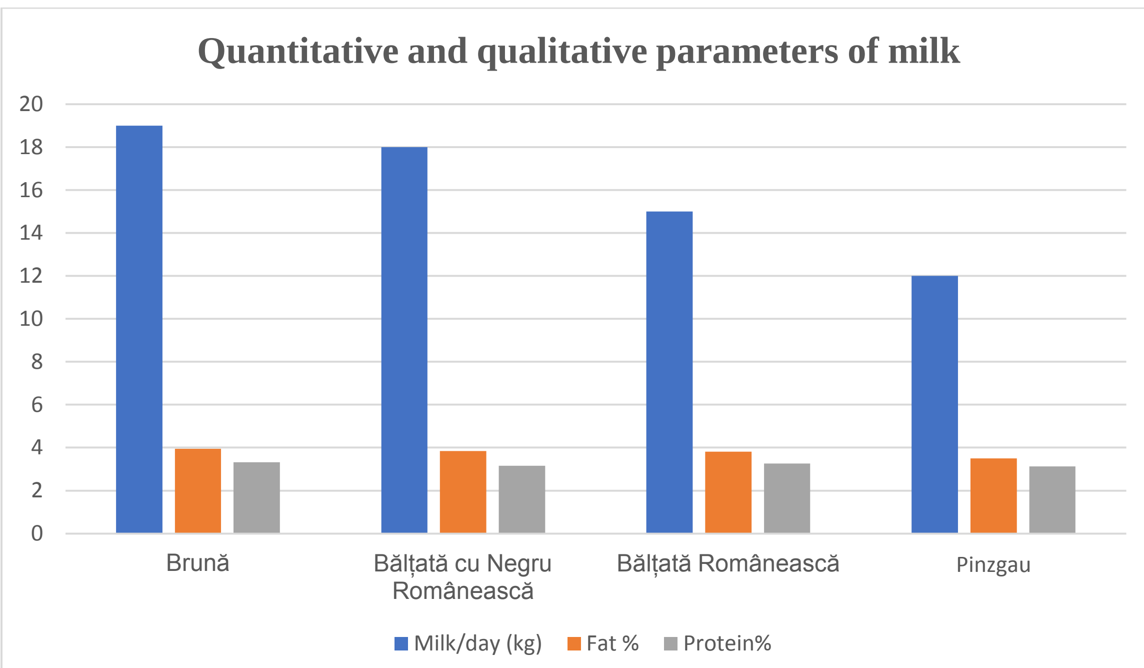
Table 1.Cattle herd by age categories and quantitative and qualitative parameters of milk

Current number	Race	Category			Total milk production/ head	Daily amount of milk / day / head	Fat %	Protein %
		Dairy cows	Heifer	Female and male youth				
1.	Brună	26	4	16	5795	19	3,94	3,32
2.	Bălțată cu Negru Românească	7	-	2	5490	18	3,85	3,16
3.	Pinzgau	3	-	1	3660	12	3,5	3,26
4.	Bălțată Românească	1	-	-	4575	15	3,82	3,12
Total		37	4	19	19520	16	3,77	3,21

(Source: Retrieval of data from the Genealogical Register)



Graph 1. Categories of cattle by breeds



Graph 2. Quantitative and qualitative parameters of milk

Table 1 shows that the breeds on the farm under study are Brown, Romanian Black Spotted, Romanian Spotted and Pinzgau. Out of a total of 60 head of cattle, 26 heads represent dairy cows of the Brown breed, 7 heads of dairy cows of the Bălțată cu Negru Românească breed, 1 of the Bălțată Românească breed, 7 heads are heifers of the Brown breed, 16 male and female youth heads of the breed Brown, 2 female and male youth heads from the Bălțată cu Negru Românească breed and 1 female youth head from the Pinzgau breed. Regarding the milk production, it can be observed that in the Brown breed a total milk production of 5795 liters was obtained, with 3.94% fat and 3.32% protein, in the Bălțată cu Negru Românească breed a total production of 5490 liters, with 3.85% fat and 3.16% protein, in the Pinzgau breed 3660 liters of milk, with 3.5% fat and 3.26% protein and in the Bălțată Românească breed a total production of 4575 liters of milk with 3.82% fat and 3.12% protein. We find that the best milk production, both quantitatively and qualitatively, the farmer obtained from the Brown breed, followed by the Romanian Black Spotted, Romanian Spotted and Pinzgau breeds. Hence the explanation for the larger herd belonging to the Brown breed, recognized for the quality of milk rich in kappa casein, but also for a good adaptability for the mountain area. Regarding the daily milk / head production, it can be observed (table. 1) that the lowest production was obtained from the Pinzgau breed, 12 liters of milk, followed by the Bălțață Românească breeds 15 liters of milk / head, Bălțată cu Negru Românească with a daily production of 18 liters of milk / head and the Brown breed with 19 liters of milk / head. The quantity of milk obtained from cows is capitalized by the Dany Lily Limited Liability Company, which belongs to the farmer, who has several varieties of cheese certified as a "mountain product" such as:

• "Călimani" svaițer (figure 2);
• Cheese „Călimani;
• "Călimani" smoked cheese;
• "Călimani" kneaded cheese;
• Telemea „Călimani."

The company processes 2000 liters of milk daily, obtained from its own farm but also from farmers in Șaru Dornei and neighboring localities. Dairy products are capitalized through their own stores but also through the agro-tourist boarding house that the company owns. The mountain products mentioned above are of superior quality, being tasty, obtained from the milk of cows that have grazed in the mountain area, where the pastures are rich in medicinal plants, giving a special taste to these dairy products. Of the 5 mountain products, some are fresh cheeses, others are matured cheeses. As impediments in the development of the activity within the farm, respectively within the milk processing unit, there is the lack of qualified personnel but also the provision of the animal feed base.

Following the analysis we can say that in the Dornelor Basin, as in the farm studied, farmers face various problems such as: that of feed areas and the possibilities to ensure diversified feed resources, skilled labor, the degree of endowment technical-material, with equipment and mechanization installations, of the biological material used in exploitation (cow breed) and last but not least of the way of capitalization of the production or even of the existing traditions. Regarding the welfare of cattle that is being talked about more and more in the U.E. and which ultimately determines the level and quality of production, farmers know and want to implement the five fundamental freedoms: freedom from discomfort - animals must have an adequate living environment, which includes a shelter and a comfortable area of rest; freedom to express their natural behavior - animals must be given sufficient space and the company of animals of the same species; freedom from hunger and thirst - animals must have unlimited access to fresh water and adequate food to maintain their health; freedom from fear and stress - animals must be treated in a way that does not cause them mental suffering; freedom from pain and disease - animals must be provided with a rapid diagnosis and appropriate treatment.

Figure 2. Svaițer ‘’ CĂLIMANI ”[https://taradornelor.ro/hai-in-tara-dornelor-locul-unde-se-produce-cel-mai-bun-svaiter/ accessed on 10.12.2020]

Conclusions

The breeds of cattle exploited on the farm are represented by Bruna which has the highest milk production, respectively 19 liters / head, Bălțată cu Negru Românescă with a production of 18 liters of milk / head, Bălțată Românească with 15 liters of milk / head and Pinzgau with a production of 12 liters of milk / head;

The farmer is faced with the lack of qualified staff to ensure the proper conduct of activities on the farm but also in the milk processing unit;

The milk on the farm is used in the processing unit owned by the farmer, resulting in high-quality dairy products, which benefit from the optional quality label 'mountain product', being both fresh and matured products.

For the mountain area, closed-flow farms, which also practice agro-tourism, are profitable.

Abstract

In this scientific paper, the analysis of milk production indices was performed, on standard lactation (305 days) in maturity equivalent (MS), on successive lactations, in the Brown of Maramureş breed, exploited at the Secuieni - Neamț Agricultural Research and Development Station. This breed of cattle belongs to the mixed morphoproductive type of milk - meat and was formed following the crossing between cows from the primitive local breeds Barn de steppe and Mocănița with bulls of the Schwyz or Brown Alpina breed (originally from N-E Switzerland). Cattle of this breed have a high degree of adaptability to all areas of landforms, especially those of hill and mountain specific to the area of Neamț County. They are also characterised by high productive longevity - up to 12-13 years. For the analysis of milk production indices, data from accredited associations was used to perform the official control of milk production (COP): the Association of Animal Breeders "Operator I.A" Neamț, as well as data from the Genealogical Register. An average milk production of 6074.00 kg, was recorded on normal lactation at lactation III, with a minimum production of 4724.00 kg and a maximum production of 7684.00 kg. Regarding the milk fat and protein content, the results recorded were also satisfactory, respectively, the average fat percentage was 4.02%, with a maximum limit of 4.40% and a minimum of 3.21%, at the second lactation when it recorded the highest values. The percentage of registered protein had an average value of 3.48%, with a maximum limit of 3.77% and a minimum limit of 3.28%, also at the second lactation. Regarding the fat/protein ratio, it recorded values of 1.19, a value that is close to the normal limits of this breed (1.20). The results obtained for the bulls of the Brown from Maramureș breed in this farm demonstrate that at optimal maintenance and feeding conditions, this breed of cattle expresses its genetic potential very well.

Keywords: *cattle, milk production, fat percentage, protein percentage, COP.*

Introduction

Cattle are the main suppliers of milk, a food product of first necessity, "of social interest", for the vigor and health of the population (Acatincăi, St., 2010). On the other hand, cattle are the animals that most efficiently transform primary production into milk production, namely 25.8% of energy consumed and 33.6% of protein consumed, having the property of successfully using cellulose feeds using microflora. and rumen microfauna (Georgescu, Gh., Ujică, V., et al., 1988). The quantity and quality of milk obtained from each dairy cow, as well as the total increased herd, depend on a number of factors, among which the most important are: genetic induced potential, quantitative level, assortments and quality of feed used in feeding dairy cows, age of cows, frequency of milking within 24 hours, duration of breast rest, duration of lactation, technological comfort offered to cows, through the rearing and endowment systems adopted, the calendar season in which lactation occurs and the state of health of cows (Georgescu Gh., Stanciu G., Velea C., Ujică V., 1990). The genetic factor must be considered first, because the productive potential of the animal depends on it, while the other factors create the conditions for expressing this potential (Dronca D., 2003). Regarding the composition of cow's milk, it varies a lot, depending on a large number of factors including breed, season, stage of lactation, milking interval, animal health, and feeding level. Milk is a repeatable production, which is obtained as a consequence of the process of reproduction of animals and cows, respectively. In order to know the productive capacity of a cow, the quantitative control must cover as long a period of its life as possible. The perfect and complete knowledge of the productive capacity of a cow requires the daily registration of the milk produced, by measuring it, establishing the production on lactations and then on the whole productive life, by summing the productions on lactations (Grosu, H., Pascal, A., 2005). This daily recording is cumbersome due to the large amount of work involved. Therefore, a solution was reached based on a mathematical criterion, namely that the entire lactation of a cow be divided into periods of a certain period of time, at which controls are performed, thus determining the production the the day of said controls. This production multiplied by the days between controls, gives the approximate production per period and by summing the productions per periods, the production on lactation results (Maciuc V., 2006). In the Secuieni Agricultural Research and Development Station, the Brown de Maramureş breed is raised and exploited, which is a mixed breed of milk-meat. It is a local breed formed by the absorption cross between the Barn of Steppe and Shepherd breeds with the Schwyz type cattle, deriving in Brown of Maramureş starting with 1881. Between 1890 and 1910, they were continuously imported from Austria and Germany, and in 1904 from Switzerland, bringing annually 200-500 cows and heifers of the Schwyz breed (Podar, C., Oroian, I., 2003). In 1907, Maramureş type cattle were brought to Moldova, loc. Mălini. Milk production varies widely depending on operating conditions, averaging 3,500 kg with 3.9% fat. The potential is over 5000 kg on normal lactation (Virginia Z., Maciuc V., Nacu Gh., Zota D., 2003).

Materials and method

In this scientific paper, the analysis of milk production indices was performed, on standard lactation (305 days) in maturity equivalent (MS), in the Brown of Maramureș on a herd of 51 dairy cows, on 3 successive lactations (lactation I - III), on a total of 89 lactations bred and exploited at the Secuieni - Neamț Agricultural Research and Development Station. In order to analyze the performance for milk production in this breed of cattle, a series of indicators were studied, such as: quantity of milk on normal lactation, fat content, total amount of fat, protein content, total amount of protein. At the Secuieni - Neamț Agricultural Research and Development Station, the periodic control, both quantitative and qualitative, is applied with very good results. The official control of milk production in cows from this farm is performed by the Association of Animal Breeders "Operator I.A" Neamț at an interval of 28 days. The primary data was extracted from the records of this holding, but also from the records of the administrative offices. They have been systematized, statistically processed and interpreted by methods specific to such research. The statistics, respectively the parameters, which characterize a normal distribution, are on the one hand the average or median ($\overline{X}$), and on the other hand the dispersion indices represented by standard deviation (s), coefficient of variation (V%), Min and Max of the pursued character.

Results and discussions

If the data in Tables 1, 2 and 3 are analyzed, it is found that the quantity of milk during normal lactation has an average value of 5089.92 kg, with individual variability limits between 3193.00 kg and 5924.00 kg of milk. At first lactation, an average value of 5683.26 kg of milk was recorded, at second lactation a minimum limit of 4797.00 kg of milk and a maximum limit of 6722.00 kg was recorded, and at the third lactation an average value of production of milk was obtained at standard lactation of 6074.00 kg milk with variables ranging from 4724.00 kg of milk to 7684.00 kg of milk at standard breastfeeding. Regarding the lactation curve, in successive lactations, it shows an upward trend from 5089.92 kg for the first lactation to 6722.00 kg for the third lactation.

These results demonstrate the very good precocity of this breed, achieving very good productive performances, starting from the second lactation, which is reflected in the economy of this breed on the productive life (Georgesu Gh., 2000).

As such, this breed of cow is responsive, if it is provided with good conditions of maintenance and feeding, managing to express its genetic potential, which in the literature is 5000-5500 kg of milk per standard lactation.

The values of the standard deviation s = 676.48 kg of milk at lactation I, s = 556.304 kg of milk at lactation II, and at the third lactation s = 1279.357 kg of milk, highlighting the pronounced variability in this population of researched cattle, which offers possibilities of genetic selection and improvement by keeping more variants and multiplying, in the process of reproduction, valuable genotypes (Maciuc V., 2006).

The fat content of milk shows the same high variability, with an average of 3.88 ± 0.091% and individual limits between 3.40 and 4.40%. Depending on the sequence of lactations, the maximum fat content between the analyzed lactations is recorded in the second lactation (4.04%), after which it decreases at the third lactation to 2.98%.

The protein content was 3.48 ± 0.025%, with a large individual variability, the amplitude of the variability having limits between 3.31% and 3.64%, at the first lactation, continued with a slight decrease at the second lactation and at the lactation the third is the lowest value, respectively of 3.32% ± 0.071%, with limits between 3.17% and 3.64%. Corresponding to the quantity of milk and the fat and protein content, the amount of fat on the entire population was 197.00 ± 7,353 kg, respectively 176.85 ± 6,741 kg protein, which proves that the milk obtained from this breed is of very good quality (Stanciu, G., 2005).

Conclusion

The natural conditions, particularly favorable for the breeding of dairy cows from the Brown breed of Maramureș, materialize in:

Neamț County has large areas of natural pastures, a total area of meadows located outside the 83 Territorial Administrative Units of 98,255 ha. (Source: Directorate for Agriculture and Rural Development), which are very well exploited by this breed of cattle.

Regarding the breed Brown of Maramureș in Romania, we must specify that, although it has a large area of expansion, it entered a continuous decline after 1990, both in number and spread, Frisian and Holstein Frisian. Even if they have a more valuable genetic potential, they fail to adapt to the conditions in the hill and mountain areas specific to this area, on the one hand, and on the other hand, if optimal conditions of maintenance and feeding are not ensured, they fail to express the potential, obtaining results that are not satisfactory.

The Brown breed of Maramureș has a uniform breastfeeding, and the quality of the milk is also remarkable, among the best, due to the high content of proteins and fats, characteristic for a breed crossed with specialized breeds for milk production, but with a low percentage of protein and fat to significantly improve these characteristics.

In the improvement of Brown of Maramureș cattle from the SCDA Secuieni farm, the aim is to increase the herd, raising the genetic potential for milk by using valuable parents, to transmit to the offspring the traits they want through appropriate pairing. The genetic structure, especially in terms of its homogeneity, but also in terms of induced potential, currently provides a production of more than 6000 kg of milk at the third lactation, on average on the farm.

Within the population, there are more variants that have achieved maximum productions of 10024 kg of milk.

The normalization of the nutritional requirements and of the zootechnical and sanitary-veterinary conditions is indispensable for cattle raising and for the profitability of the farm.

STUDY OF THE DYNAMICS OF BETA-HYDROXYBUTYRATE AND HEPATO-SPECIFIC MARKERS IN THE BLOOD OF NEWLY CALVED COWS WITH DIFFERENT BODY CONDITION

Svetlana V. VASILEVA*, Roman M. VASILEV

Federal State Budgetary Educational Institution of Higher Education «St. Petersburg State University of Veterinary Medicine», St. Petersburg, Russia

Abstract

Most cows have an increase in ketone body production a few days before calving. After calving, the prerequisites for ketogenesis are even more enhanced in cows. Lack of glucoplastic substances in the diet leads to the mobilization of fats and the development of ketonemia and liver lipidosis. We carried out a study in newly calved cows in the conditions of livestock farming in the Leningrad region (Russia). Two groups of 12 cows were formed. The criterion for the formation of groups is fatness (BSC) at the beginning of the dry period (in the first group - over 3.75, in the second group - 3.0-3.5). Blood samples were taken three times - 3-5 days after calving, then twice more with an interval of two weeks. In the blood serum, the content of BHB, total bilirubin, bile acids, as well as the activity of the enzymes AST and GGT were investigated. Studies have shown that in cows in both groups, the dynamics of changes in ketones, bilirubin and bile acids is unidirectional, but in cows with increased body condition these indicators were higher. Immediately after calving, the difference between the groups for these parameters was 21.3, 36.6 and 10.8%, respectively. The maximum values were determined 2-3 weeks after calving, then their decrease was observed. One month after calving, in cows with increased body condition, the activity of AST and GGT was higher by 19.2 and 16.0% in comparison with the indicators of cows in the second group. The results obtained confirm the negative effect of obesity in cows at the end of pregnancy on metabolic processes after calving.

Keywords: *Cows, Blood serum, Biochemical parameters, Metabolism, Body condition*.

Introduction

Most cows have an increase in ketone body production a few days before calving (Senger, 2012). This is facilitated by increased absorption of glucose from the maternal circulatory system by the fetus (Korochkina *et al*., 2017, Kozitsyna *et al*., 2018). In the last two months of pregnancy, there is an intense increase in fetal weight. Therefore, with a deficiency of glucoplastic substances in the cow's body, ketogenesis is activated to provide energy for the growth of fetal tissues (Esposito *et al*., 2014, Leibova *et al*., 2018). After calving, the prerequisites for ketogenesis are even more enhanced in cows. If the ration of a fresh cow is not properly provided with easily digestible glucoplastic feed, then the mobilization of fats from the depot is sharply increased (Smith *et al*., 1997, LeBlanc, 2010, Solomakhin *et al*., 2019).

The subsequent cascade of events leads to the development of ketonemia and liver lipidosis (Moiseeva *et al*., 2019). In the blood, the concentration of non-esterified fatty acids increases sharply, which migrate from peripheral tissues to the liver, which is one of the most important organs of lipid metabolism (Cherepanov, Agafonov, 2009, Irons *et al*., 2014). Here, part of the

fatty acids undergoes beta-oxidation to ensure oxidative metabolism and ketogenesis; part is used for the resynthesis of triglycerides and the incorporation of the latter into very low density lipoproteins, which are subsequently exported to mamillar tissue to participate in the formation of milk fat. In highly nourished cows, tissue lipolysis occurs intensively and an excess of lipid molecules occurs in hepatocytes, which do not have time to oxidize or be incorporated into lipoproteins, which are the transport form of lipids in the systemic circulation (Plemyashov, Moiseenko, 2010, Omarov, Slesareva, 2017, Karpenko *et al*., 2018).
At the same time, an increase in tissue lipid mobilization suppresses the appetite of a newly calved cows, which subsequently leads to a decrease in feed intake and aggravation of energy starvation. There is evidence of the detrimental effect of obesity in cows on their health in the postpartum period. In connection with the above, we set the task to study the content of β-hydroxybutyrate and hepato-specific markers in the blood serum of fresh cows with different body condition.

Material and Methods

We carried out a study in newly calved cows in the conditions of the Osminskoye livestock farm in the Leningrad region (Russia). Two groups of newly calved cows, 12 heads each, were formed. The criterion for the formation of groups is fatness at the beginning of the dry period. The cows of the first group have fatness over 3.75 points, cows of the second group - 3.0 - 3.5 points on the BSC scale. Blood was taken three times - the first stage - 3-5 days after calving, the second stage - after 15-20 days and the third stage - 30-35 days after calving. In the blood serum, the content of β-hydroxybutyrate (BHB), total bilirubin, bile acids, as well as the activity of the aspartate aminotransferase (AST) and gammaglutamyltransferase (GGT) enzymes were investigated. The study was carried out in the winter-spring season: the beginning of the dry period in January-February, calving in cows - in March-April.

Results and Discussion

The results of the studies carried out are presented in tables 1, 2.

Table 1. Assessment of body condition of cows before and after calving

Study period:	Group 1	Group 2	Certaintly factor in intergroup comparison (P)
The beginning of the dry period	4.04±0.08	3.33±0.06	P<0.001
3-5 days after calving	3.63±0.05***	3.15±0.12	P<0.001
30-35 days after calving	2.96±0.07***	3.0±0.08***	P>0.05

* - P<0.05, ** - P<0.05, *** - P<0.01(when compared with the baseline within the group)

Studies have shown that in cows of the first group, body condition according to points for the dry period decreased by 10.2% (P <0.001), in cows of the second group - by 5.4%. During the first month of lactation in the first and second groups, there was a decrease in body condition by

18.5% and 4.8%, respectively. At the same time, in both groups, there is a significant decrease in the indicator in comparison with the initial value (P <0.001).

Table 2. Dynamics of biochemical parameters in cows in the first month after calving

Investigated indicators	Research stages	Group 1	Group 2	Certaintly factor in intergroup comparison (P)
BHB, mmol/l	1	1.36±0.10	1.07±0.06	P<0.01
	2	1.63±0.18	1.23±0.11	P>0.05
	3	1.44±0.11	1.01±0.07	P<0.001
Bilirubin, μmol/l	1	5.82±0.67	3.69±0.37	P<0.05
	2	7.29±0.56	5.18±0.54*	P<0.05
	3	6.11±0.62	3.17±0.39	P<0.001
Bile acids, μmol/l	1	50.56±2.3	45.11±2.61	P>0.05
	2	64.91±4.31**	48.85±5.24	P<0.05
	3	58.95±2.90*	44.06±5.00	P<0.05
AST, U/l	1	112.26±4.27	106.14±3.68	P>0.05
	2	119.03±7.07	103.6±5.98	P>0.05
	3	123.89±6.3	100.12±2.8	P<0.01
GGT, U/l	1	27.04±1.77	25.84±1.35	P>0.05
	2	25.3±1.85	26.88±1.31	P>0.05
	3	30.42±1.65	25.56±1.61	P<0.05

* - P<0.05, ** - P<0.05, *** - P<0.01 (when compared with the baseline indicator within the group for each indicator)

The BHB concentration in cows of the first and second groups immediately after calving was 1.36±0.10 and 1.07±0.06 mmol/l, after two weeks - 1.63±0.18 and 1.23±0.11 mmol/l. Thus, in both groups, an increase in ketogenesis is revealed - by 16.6% and 13.0%, respectively. A month after calving, the concentration of BHB in the blood decreases and is 1.44±0.11 mmol/l in cows of the first group, and 1.01±0.07 mmol/l in the second group (P <0.001 by intergroup comparison).

The post-calving bilirubin level was significantly higher in cows of the first group by 36.6% and amounted to 5.82±0.67 μmol/l. Two weeks later, in cows of the first and second groups, the indicator increased by 20.2% and 28.7%, respectively. A month later, there is a decrease in the level of bilirubin in both groups, however, in cows with optimal body condition, the indicator is 34.0% lower (P <0.001).

The level of bile acids in the blood serum is initially higher in the first group by 10.8%. In the future, there is an increase in the indicator in both groups, while the maximum values are determined within 15-20 days after calving. Further, at the end of the observation period, the concentration of bile acids decreases, but in the first group the indicator remains above the initial level, and in the second it returns to the initial value. When comparing between the groups at the second and third stages of the study, a significant increase in the indicator is determined by 24.7% and 25.3% (P<0.05).

When comparing the activity of blood serum aspartate aminotransferase, the progressive increase in the indicator in cows of the first group during the observation period from 112.26±4.27 to

123.89±6.3 U/L is determined. In cows of the second group, there is a slight downward trend - from 106.14±3.68 to 100.12±2.8 U/L.
With regard to the activity of GGT, there is a tendency to an increase in the indicator in animals of the first group at the end of the experiment, while in the second group, slight fluctuations of this indicator are revealed. In the period of 30-35 days after calving, the GGT activity is higher by 16.0% in cows of the first group ($P<0.05$).

Conclusions

Summing up, it can be argued that cows with increased body condition during the dry period during early lactation undergo adverse changes in comparison with animals with optimal body condition. There is progressive weight loss during the first month of lactation. Obese cows have increased production of ketones, bilirubin and bile acids compared to cows with optimal body condition. An increase in the activity of hepato-specific enzymes - AST and GGT is also determined. Studies have shown that cows with a body condition of 3.0 - 3.5 points, all other things being equal, cope better with the load during the transit period. It is important to control the fatness of lactating cows and prevent their obesity at the end of the lactation period.

Abstract

In this paper, the influence of ground nettle leaves as a phytogenic supplement in broiler nutrition on production results and growth parameters was examined. The diet test was performed according to the principle of group control and lasted 42 days. One-day-old Cobb 500 provenance chickens were used for the experiment, and tests were performed on chickens of both sexes with an average body weight of 48.67 ± 2.49 g. The experiment was performed on a total of 120 broilers divided into 4 groups of 30 chickens. That is, the chicken was divided into control group K (no phyton-nettle supplement), experimental O-I group (phytogen-nettle supplement, 1%), experimental O-II group (phytogen-nettle supplement, 1.5% in food) and experimental O-III group (with phytogen-nettle supplement, 2% in food). In fattened chickens the best result of body weight was found in chickens of experimental groups: O-III those consuming food with the addition of 2% nettle (2658.94 g), O-II those consuming food with the addition of 1.5% nettle (2450.00 g) and O-I those consuming food with the addition of 1% nettle (2330,20 g) relative to the control group K having the lowest body weight (2120.10 g).; Average food consumption was highest in the O-I trial (128.00 kg) compared to the control group consuming more food (12.70 kg) compared to the O-II (121.60 kg) and experimental groups O-III (112.23 kg). Obtained food conversion results per kilogram increment show that the experimental group O-III receiving nettle supplement of 2% had the best food conversion per 1 kg increment (growth 1.37 kg / kg) compared to the experimental groups receiving nettle supplement of 1.5% (1.66 kg) / kg growth), ie. nettle content in the mixture of 1% (growth of 1.77 kg / kg). The worst results were shown by the control group consuming food without adding nettle.

Key words: *broilers, phytogenic additives, nettle, conversion, growth.*

Introduction

Livestock production as a branch of animal husbandry has made remarkable progress in the last thirty years. The newly created hybrids for both meat production and egg production have contributed to the poultry production taking on the character of industrial production. The greatest importance of livestock production is reflected in the fact that products of high biological value for human consumption are obtained in a short time. Many years of genetic research in modern poultry production is based solely on the creation and utilization of line hybrids. The production of high quality hybrids is a very long and complex business. In fact, it comes down to the formation of mostly pure, and rarely synthetic, lines that give offspring with highly expressed production traits. Due to the specific structure and function of the poultry digestive system, the diet differs from other animals, so quality poultry concentrates are mostly used in poultry. Mercury cooks carbohydrates almost over 90%, and proteins and fats between 80 and 90%. Due to the high efficiency of food utilization, poultry growth is very intense. The main feature of modern poultry production today is the tendency to reduce the use of antibiotics in food, while exploring alternatives, to ensure effective disease control and high production (Pešić et al., 2011). Uses include probiotics, prebiotics, organic acids, enzymes, and increasingly, herbal additives, with some stimulating effect and antibacterial potential. Such herbal supplements are called phytobiotics and their use and research into their effects are becoming increasingly popular. They are attributed to effects such as: stimulation of food consumption, action against bacteria, coccidia, parasites, then anti-inflammatory and immunostimulating action.

Phytobiotics have great potential for use in broiler fattening because of their antioxidant properties, their effect on improving food quality, digestive functions, as well as their ability to improve the body's immune status. This is further compounded by their antibacterial properties, making phytobiotics a natural iantioxidant and a substitute for growth stimulants (Windisch et al., 2008). One such phytobiotic is nettle, it is extremely rich in various useful ingredients: protein, carbohydrates, fats, calcium, phosphorus, iron, vitamins C, A, B2 and K, carotene, pantothenic acid, etc. It also contains flavonoids, organic acids, nitrogenous substances and more. Nettle leaves (Urtica dioica) are rich in caffeic acid ethers and flavonoids, which are attributed to certain immunostimulating, anti-inflammatory effects, and are good growth stimulants and antioxidants. Safamehr et al. (2012), in their research, show the influence of the addition of different concentrations of nettle mixed in the fattening mixture on production results and selected biochemical parameters and found that the experimental groups showed a statistically significant weight gain on the 42nd day of fattening and Conversion rates were significantly lower, and Pilad also had significantly lower serum triglyceride and cholesterol concentrations than controls.

Al-Mashhadani et al. (2013) set up a similar experiment with the addition of different concentrations of chamomile oil in the fattening mixtures of chickens, conducted and concluded that the chickens of the experimental groups had statistically significantly higher final weight and gain as well as statistically significantly lower food conversion compared to the control group chickens. . They also found that the test group chicks had statistically significantly lower plasma cholesterol and glucose concentrations than the control group chicks. Similar results were obtained by Al-Kassei and Kalhel (2011) in the experiment of the effect of dandelion added at different concentrations in compound feedingstuffs for fattening chickens on the production results of fattening chickens. The aforementioned authors found that the chickens of the experimental groups had a statistically significantly higher final live weight and gain compared to the chickens of the control group.

The aim of the experiment was to examine the effect of the contents of nettle leaf on production results (body weight, weight gain, feed conversion) of chickens in fattening.

Material and Methods

In this paper, the influence of minced nettle as a phytogenic supplement in broiler nutrition on the production results and parameters of chicken growth was examined. After harvesting, the nettle leaves were dried in natural light, after which they were ground and added to the concentrate mixture. The grinding of nettle leaves exposes the influence of the main constituent of flavonaid leaves.

Investigations were performed with experimental chickens housed in the production facilities of the poultry farm "Pilepromet", in the period from March to April 2020. The diet test was performed according to the group-control principle and lasted for 42 days. One-day-old Cobb 500 provenance chicks were used for the experiment, and chicks of both sexes with an average body weight of 48.67 ± 2.49 g were used for testing.
The experiment was performed on a total of 120 chickens divided into 4 groups of 30 chickens. That is, chickens were divided into control group K (without phytogen-nettle supplement), experimental OI group (with phytogen-nettle supplement, 1%), experimental O-II group (with phytogen-nettle supplement, 1.5% in food)) and the experimental O-III group (with the addition of phytogen-nettle, 2% in food). The experiment lasted for 42 days and was divided into two phases. The first phase lasted 0-20. and the second phase of 21-42. of the day. In the first phase, chickens consumed food with 22% of CP, while in the second phase, they consumed food with 17% of CP.
At the beginning and end of each phase of the experiment, the body weight of each animal was individually measured and the food consumed, all with the aim of obtaining data that was used to calculate other production results. The statistical program SPSS Statistics 25 was used to process the results. Significance of differences between group mean values was checked by line method (GLM), analysis of variance (ANOVA), at significance level P <0.05 and P <0.01.

Results and Discussion

The tables show the results as mean and standard deviation. For the purpose of monitoring body weight as one of the four basic production indicators, the body weight of chickens was checked once a week, and the results obtained were statistically processed, shown in Table 1.

Table 1. Average weight of chickens per week, (g).

(K) -control group, (O-1) -concentrated mixture + 1% nettle flour, (O-2) - concentrated mixture + 1.5% nettle flour, (O-3) - concentrated mixture + 2%, $\bar{X}$- arithmetic mean, sd-standard deviation, p-statistical probability * p <0.01 ** p <0.05

Table 1 shows that the average body weights of the chicks at the beginning of the experiment were uniform, and as expected, there were no statistically significant differences (P> 0.05) between the groups. At the end of the first week, the average body weight of the control group chickens was greater than in the other three experimental groups, but the differences between the groups were small so that there was no statistically significant difference. The weight of the chickens in the experimental groups achieved by the addition of nettle is in line with the results obtained by Tabari et al., 2016; Keshavarz et al., 2014; Loetscher et al., 2013; Nasiri et al., 2010. Measurements in test group O-3 showed the highest body mass at the end of the second week, while the lowest values were recorded in control group K. The differences in average body masses between test group O-2 and group O-2 and O-3 were statistically significant. significant (P <0.05). In the following weeks, the trend of body mass movement by groups continued, so that at the end of week 3 and week 4, when the best values were achieved by the O-3 group of chickens with statistical significance (P <0.01), and the best body mass at at the end of week 5 and week 6 it was achieved in chickens of the O-3 experimental group with statistical significance (P <0.05). The highest final weight gain was achieved by chickens from O-3, (2658.94 g), slightly lower values were observed in O-3 and O-2, (2450.00 g; 2330.20 g). while the lowest was in control group K chickens (2120.10 g). The consumption of chicken feed in the experiment was monitored weekly by groups, and the results obtained in absolute and relative values are shown in Table 2.

Table 2. Table 2. Average food consumption by groups and weeks of fattening, (kg).

(K) -control group, (O-1) -concentrated mixture + 1% nettle flour, (O-2) - concentrated mixture + 1.5% nettle flour, (O-3) - concentrated mixture + 2%, $\bar{X}$ - arithmetic mean,% -index

The previous table shows that the food consumption in the first week of the experiment was higher in the experimental groups compared to the control group, and the highest food consumption had the chickens of the experimental group O-2 (5.2 kg), which is in comparison with the control group. group (4.4 kg) by 18.18% more. Chicks in the O-1 and O-3 experimental groups (4.9 kg; 5.1 kg) consumed 11.13% and 15.90% more food, respectively, than the control group chicks. The result obtained with the addition of nettle (experimental groups 1,2,3) is in line with the results of the study by Tabari et al., 2016; Keshavarz et al., 2014; Loetscher et al., 2013; Nasiri et al., 2011. When observing the period of consumption of food in the second, third, fourth, fifth and sixth weeks of the experiment, the trend of food consumption in the test group chickens was changed relative to the control group of chickens. The observed difference is most clearly visible when looking at the three-week review, with the O-1, O-2, and O-3 experimental groups consuming less food by 2.21%, 0.63%, and 7.87%, respectively. control group.

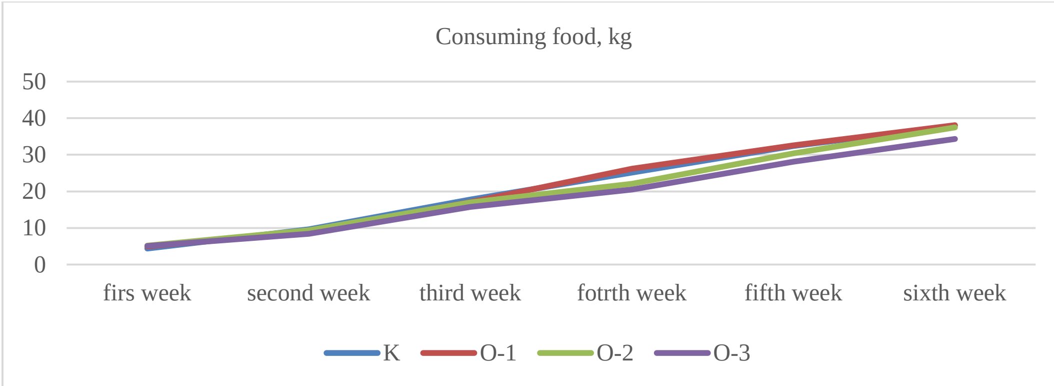

Figure 1. Average food consumption by groups and weeks of fattening, (kg).

This trend of food consumption by groups also continued in the next three-week period, that is, the fourth, fifth and sixth weeks of the trial. The results obtained show that during this period only the experimental group O-2 had higher food consumption in comparison with the control group by 1.57%, while the experimental groups O-1 and O-3 consumed less food compared to the control group by 5.67% and 13.08%, respectively. The significance of the obtained results was increased by their comparison with the results of scientists who published the results that examined different concentrations of nettle supplement in food, e.g. 1% (Safamehr et al., 2012) and 1.5% (Mansoub, 2011), while Kwiecien and Winiarska - Mieczan (2009) and Ghasemi et al. (2014) obtained such results by adding 2% nettle. On the basis of the known values of weekly fattening increments of chickens and food consumption, the conversion of food per kilogram of growth was calculated, which is calculated from the ratio of total food consumption and total growth. The obtained food conversion results are shown in Table 3.

Table 3. Average feed conversion per kg of growth (by groups and weeks of fattening), (kg).

WEEK OF WEIGHT	CONTROL (K)		VIEW GROUP (O-1)		VIEW GROUP (O-2)		VIEW GROUP (O-3)	
	kg/kg	%	kg/kg	%	kg/kg	%	kg/kg	%
first week	1,32	100,00	1,29	97,77	1,34	103,87	1,15	85,82
second week	1,77	100,00	1,86	105,08	1,97	105,91	1,30	65,99
third week	2,06	100,00	1,54	74,75	1,30	84,41	1,33	102,30
<u>Total first-third</u>	1,71	100,00	1,56	91,22	1,54	98,71	1,26	81,81
fourth week	1,81	100,00	1,76	97,23	1,59	90,34	1,37	86,16
fifth week	1,75	100,00	1,85	105,71	1,80	97,30	1,37	76,11
sixth week	2,90	100,00	2,31	73,44	1,92	83,11	1,72	89,58
<u>Total fourth-sixth</u>	2,10	100,00	1,97	93,80	1,77	89,84	1,48	83,61
TOTAL	**1,95**	**100,00**	**1,77**	**90,77**	**1,66**	**93,78**	**1,37**	**82,53**

(K) -control group, (O-1) -concentrated mixture + 1% nettle flour, (O-2) - concentrated mixture + 1.5% nettle flour, (O-3) - concentrated mixture + 2%, (kg / kg)¯- food conversion per kg. increment,% -index

Considering the results presented in Table 3. we can see that the best food consumption was achieved by the experimental groups in the whole period of the crane conversion, with the emphasis on the experimental group O-3, which in the total observed period of 42 days achieved lower food consumption compared to the control group by 17.47%, while the experimental groups O-2 and O-1 also performed better by 9.23% and 6.22%, respectively. Addition of nettle at a concentration of 2% in the concentrated mixture resulted in less food consumption. These results are consistent with the results obtained by several authors (Tabari et al., 2016; Loetscher et al., 2013; Nasiri et al., 2011; Safamehr et al., 2012; Ghasemi et al., 2014).

Conclusion

The effect of the nettle, and especially of the phytogens found in the nettle leaf, has shown an impact on the production results of COBB 500 fattening chicks; In the fattened chickens, the best results in body weight had the chickens of the experimental groups: O-3 who consumed food with the addition of 2% nettle (2658.94 g), O-2 who consumed food with the addition of 1.5% nettle (2450.00 g), O-1 who consumed food with the addition of 1% nettle (2330.20 g) relative to the control group having the lowest body weight (2120.10 g); Average food consumption was highest in the O-1 (128,00 kg) experimental group compared to the control group that consumed more food (127.20 kg) compared to the O-2 (121.60 kg) and O experimental groups. O-3 (112.23 kg); Obtained food conversion results per kilogram of increment show that the O-3 experimental group receiving 2% nettle supplement had the best conversion of food per kg increment (1.37 kg / kg increment) compared to the experimental groups receiving 1.5% nettle supplement (1.66 kg / kg increase), ie nettle content in the mixture of 1% (1.77 kg / kg increase). The worst results were shown by the control group who consumed food without the addition of nettle.

Abstract

The paper presents potential residues of polychlorine biphenyls (PCBs) and sulfonamides in honey. Investigation was performed analyzing 20 samples of acacia and meadow honey. The samples were collect from 4 different parts of Republic of Srpska (RS), Hercegovina, Romanija, Doboj and Karajina region. For determination of residual levels of polychlorine biphenyls, gas chromatography with electron-capture detection (GC/ECD) was used. Analysis of sulfonamides was done with ELISA test in honey (5-600 µg/kg). Results indicate that in the described beekeeping zones very small amount of investigated residues in honey were detected. Also the results are evaluated with current regulations: Commission Regulation (EU) n 37/2010; Official Gazette of BiH, No. 89/12, 92/17 and 21/19 and Official Gazette of the FRY No. 5/92 and 11/92". Honeybees are the main indicators of the environment. Where pollution with toxic gases is high, honey bees find it difficult to survive, which is also a sign that the environment is endangered. Therefore, by raising honey bees, people protects nature and themselves as someone who belongs to nature and its environment. The analysis in 4 regions of RS has determined the ecologically clean environment that provides an opportunity for the development of beekeeping in the other parts of the state.

Keywords: *Honey, polychlorine biphenyls, sulfonamides, residues, environment.*

Introduction

Honey bees play an extremely important role in the ecosystem and their importance should not only be measured by the benefits they give from the direct production of high quality food, they also have an irreplaceable role in pollination, which certainly results in a contribution of billions of dollars. Bees are the most dominant and most specialized pollinators, there are about 17,000 known species (Michener, 2000). The damage caused by the absence of their activity can be much greater and there is not only the question of lost earnings but the overall reduction of food of plant origin, which directly threatens our survival (Kićović, *et al.,* 2004).

Honey as the primary product of the honey bee is a natural product, variable not only in color, taste and smell but also in its chemical composition (Abadžić, 1982), and depends on the ecological environment and plant cover of honey plants. Having in mind the number of possible sources of honey pasture, it is understandable that there are no completely identical honeys from different localities (Ađić, 1932).

In the countries of the European Union (EU), the results of analyses of honey for the content of heavy metals and pesticide residues serve as an indicator of the degree of environmental pollution, ie the state of product quality in that area.

The presence of polychlorine biphenyls are the results of uncontrolled spillage and atmospheric deposition is associated with excessive use in the past (González Sagrario, *et al.* 2002).

Polychlorinated biphenyls are especially toxic because they decompose slightly during metabolic reactions in living organisms. They are also susceptible to biomagnification, ie they enter the food chain through accumulation in lower organisms and plants. All these properties of polychlorinated biphenyls make it a big problem in the field of environmental protection (Gavrančić and Skala, 2000).

The bioindicators of environmental pollution are honey bees and their products owing to their intense foraging activity in nearness to their hive (Santosa, *et al.,* 2021). During their collection of water, nectar, and pollen from flowers, bees can carry environmental contaminants in their hives, via inhalation, or ingestion, when being exposed to a large number of pollutants such as pesticides, in a radius ranging from 1.5 to 3 km around the hive, depending on food abundance (García-Valcárcel, *et al,*. 2016; Herrera López, *et al.,* 2016; Drummond, *et al.,* 2017).

The environment may be affected with organic pollutants, for example, PCBs, which are chemicals that bioaccumulate through the food chain and pose a risk of causing adverse effects to human health and the environment (Zhao, *et al,*. 2017). In past (also nowadays in some states) PCBs were primarily used in electrical equipment, such as transformers and capacitors, as insulators and they reached accumulated global production approximately 1.3 million tons (Zhao *et al.,* 2017). Due to inappropriate disposal of equipment containing PCBs environment is contaminated through the anthropogenic activities. Therefore, research has proven the presence of PCBs remains in water, soil, food, animals, and humans (Roszko, *et al.,* 2014; Mohr, *et al.,* 2015). Also those environmental pollutants is associated with adverse health effects, including cancer and diabetes, in addition to neurobehavioral and immunological changes in humans (Ali, *et al.,* 2016; Mustieles, *et al.,* 2017; Vafeiadi, *et al.,* 2017; Ziegler, *et al,*. 2017).

In Republic of Srbska prescribed value for PCBs in honey is not defined, only respecting the regulations Official Gazette of the FRY No. 5/92 and Official Gazette of the FRY No. 11/92, where milk and milk products, eggs, poultry, other animal meat, fish, shellfish, crustaceans and molluscs, the permitted concentrations of PCBs are indicated. EU and some other countries implemented Stockholm Convention on Persistent Organic Pollutants (POPs). States Parties to this Convention have an obligation to establish, prohibit or restrict the production, trade and use of POPs, as well as to reduce or eliminate emissions of 12 POPs chemicals (aldrin, chlordan, DDT, dieldrin, endrin, heptachlor, hexachlorobenzene (HCB), mirex, toxaphene, PCB, PCDD / PCDFs) into the environment.

The use of different antibiotics in honey and other honey bee products are usually treat in a veterinary setting, such as streptomycin, sulfonamide, and chloramphenicol. Generally, beekeepers has practice to use antibiotics (at relatively high doses) to treat infections, or as "growth promoters (Duarte, *et al.,* 2020). Residues that occur, as a result of unconscious use of antibiotics in order to prevent honey bee diseases cause food safety issues (Korkmaz, *et al.,* 2017) .

In terms of public health, antibiotic residues are also potentially dangerous (Bogdanov, 2006, Al-Waili, *et al.,* 2012). For the majority of food produced by animals treated with sulfonamides and tetracyclines, maximum residue limits (MRLs) have been established, but not for bee products such as honey. The honey is traded as international product for human's consumptions and most of countries accept standards set by the Codex Alimentarius (Tillotson and Theriault 2013).

In EU countries, the use of antibiotics in beekeeping is not legal and MRLs is not established for antibiotics in honey according to the regulations, which means that honey containing antibiotic residues is not permitted to be sold.

In Republic of Srbska Official Gazette of the FRY No. 5/92 and 11/92, is recognized, where milk and milk products, meat and meat products, eggs and egg products, freshwater fish, honey and other foodstuffs of animal origin may be placed on the market if they do not contain sulfonamides residues in quantities greater than 0.10 mg/kg.
The honey bees are the main indicators of the environment. Where pollution with poisonous gases is high, bees have a hard time surviving, which is also a sign that the environment is endangered. Therefore, by raising honey bees, man protects nature and himself as works of that nature;
This paper indicates presenting the possibilities of production honey in 4 regions of RS with emphasis on environmental quality of beekeeping areas.
Presented research should show the environment in which we are engaged in agriculture, ie the possibilities of sustainability of our products, through quality, on the world market.

Materials and Methods

Samples were collected at the end of the honey collection season. A total of 20 samples of different species of honey (acacia and meadow honey) were taken from 4 different parts: from Hercegovina region were collected 5 samples of meadow honey, the same was in Romanija region in Bosnia and Herzegovina, for both, Doboj and Krajina were taken 5 samples of acacia honey (Bilić-Šobot, 2020). After collection of samples they were sent at the Institute of meat hygiene and technology in Belgrade for future analysis. For determination of residue of polychlorine biphenyls it was used solid-phase extraction cleanup followed by gas chromatography with electron-capture and nitrogen-phosphorus detection (GC/ECD) detection limit mg/kg: 0.001 described by Herrera *et al.* (2005). The analysis of sulfonamides was done with ELISA test in honey (5-600 μg/kg). It was used documented method according to the manufacturer's instructions for diagnostic kit: Sulphonamides ELISA test kit Cat No 1056, (5-600 μg/kg) MaxSignal® Bioo Scientific Corporation, USA. Respectively, samples were prepared and analyses by described manufacture procedure "MaxSignalTM Chloramphenicol (CAP) ELISA Test Kit Manual Catalog #: 1013" available at http://www.medibena.at/media/bioo/produc
In this paper, the results were compared with the following legal regulations: Official Gazette of BiH No. 37/09 and 25/11 and 21/19 and Official Gazette of the FRY No. 5/92 and Official Gazette of the FRY No. 11/92.

Results and Discussion

Table 1 shows the results for the presence of polychlorinated biphenyls and sulfonamides. The values obtained for all 20 honey samples were 0.001 for biphenyls and 0.005 mg/kg for sulfonamides. The prescribed values are not defined by Official Gazette of the FRY No. 5/92 and Official Gazette FRY no. 11/92 for PCBs, while sulfonamides residues are under prescribed value max. 0.10 mg/kg.

Table 1. Results of laboratory test of honey samples for the presence of residues of polychlorine biphenyls and sulfonamides

	Meadow honey	Acacia honey	Prescribed value
Units	mg/kg		
Number of honeys	10	10	
Polychlorine biphenyls	< 0.001		not defined
Sulfonamides	< 0.005		max. 0.10

max.- maximum

The research of Erdoğrul *et al.*, (2007) examined 35 samples of honey for the presence of polychlorinated biphenyl residues, where 8 of 35 samples of residues were founded in ranged around 0.25 to 3.07 ng g−1. Recently published study by Santos *et al*,. (2021) shows the investigation of PCBs residues in honey on 90 samples of tasted commercial honey. Where 15 of 90 samples had PCBs residues, with most highly detected concentration 531 ng g^{-1}. Reported data were not in agreement with ours, where residues of polychlorinated biphenyls ether for meadow and acacia honey, was 0.001 mg/kg, which is far less according to the research of Erdoğrul *et al*., (2007). The same reports were published by Saitta *et al.*, (2017) with not detect any of the 18 PCBs analyses in Italian honey samples from the regions of Sicily and Calabria by GC-MS/MS. The presence of PCBs in the honey indicates that the honey bees were exposed to these pollutants, confirming the presence of environmental contamination, reported in some countries (Herrera, *et al*., 2005; Chiesa, *et al*. 2016, Erdoğrul, *et al.*, 2007, Santos, *et al*., 2021)
This contamination in different geographical origins and countries is probably associated with the micro-regions visited by the honey bees or with some global pollution. As most countries respect and implement the Stockholm Convention, monitoring of PCBs in the environment and in food is necessary to prevent human exposure, especially through food intake. Honey quality and safety are essential concerns of current society. The presence of antibiotic residue in food is particularly dangerous for human health, its monitoring (on residues in honey and food) is essential because of humans' health. Presented results indicated some residues of sulfonamides in the meadow and acacia honey but in regular values (prescribed by Official Gazette of the FRY No. 5/92 No. 11/92). Also some other authors reported presents of sulfonamides residues in honey (Duarte, et al., 2020; Mahmoudi, et al., 2014; Reybroeck, 2003) The results obtained from study Mahmoudi et al., (2014) indicate the differences between autumn and summer honey samples on sulfonamides residues, where from 135 honey samples, 20 (14.8%) were positive on sulfonamides residue in samples from autumn season. As indicate before, presents of antibiotic/sulfonamides primary depends of beekeeper himself and implemented biosecurity measures in the apiary. Ours results are encouraging, since reduced sulfonamide values were detected, but even that it is desirable to every beekeeper have monitoring of antibiotic residues as regulars biosecurity plan (once on year) in all beekeeping products, such as wax, bee venom, pollen, and royal jelly. Since mostly of these products are used either as dietary supplements or as medicinal remedies, especially for infants.

Conclusions

Quality and health testing is expensive, often inaccessible to honey producers, and some types of testing need to be covered by regular annual monitoring planned and funded by the state. It is necessary to complete the legal regulations governing this area and the areas of the laboratory that meet the requirements in order to give full legitimacy to the tests and so that legal measures can be implemented. Testing the quality and health of honey and other bee products results primarily in protecting human health from unsafe products, and thus protecting producers and markets, stimulating producers to raise product quality and safety, which would make way for the EU "flower gold" of the region .This would prevent the placement of unhealthy and low-quality honey, both on the domestic and foreign markets, would help producers to gain confidence in the quality of honey. Presented results indicated, that RS is convenient to production of all honey bee products in a clean living environment.

Abstract

In four-year monitoring of two generations of honey bee colonies (queen bees and their offspring), the correlation coefficients between morphological traits for the amount of foraged pollen, traits on which the foraging activity of honey bees depends. Considering morphometric traits, the tongue length, the length and width of the wings and basitarses were measured. In field conditions, scouts and forager bees were counted, the total amount of foraged pollen and the amount of foraged alfalfa pollen were measured. It was found that there is a very strong correlation between the amount of foraged pollen and the observed traits that determine the foraging activity of the honey bee, as well as the size of the basitarus at a statistically very significant level ($p < 0.01$). There was a strong correlation between the traits that determine the foraging activity with each other ($p < 0.01$). The size of the basitarsus (length and width) was strongly correlated with most traits. The wing length was in medium correlation with most traits ($r = 0.3$-0.6), while the wing width with all traits was weakly or negatively correlated. The length of the proboscis was in the medium strong correlation with most of the observed traits. It is weakly correlated with the width of the basitarus and the wing, and weakly to negatively correlated with the wing length.

Keywords: *honey bee, correlation coefficients, pollen foraging, morphological traits, number of foragers.*

Introduction

In addition to the amount of nectar, the amount of pollen that the bee colony collects during the year is just as important for the normal nutrition of the honey bee colony. Bees get the energy component of their diet (sugars) from nectar, and the building component (proteins, fats, vitamins, amino acids, etc.) from pollen. Farrar (1936) also proved that the strength of the colony in the spring (the amount of bees that survive the winter) is positively correlated with the pollen stocks in the fall. In addition, colonies with larger pollen reserves grew faster in the spring and foraged more honey during the grazing period. The amount of pollen collected by the colony has a very wide range considering a variety of authors, from 5.56 kg, as reported by Synge (1946) and Keller *et al*., (2005) to 221.79 kg per colony as noted by Eckert (1942). The amount of pollen in a colony is influenced by a large number of factors that can be positively or negatively correlated. Keller *et al*., (2005) stated that the amount of foraged pollen per colony is influenced by 10 or more variables (e.g. strength of the colony, i.e. population size, abundance of brood,

surrounding honey plants, weather conditions, etc.). In colonies with higher abundance of brood, pollen stocks are reduced because they are intensively spent on brood nutrition. The size of the colony affects the pollen foraging because it was found that smaller colonies forage significantly more pollen. It was also determined that the number of pollen foragers increases if empty honeycomb is added between the frames with the brood. The amount of pollen in the colony increases in proportion to the increase in the amount of brood (Georgijev *et al*., 2003). In the research of Jevtić *et al*., (2005), the strength of the colony (quantity of bees and brood area) had a great influence on pollen foraging and consumption. A two-year study by Georgijev and Plavša (2005) proved that there is a positive correlation between the amount of bees and the amount of brood with the productivity of colonies (honey yield). Mladenović and Radoš (2010) determined the positive correlation between the strength of the colony and pollen stocks per colony. The highest degree of interaction was found between the amount of bees and the amount of pollen per colony ($r = 0.48$), while the lowest interaction was recorded between the amount of pollen and the amount of honey per colony ($r = 0.13$). Bilaš and Krivcov (1991) claimed that certain morphological traits (proboscis length) are positively correlated with the productivity of the colony. However, the same trait is negatively correlated with queen fertility and resistance of bees to nosemosis.
The aim of this study was to determine the correlation coefficients between the total amount of foraged pollen, the amount of foraged alfalfa pollen, the number of scouts and foragers and morphological traits that affect pollen foraging.

Material and methods

The experiment lasted four years, and two generations of honey bee colonies sampled from different regions of Serbia (Rasina, Peshter, Moravia, Banat, Timok and Kopaonik) were studied. All colonies were in standard LR hives. The queens in the first generation were from the original regions, and in the second generation they were produced in apiaries from their own localities, so that the best queens from each region were used for the mothers, and the fathers were mixed (free mating).
Morphological traits were determined using binocular microscope of the "Olympus" brand with a magnification of 25 times, with a measuring thread on the eyepiece with which body parts of bees were measured. During the spring inspection, 50 bees were taken from each company, which were suffocated, and then their body parts (head, wing and leg) were separated, placed on a glass slide and measured using binocular microscope.
The traits on which the amount of foraged pollen per colony depends (number of scouts and number of foragers) were determined at the time of alfalfa flowering. In the first year, the colonies were located on an alfalfa plot of 30 ha in the vicinity of Smederevska Palanka. In other years, the colonies were stationed at the alfalfa site in Dobričevo near Ćuprija (area of 20 ha). The following traits were monitored:
- Number of scouts per colony: the total number of honey bees flying out of one colony in 3 minutes was recorded. Counting was performed four times during the day, twice in the morning (at 9^{00} and 11^{00}) and twice in the afternoon (15^{00} and 17^{00}).
- Number of forager bees per colony: in all experimental colonies in the specified time period (3 minutes) and terms (before and after noon) the number of bees returning to the colony with a load of pollen was recorded.

- Quantity of foraged pollen per colony: in order to determine the amount of foraged pollen, as well as the types of plants from which pollen was collected, pollen catchers were set up in all colonies. Pollen was taken from the catchers a total of 5 times during the experiment, then dried, measured and analyzed to determine which plant species it came from.
- Quantity of alfalfa pollen per colony: after drying and sorting, the amount of alfalfa pollen per colony was determined by measurement. Correlation coefficients were calculated for all monitored traits using STATISTICS 10.0 program.

The following scale was used to assess the strength of the correlations.

0.00 - 0.30 - weak correlation
0.31 - 0.60 - medium strong correlation
0.61 - 0.90 - strong correlation

Results and discussion

During the observation, the colonies foraged an average of 79.19 ± 20.8 g of pollen per measurement, a maximum of 108.63 g and a minimum of 55.25 g (Table 1).

Table 1. Statistical indicators for the amount of foraged pollen, number of collectors and morphological characteristics

Traits	Pollen total (g)	Pollen alfalfa (g)	No. of scouts before noon	No. of scouts after noon	No. of scouts before noon	No. of scouts after noon	Basitarsus length (mm)	Basitarsus with (mm)	Wing length (mm)	Wing width (mm)	Proboscis length (mm)
Average	79,19	18,69	275,13	251,56	86,68	42,26	2,07	1,10	9,61	3,21	6,41

Cv	0.26	0.46	0.16	0.15	0.22	0.24	0.03	0.04	0.02	0.04	0.04
N	18	18	18	18	18	18	18	18	18	18	18
Std.Err.	4.90	2.01	10.13	9.08	4.56	2.42	0.02	0.01	0.05	0.03	0.06
t-value	16.15	9.28	27.16	27.71	19.00	17.46	124.68	101.72	200.48	111.46	110.42

The total amount of foraged pollen was significantly correlated with most of the observed traits (Table 2). It had particularly high correlation coefficients with the amount of foraged alfalfa pollen (r = 0.96) and with the amount of foragers in the morning (r = 0.92). In addition to the above traits, the amount of foraged pollen was in strong correlations with the number of scouts, the number of pollen grains and the size of the basitarzus (length and width). The obtained results for these traits were statistically very significant (p <0.01). This trait was in a medium strong correlation with wing length and proboscis length. Wing width did not have a significant effect on pollen foraging, so the correlation coefficient was extremely low (r = 0.04). Lebedev (2001) reports that pollen intake is highly correlated (r = 0.82) with the strength of the colony and the abundance of brood per colony. Georgijev *et al*. (2003) found that the correlation coefficient between the amount of brood and the amount of pollen foraged in the spring is extremely high r = 0.93, while in the fall it is significantly lower r = 0.16. Jevtić *et al*., (2009) found that the amount of pollen at the spring inspection was negatively correlated with the amount of honey at the spring and autumn inspection (r = -0.30 and r = -0.23). Analyzing the studies of a large number of authors, Keller *et al*., (2005) found that all but one source (Mc Lellan, 1978) agree that there is a positive correlation between pollen stocks and brood surface in bee colonies. Wille *et al*., (1985) found that there is a negative correlation (r = -0.283) between annual pollen intake and worker bees lifespan. This negative correlation changes to positive but weak (r = 0.145) when pollen intake per bee is taken into account. In strong colonies, pollen foraging does not negatively affect the lifespan of worker bees.

Table 2. Correlation between the amount of foraged pollen, the number of foragers and morphological traits of honey bee colonies from six regions in Serbia

Trait	Pollen alfalfa	Scouts b.n.	Scouts a.n	Foragers b. n.	Foragers a. n.	Basitarsus length	Basitarsus width	Wing width	Wing length	Proboscis length

The amount of foraged alfalfa pollen averaged at 18.69 ± 8.55 g per measurement and ranged from 8.98 g to 28.45 g. This trait has a high coefficient of correlation with the number of scouts and the number of foragers (before and after noon) and the size of the basitarzus. Such high coefficients are quite understandable, bearing in mind that the monitoring of the amount of foraged pollen was performed at the time of alfalfa flowering. In addition, the activity of the honey bees in foraging pollen in this period (July) is significantly higher in the morning compared to the afternoon. It is important to point out that there is a medium strong (almost strong) degree of correlation (r = 0.54) between the length of the proboscis and the amount of foraged alfalfa pollen. This leads us to the conclusion that colonies that forage a larger amount of alfalfa pollen have a longer proboscis. It is known that alfalfa has a special mechanism of flower opening that is not adapted to the pllination by honey bees, so they usually avoid collecting pollen on this species. Considering the high degree of correlation with the size of basitarzus, we can conclude that colonies that have a longer proboscis and larger basitarzus forage more alfalfa pollen and thus better pollinate this important field crop. The traits on which the foraging activity of the honey bees depends (the number of scouts and foragers) were strongly correlated with each other. During the experiment, an average of 275.13 ± 42.98 bees were counted per colony in the morning count, and 251.56 ± 38.51 in the afternoon. More pollen was counted in the morning (86.68 ± 19.35) compared to the afternoon count (42.26 ± 10.27). The number of scouts in the morning had the highest correlation with the number of scouts in the afternoon (r = 0.91). Considering other traits, the correlation coefficients ranged from r = 0.66 to r = 0.80 (Table 2).

There are several studies that have observed the relationship between pollen stock and colony size (number of worker bees). Mc Lellan (1978) found no significant correlations between the number of bees and the amount of pollen retained in the catchers on any of the six days studied. Similarly, Wille (1981) found that pollen stock and colony strength do not change synchronously during the season (they are not correlated). Dreller *et al*., (1999) found that the number of pollen

foragers decrease in colonie with more capped brood compared to those with more open brood. Schmickl and Crailsheim (2004) found that the number of pollen foragers increases significantly if an empty honeycomb frame is placed between the frames with brood, i.e. if the empty space increases. The morphological traits obtained by measuring 50 bees per each colony had the following values: proboscis length 6.41 ± 0.25 mm, wing length 9.61 ± 0.20 mm, wing width 3.21 ± 0.12 mm, basitarsus length 2.07 ± 0.07 mm and basitarsus width 1.10 ± 0.05 mm.
The length and width of the basitarzus were strongly correlated with each other (r = 0.73), which was not the case for the length and width of the forewing, which were negatively correlated (r = -0.35). Negative but very low correlation (r = -0.15) was noted beween proboscis length and wing length so it can be concluded that colonies with a longer proboscis value have slightly shorter wings. It is interesting to note that the wing width has almost no correlation with both pollen foraging in general and the amount of foraged alfalfa pollen (Table 2).
In the research of Jevtić *et al*., (2011), most morphological traits showed moderately strong and strong correlation both with each other and with the productivity of colonies. Milne et al., (1986) measured 387 bee samples and determined that the size of the tibia is 1.54 - 2.28 mm^2. The same authors found that there is a high correlation between the size of the corbicula and the amount of foraged pollen. The honey bee lines that foraged the largest amount of pollen had the largest corbicula. Souza *et al*., (2002) found that there is a correlation between morphological traits and productivity of honey bee colonies. The highest degree of correlation with productivity was in the size of the corbicula (r = 0.58). In this study, all morphological traits were mutually in a mildly strong and strong correlation relationship. Zarate *et al*., (2008) found in an Africanized bee in Mexico that there is a high correlation between colony productivity and weight gain per society, size (volume) of honeycomb, foraging activity, and syrup intake rate. They also found a very low correlation coefficient between the productivity of the colony and the life expectancy of worker bees.

Conclusion

After four years of monitoring of honey bee colonies, it was determined that the amount of foraged pollen per colony is strongly influenced by the number of scouts and foragers(strong correlation r <0.61), the size of the basitarus (length and width) and the time when pollen was foraged. The traits on which the foraging activity of the honey bee depends (the number of scouts and foragers) are in strong correlations with each other, with the total amount of foraged pollen and the amount of foraged alfalfa pollen. The length of the proboscis and the length of the wing are in a medium strong correlation with the pollen foraging, both with the total amount and with the amount of alfalfa pollen. Wing width was very weakly correlated with the observed features, and it was also negatively correlated with wing length (r = -0.35).

Abstract

The Republic of Serbia has a long tradition in the pig production. Serbia is one of the few countries in the region with the notable pig production without the implemented system for categorization of carcasses based on the lean meat content. Some of the ex-Yugoslavian countries started with the implementation of this system in the late 1990-s while the challenges of implementation of carcass classification is still in front of Serbia. The purpose of every pig breeding program is in the function on the increase in animal performance to obtain as many as possible of fattening pigs in as short as possible period with the good characteristics of the carcasses. There is a characteristic situation in Serbia. There are two types of producers: 1) large scale farms with the huge production of fattening pigs per year and 2) relatively important number of small, family orientated farms with small capacity, especially in Vojvodina, the north part of Serbia. However, meat processing industry is very concentrated and five meat processing plants take about 80% of the all market. Producers who invested in the breeding program are not rewarded and do not have stimulation for the further improvement. Moreover, some meat processing plants started to implement the carcass classification system. However, it put the producers even in more depending position toward the meat industry. There is a need for the introduction of carcass classification system by the independent body in the Republic of Serbia.

Key words: *pig production, carcass classification system.*

Introduction

Pig production has long tradition in Serbia. The annual production is about 300 thousand of tones (Statistical Office of the Republic of Serbia, 2018). In comparison of the pig production with the neighboring countries, Serbia is still at the first place. In Croatia, for example, annual production is about 100 thousand of tones (Kralik et al., 2017). The producers in the pig sector roughly can be divided in two groups: huge number of small producers with small number of animals per farm, and about 400 commercial farms with huge number of animals per farms (Lierop et al., 2015). The economic power of small producers is modest as the use of the new technology and breeding programs. On the other side the meat processing industry is very concentrated; five companies take up to 80% of the market. They have huge economic power. The small producers have small accumulation of capital, the extreme climate condition as the drought or the excessive rain affects more this producers. More over for the small producers is more difficult to get bank loan necessary for improvement in equipment, breeding program.
One of the characteristics of pork market is cyclicality in the production volumes and prices (Jeremić et al., 2018). The characteristic of the cyclicality is imbalance of production and

demand which usually resulting in the price drop. It is easy to assume that small scale producers are more burdened by this cyclicality. The quality of meat carcass is very important trait for the producers and end consumers. Some European countries started developing the model to assess the quality in the early sixties (Petrovic et al., 2009). The early standard SEUROP was developed and started to be use in 1989. In Serbia the legislation regarding pork carcasses, still partially in use, is from 1985. The legislation has lot shortcomings, due to the fact that is outdated.

The purpose of every breeding program is to improve the growth and carcass traits of pigs. Heritability (h2) is a measure of the variation of some investigated trait in the population due to the genetics. Heritability for the quality of carcass is medium to high (Radovic et al. 2013). That means that that this trait can relatively be easy improved in population. Serbia, especially north part of Serbia, has good condition for the intensive farming, a lot of very fertile land good for crop production. Moreover Serbia is one of the main exporters of corn in the region.

Results and Discussion

The data from the Republic of Serbia indicates the huge possibilities for the improvement in the pig sector. Pig production has a good possibility for the further development and increase of the production. However, at the moment producers are not stimulated to produce the pig carcasses with the better carcass traits, all carcasses regardless of the quality are paid the same. The producers are not stimulated to produce pig's carcasses with the better quality and to invest in breeding program. All fattening pigs are paid on the base of the live weight regardless of carcass quality. The SEUROP system of classification in EU has been existed already for several decades. It was developed from the need to harmonize the system of carcass classification and that this system to be a base for a price for fattening pigs. By this system it is possible to compare the price of fattening pigs in the different countries EU members.

Almost all neighboring countries of Serbia started to use the SEUROP system of classification for pig carcasses. The system gives good results in the increase of quality of carcass traits and lean meat content. First ex Yugoslavian country which started with this system was Slovenia in 1996, before that in the use was the legislation from 1985 which is still in the use in Serbia. As the results of the use the SEUROP system in Slovenia in the period of eight years (1996-2004) the average lean meat content in the carcasses was increased from 51.9 to 55.9% in 2004. As the result of this the percent of the carcasses of S and E class has been almost tripled (from 21.3 to 58.2%) during this period (Čandek-Potokar et al., 2005). The Bulgaria started to use the SEUROP system of classification in 2005. It resulted in the significant increase of the carcasses in the S class and decrease of those in E and U class during the years of observation (Nakev et al. 2019). The similar situation was in Romania, the implementation of SEUROP standard generated the increase in lean meat content and carcass quality (Balan et al. 2010)

There is really not a lot of data regarding carcass classification and lean meat content of pigs slaughtered in Serbia. One of the reasons is that in the last 20 years lean meat content was not measured on the slaughter line in Serbia (Dokmanović et al. 2013). Occasionally, some data can be found as a part of the study regarding measuring lean meat content in the pigs carcasses, however the results are not very encouraging (Dokmanović et al. 2013; Vasilev et al., 2009; Kosovac et al., 2009). During 2018 the study was done regarding the average lean meat content in the carcasses of pigs in the eight slaughterhouses in the region of Vojvodina, Serbia. Lean meat content was measured in 65764 of carcasses. The majority of carcasses were in E and U class (from 50-60% of lean meat content). However only 3.15% of carcasses were in the S superior class with more than 60% of lean meat (Radović et al. 2021). In Slovenia, as a consequence of carcasses being graded, the carcasses in the classes E and S were almost tripled in the period from 1996-2004 (Čandek-Potokar et al., 2005) The experience from the neighboring countries which implemented SEUROP system is a very encouraging. Investment in better breeding program and nutrition gives good results in pig production and enhance competitiveness of this production. The positive effect of implementation of SEUROP classification will be visible and will have good effect on the basic pig production as soon as system starts to be implemented. Previously there were some attempts in this direction, however it was never brought to the end. The most expenses in the live pig production go to animal nutrition about 70-80%. The protein deposition necessary for the lean growth is energy more efficient that the fat growth expressed in the needed metabolic energy. Fat deposition requires about 16% more energy per unit of gain. However the water deposition is big part of lean meat gain which increases advantages of lean: fat growth to the 4:1 ratio (Patience et al., 2015). Profitability of production is on the thin line between the price of the fattening pigs and the expenses needed for the production. For one kilogram of meat it is needed 1.25 kg of feed, while for one kilogram of fat it is needed 4kg of feed Ministry of Agriculture, Food and Rural Affairs). The lean meat growth is much more efficient than the fat. It is very clear that production of pigs with the higher lean meat content is economically more purposeful. The average annual production is about 300 thousand of tons. Average weight of fattening pigs is about 100kg that means 3 millions of pigs. The estimated carcass yield of pigs is about 75% which means 225.000t of carcasses. Average lean meat content of pig carcasses in Serbia is 54%. Hence the annual production of lean meat is about 121.500 t. With the increases of lean meat content in only 1% the meat production can be increase for about 3 thousand of tones with the same production. Meat is more expensive and production costs are less, while fat is less expensive and production costs are much higher. Therefore, producers and meat industry will easily recognize the need to put more effort to improve selection work needed to increase lean meat content.

Conclusion

Serbia is one of the rare countries in Europe without SEUROP system of classification with relatively developed pig production. The data from the Republic of Serbia indicates the huge possibilities for the improvement in the pig sector. Pig production has good possibilities for the further development and increase of the production. However, at the moment producers are not stimulated to produce the pig carcasses with the better carcass traits because all the produced carcasses regardless of the quality are paid the same. It is needed to make system which will be adequate in the present condition in Serbia. On one side we have very dichotomous group of producers who are too much burdened with the fluctuation on the market. On the other side there is Serbian meat industry, which is very concentrated, about 80% of this industry is owned by only five companies. Their interest is only profit regardless of pig production. So it is not so rare import of pig meat or pig meat products. Serbia is a huge exporter of corn. It would be much better and economically justified to incorporate that corn in animal production and then export the animal products as meat and meat products.

INFLUENCE OF REARING SYSTEM ON THE CARCASS TRAITS AND CARCASS CONFORMATION OF FATTENING CHICKENS

Lidija PERIĆ*, Mirjana ĐUKIĆ STOJČIĆ, Sava SPIRIDONOVIĆ

University of Novi Sad, Faculty of Agriculture, Department of Animal Science, Novi Sad, Serbia

Abstract

The aim of the research is to determine the slaughter characteristics and carcass conformation of chickens reared in the conventional production system or in organic production. Random samples of 6 carcasses from each production system were taken for the determination of basic slaughter traits: carcass weight, yield and percentage of individual carcass parts and weight and share of abdominal fat. The following characteristics of carcass conformation were measured: abdominal wall thickness, breast depth, keel length, breast angle, breast girth and drumstick girth. Also, pH values of breast and drumstick meat were determined. The collected data were analyzed by ANOVA, using Fisher LSD post hoc test, in the program Statistica, TIBCO, version 14. The results showed that the system of meat production had a significant effect on most of the examined parameters. Chickens raised in conventional system had significantly higher carcass weight and consequently higher weight of the all carcass parts. The share of breast was higher in birds from conventional system, while the share of the wings, thighs and back was higher in organic chickens. The content of abdominal fat was significantly higher in organic chickens. Regarding the carcass conformation organic chickens had significantly lower values compared to conventional ones for all examined traits. The results confirmed that there is a significant difference in carcass quality and yiled of different carcass parts between organic and conventional chickens which could have a strong influence on consumers preferences.

Key words: *Chickens, Carcass, conformation, Organic production.*

Introduction

Consumer interest in organic products is constantly growing in recent decades (Castellini *et al.*, 2008). They are especially interested in chicken meat from the organic system because the intensive poultra meat production has led to the deterioration of poultry welfare and meat quality (Mikulski *et al.,* 2011; Perić *et al.*, 2018). Many consumers assume that the meat of free-range chickens is tastier and healthier than that of birds kept in a poultry house (Fanatico *et al.*, 2007; Li *et al.*, 2017). Also, the meat yield and the carcass conformation are different in chickens from organic production compared to broiler chickens raised in intensive systems (Perić *et al.*, 2016). Conformation means the general structure and appearance of the animal, with the focus on development of certain parts of the body. From the point of view of the slaughter industry and consumer interests, it is very important that chickens have good meat yields, desirable conformation, optimal fat distribution and appropriate skin color (Bogosavljević-Bošković *et al.*, 2006).

In Serbia, organic production is still at the beginning, although the demand for organic products is growing (Rodić *et al.*, 2006). Bogosavljević-Bošković *et al.* (2011) pointed out that reasons for

the development of extensive systems in poultry production are to improve rearing conditions, reduce environmental pollution and enhance meat quality.
The key factor which affects the production and slaughter traits of broilers is the genotype (Berri *et al., 2005*). According to Castellini *et al.* (2008) and Araújo (2011) meat quality is the result of the interactive effects of many factors like the strain of birds (fast- or slow- growing), stocking density, age of the birds, access to pasture, environmental temperature, physical activity and feed. All these factors significantly differ in intensive broiler production compared to alternative systems.
The aim of this work was to determine and to compare the slaughter characteristics of chickens raised in two different production systems: conventional and organic system.

Materials and methods

Research has been conducted at the University of Novi Sad, Faculty of Agriculture. Chickens were smpled from commercial farms. Organic chickens were raised on the certified organic farm in Vojvodina. Birds of slow growing strain Red Ranger were used for fattening which lasted for 81 days. Birds were housed and managed according to the principles of organic production. Birds were fed with four different mixtures which were based on organically grown triticale (70% of the diet), corn and pasture.
The second group of birds was raised on the conventional farm for 6 weeks. ROSS 308 broilers were raised inside the barn, on a deep litter, with stocking density of 17 birds/m^2. They were fed with standard mixtures (starter, grower and finisher) and the feed was provided *ad libitum*.
At the end of the fattening periods, random samples of 6 carcasses from each production system were taken for analyses. Analyses had been done at the Laboratory of chicken meat and egg quality, Department of Animal Science, Faculty of Agriculture, Novi Sad. The dressed cold carcasses were dissected into primal cuts (breast, drumstick, thigh, wing and back) following the method established by the Regulation on Poultry Meat Quality (Rašeta and Dakić,1984). Carcass conformation was measured by calliper and tape measure. Breast angle was measured with special device created for that purpose. The pH value was determined using a pH meter device (TESTO 205) with a glass electrode (Mettler Toledo, Greifensee, Switzerland) for direct determination of the pH value in meat. The pH meter was calibrated with standard phosphate buffers (calibration buffer pH was 7.02 and 4.00 at 20^0 C) and adjusted to the measured muscle temperature.
Statistical analyses were done in program STATISTICA 14 (TIBCO, 2020). All data were analyzed by ANOVA and significant differences among treatments were determined using Fisher LSD post hoc test. Significance levels were set at $p < 0.05$ and $p<0.01$

Results and discussion

Rearing systems had a significant effect on weight and share of carcass cuts (Table 1). Birds from conventional systems had significantly higher weight of whole carcass and breast ($P<0.01$) compared to organic chickens. The weight of drumstick, thigh and back was also higher in conventional birds, but the differences were not statistically significant ($P>0.05$). Only weights of wings were slightly higher in organic birds.

Table 1. Effect of production system on weight and proportion of carcass cuts (mean ±SD)

Carcass parts	Weight of the carcass parts,g		Share of the carcass parts,%	
	Conventional	Organic	Conventional	Organic
Whole carcass	2179 ± 140.6^{A}	1696 ± 275.2^{B}	100.00	100.00
Wings	217.33 ± 11.99	219.17 ± 53.19	9.98 ± 0.42^{B}	12.80 ± 1.10^{A}
Drumsticks	307.17 ± 29.52	267.51 ± 74.04	14.09 ± 0.92	15.57 ± 1.55
Thighs	310.67 ± 51.59	271.67 ± 31.39	14.22 ± 1.78^{b}	16.11 ± 0.96^{a}
Breast	851.00 ± 67.62^{A}	468.83 ± 67.72^{B}	39.06 ± 1.94^{A}	27.75 ± 1.63^{B}

$^{A\text{-}B}$ Values in the same raw with different superscripts are significantly different (P<0.01)
$^{a\text{-}b}$ Values in the same raw with different superscripts are significantly different (P<0.05)

Reagrding the share of carcass parts it can be seen that organic birds had higher share of wings, drumstick, thighs and backs, while the conventional birds had significantly higher share of breast in the carcass. Similar results were reported by Grashorn and Serini (2006) and Perić *et al*. (2016) who stated that broiler chickens have a genetic predisposition for high breast meat yield compared to pure or slow growing breeds. Comert *et al.* (2016) suggested that for the yield and share of carcass parts the genetic strain might be more significant than system of rearing.
It is interesting that weight and share of abdominal fat pad was significantly higher in organic birds which indicate that organic birds had higher content of fat in the body. On the contrary, Perić *et al.* (2016) found lower content of abdominal fat in organic chickens compared to conventional ones. Castellini *et al.* (2002) reported significantly higher content of abdominal fat in birds with 81 days of age compared to the birds raised for 51 days. It seems that age of the birds has a significant influence on the content of the abdominal fat. Blagojević *et al.* (2011) reported a higher yield of abdominal fat in fast growing chickens compared to slow growing strains but both strains were raised for 81 days.
The measured parameters clearly showed a highly significant difference (P<0.01) in carcass conformation between chickens from organic and conventional production (Table 2). It can be noticed that all measured parameters are higher in conventional chickens, which is mainly a consequence of the genotype. Fast-growing hybrids have been selected for higher meat yield, which means that they have greater widths, depths and girths of those parts of the body where the highest quality portions of meat are located. This is confirmed by the size of the breast angle, which is significantly higher in broiler chickens, which indicates better breast development and higher white meat yield.

Table 2. Effect of production system on carcass conformation (mean ±SD)

Parameters	Conventional production	Organic production
Carcass weight, g	2179 ± 0.16^{A}	1696 ± 0.27^{B}
Abdominal wall depth, cm	0.9 ± 0.12^{B}	1.17 ± 0.12^{A}
Breast depth, cm	14.67 ± 0.81^{A}	10.83 ± 0.75^{B}
Drumstick girth, cm	18.25 ± 0.82^{A}	15.17 ± 1.08^{B}
Breast girth, cm	37.92 ± 1.06^{A}	31.75 ± 2.11^{B}
Keel length, cm	17.5 ± 0.83^{A}	11.25 ± 0.75^{B}
Breast angle, ^{o}	145 ± 10.48^{A}	101 ± 8.75^{B}

$^{A-B}$ Values in the same raw with different superscripts are significantly different (P<0.01)

The only parameter that was higher in organic chickens was the thickness of the abdominal wall, which is primarily a consequence of the older age of the chickens. Hopić *et al.* (2000) and Pavlovski *et al.* (2007) established that main factors which affect the carcass conformation are genotype and sex of the birds. Blagojević (2011), reported significantly better conformation measures with better development of breasts in Hubbard Classic genotype compared to slow growing strains (Master Gris and Farm Q). Results published by Strugar (2018) who found better conformation of the birds of hybrid ROSS 308 compared to pure breed White Rock, confirmed highly significant effect of genotype on the measures of carcass conformation.
The pH value is a reliable parameter to obtain information about the meat quality. The pH value of muscle tissue is related to the biochemical state of the muscles at the time of slaughter. It directly or indirectly affects other properties of meat such as: ability to bind water, color, softness, taste, durability and more. (Vučić G., 2014). In our research, there were no significant differences in pH value of meat neither in thigh nor in breast meat (Table 3).

Table 3. pH value of drumstick and breast meat

Type of meat	Conventional production	Organic production
Thigh	6.13 ± 0.13	6.27 ± 0.12
Breast	5.84 ± 0.10	5.97 ± 0.15

It is considered that the pH value of chicken breasts ranges from 5.8 to 6.3 for normal meat quality (Ristić and Damme, 2013) which is in line with our research. Castellini *et al.* (2002) reported that pH of breast meat in organic chickens ranged from 5.75 to 5.80.

Conclusions

From the results of this work it can be concluded that the production system had a significant effect on carcass characteristics of chickens. Chickens raised in conventional system had significantly higher carcass weight and consequently higher weight all of the carcass parts. The share of breast was higher in birds from conventional system, while the share of wings, thigh and back was higher in organic chickens. The content of abdominal fat was significantly higher in organic chickens. Regarding the carcass conformation organic chickens had significantly lower values compared to conventional ones for all examined traits. The results confirmed that there is a significant difference in carcass quality between organic and conventional chickens which could have a strong influence on consumers preferences.

Abstract

The authors present the specifics of organic production and its impact on the environment when it comes to poultry production - geese. Geese are characterized by modesty in terms of breeding conditions and they are a type of poultry that enters breeding relatively late, characterized by modest egg production during the season, while the results suggest a general conclusion that the age of geese has a significant impact on egg fertilization and laying goose, as well as the mass of eggs, and thus the final product. Having in mind the characteristics of geese that significantly distinguish them from other poultry, it is important to point out the minimized negative impact on the environment of this type of production, which was carried out according to the standards of the Common Agricultural Policy of the EU. Organic production provides high value products certified as organic food, which increases the price of a unit product, reduces consumer health risks and enables the entrance on the global market.

Key words: e*nvironmental protection, European Union, Geese production, Organic production, Poultry production.*

Introduction

The methods of organic agriculture are ecological forms of production which enable the protection of agro-ecosystems if biological and ecological findings about the environment are added to the existing knowledge of agronomy. This type of production is based on the principles of agroecology and has been applied in the European Union (EU) member states since 1991 (Regulation (EEC) 2092/91), whereas today it is a key objective of the Common Agricultural Policy (1992) of the EU whose main goal is the preservation and protection of the environment and rural areas (Regulation (EU) 2020). It is precisely for this reason that organic production is a controlled way of producing 'from field to table', which prevents a potential harm on the ecosystem and, consequently, human health.

In order to achieve these goals, the EU through positive regulations requires agricultural producers to take care of the effects of their agricultural activities and their impact on the environment. In this way, the environmental protection unites not only producers with consumers, but policy creators, too (Kaljević Zimonja et al., 2012).

Food and Agricultural Organization (FAO, 1961) defines organic agriculture as a process of sustainable development of rural areas in accordance with available resources, tradition and biodegradable potential of habitats, which comprises finalized crop and livestock production, the preservation and renovation of natural resources and return to the traditional values and knowledge. Organic agriculture can be best understood as an attempt to identify methods for production of organic food with the minimization of negative effects of intensive agriculture on the environment. Finally, organic agricultural production is a completely controlled production cycle, according to the binding provisions of the International Federation of Organic Agricultural Movements (IFOAM, 2016).

The problem that organic production faces is the impossibility of functioning in more developed countries in which contemporary agriculture with its aggressive application of all disposable chemicals has caused the deterioration of water, air and soil quality. Organic products make only about 1% of the total world food market today, although there is a quite high global demand for them (Vehapi, 2019).

Our country fulfills almost all conditions required for the organized development of certified organic food of high quality which meets the needs of consumers and increased export and, in accordance with this, the making of profit that does not harm the environment.

Finally, contemporary scientific findings and technological achievements, with an undeniable legal support, make the implementation of organic production in all forms of agriculture possible. It should not be forgotten that one of the crucial characteristics of organic production is the principle of unity of crop and livestock production (Written Questions E-0079/99 and E-0197/99). The general principle in organic livestock production is the emphasis on selecting animal breeds according to their adaptability to local conditions, their vitality and resistance to diseases; organic livestock production needs species and breeds resistant to contagious diseases and not susceptible to health problems. The advantage should be given to the autochthonous species and breeds (Hirstov i Relić, 2005).

This paper shows the results of organic production of goose, meat and eggs, in adequate ecological conditions, since geese are mostly bred in semi-extensive conditions in our country (Republic of Serbia) and in the region. More specifically, the contemporary tendencies of developing self-sustainable agriculture and self-sustainable poultry breeding, especially within the framework of producing natural ecologically-friendly food, reaffirm using the diverse breeds of poultry, primarily geese, and ducks (Mitrovic and Djekic, 2013). Geese typically require modest breeding conditions, especially regarding food and housing. Modern goose farms are rare not only in our country and region, but in the whole world (Milošević and Perić, 2011).

Material and methods

The experimental part of research has been done in the private farm 'Anser' (Triješnica, Bijeljina, Republic of Srpska, Bosna and Herzegovina). where the breeder flock of Italian white goose is bred in a semi-intensive keeping system. The farm produces eggs for setting and one-day old goslings. The farm has an adequate number of adapted facilities in which geese dwell during night and poor weather conditions. Geese spend the rest of the time in a free space – pasture which is abudnant in this farm. As a result, they mostly only need a modest additional meal (grain seeds). It is desirable to keep geese in the fields after the harvest of cereals and legumes, feed them with kale, carrots, turnip heads or whole turnip split into halves, fresh turnip porridge and boiled potatoes, because the digestive tract of geese is capable of digesting cellulose from most nutrients. For this reason, in summer geese can graze and additionally have a slight meal, whereas in winter this is not possible (Labatut, 2002).

Italian white goose is both an egg-laying and lean goose of an extraordinary quality. Rosiński (2000) points out that Italian white goose is a good egg-layer (more than 65 eggs), that fertilization of eggs is around 81.4% and hatchability of goslings out of the total number of fertilized eggs is around 80.8% and that the quality of meat is good.

A random sampling method was used during the season of laying: 1200 breeding eggs were incubated successively from February to July (6 times – each month) in four production cycles i.e. during four years (2014 – 2017). During the season of egg production (February- July) for each production cycle 50 eggs were incubated each month (50 eggs x 6 months = 300 eggs) and during the four year long period of using the breeder flock of geese the total of 1200 breeding eggs were incubated (300 eggs x 4 production cycles = 1200 eggs).

During the incubation periods, the nubmer and percent of fertilized eggs (fertilization value) were determined as well as the number and percent of hatched goslings out of incubated and fertilized eggs. Automatically, the number and percent of unfertilized eggs were determined as well as the number and percent of fertilized eggs with dead embryos.

Before being placed into the incubator, eggs were individually measured (their weight, width and length), their shells were marked with a grafite pencil and disinfected. All eggs (fertilized, unfertilized, eggs with dead embryos) were individually measured on the 25^{th} day of incubation.

The elementary data processing was done by applying standard varioational statistical methods (descriptive statistics). For the majority of characteristics of incubated eggs, or hatched goslings, the following parameters were calculated: the arithmetic mean (x), the standard deviation of the arithmetic mean ($S\bar{x}$), the standard deviation (S) and coefficient of variation (C.V.).

Results and discussion

It should not be forgotten that geese and ducks have significantly lower reproductive potential in comparison to hens, since the production of eggs is seasonal. For this reason, a significantly lower number of eggs is produced during a production cycle, with embryo mortality during egg incubation being siginificantly higher than in hens (Rosiński and Bednarczyk, 1997).

Similarly to the situation in the majority of the EU member states, domestic autochtonous breeds such as the Sombor Kaporka (Sombor crested), the black Svrljig Hen, the Naked Neck and the Banat Naked Neck are bred in the Republic of Serbia in solid nubmers in rural farms in semi-extensive or extensive systems and also in a certain way in the production of organic eggs and even meat. The foreign pure breeds bred in Serbia are the New Hampshire, Neked Neck, White Leghorn and Rode Island Red.

Based on conducted experiments and obtained results, Mitrović et al. (2014) gave a detailed review of the comparative study of production and reproduction characteristics of two breeds (the New Hempshire and Sombor Kaporka) , two breeds of hens widely bred in the Republic of Serbia. Both breeds are bred in the semi-extensive system of keeping. The authors examined the intensity of laying capacity (egg production) in a certain time period (60 days), egg mass, external indicators of egg quality (length, width and the egg shape index), the mass of chicken hatched in a natural traditional way and a relative proportion of chicken in the egg mass. On top of that, they determined the coefficient of phenotype correlation and the strength of the relationship between the majority of measured indicators. On the basis of obtained and displayed results, the authors argue that breeds the New Hampshire and the Sombor Kaporka showed satisfactory production and reproduction characteristics in the semi-extensive system of breeding and that both breeds can be successfully used in the organic poultry production. In addition, the authors emphasize that the natural way of lying (under the brood hen) in comparison to the artificial incubation of eggs give better incubation results, and especially the percentage of hatchability from fertilized eggs and relative share of chicken in the egg mass.

Đermanović et al. (2013), Đermanović and Mitrović (2013) determined phenotype variability of external indicators of the quality of breeding stock eggs (egg mass, length, width and egg shape index) of the Partridge-Coloured Italian and Leghorn breed raised in the semi-intensive system. The eggs of the Partridge-Coloured Italian compared to the eggs of the Leghorn had greater mass (62.25 g - 61.01 g), greater length (55.72 mm - 55.19 mm), whereas the egg shape index was insignificantly higher in the Leghorn eggs (76.08% - 75.65%), but the differences were not statistically confirmed (P>0,05).

Similarly to the egg production, a great number of domestic and foreign authors in different time period examined the possibility of using pure, autochthonous breeds and their hybrids (slow-growing and fast-growing) bred in different systems of keeping in the production of organic meat, and all this respecting the binding provisions of the EU legislation that regulates organic poultry production.

When incubational values of eggs for setting are mentioned, people usually think of the percent of fertilized, and the percent of hatched goslings, out of the total nubmer of incubated and fertilized eggs, dynamics of embryo growth (the loss of egg mass during the embryo development), egg characteristics and hatched goslings, as well as their mutual connections. In order to show results in a clearer way, all the mentioned indicators will be presented separately, although it should be taken into account that all these characteristics are more or less interrelated – they condition each other.

During the four production cycles, the total of 1200 eggs were incubated, out of which 1066 were fertilized, i.e. 88.83% (Table 1). The greatest fertilization of eggs was realized in the second year (272 eggs – 90.67%), and the least in the fourth year (262 eggs – 87.33%), although the egg fertilization was on a satisfactory level each year.

Table 1. – Fertilization and hatchability of goose eggs for four production cycles (1 - 4 years of age of geese; I, I I, I I I, IV) and by phases (months) of the production cycle (February – July; F - J)

Indicators/years	**I**	**II**	**III**	**IV**	**F**	**M**	**A**	**M**	**J**	**J**	Total
No. of eggs incubated	300	300	300	300	200	200	200	200	200	200	1200
Fertilized eggs % of fertilized eggs	268 89.33	272 90.67	264 88.00	262 87.33	181 90.50	187 93.50	179 89.50	176 88.00	174 87.00	169 84.50	1.066 88.83
Unfertilised eggs % of unfertilised eggs	32 10.67	28 9.33	36 12.00	38 12.67	19 9.50	13 6.50	21 10.50	24 12.00	26 13.00	31 15.50	134 11.17
Eggs with dead embryos (A) % of eggs with dead embryos	32 10.67	36 12.00	27 9.00	28 9.33	23 11.50	18 9.00	19 9.50	19 9.50	22 11.00	22 11.00	123 10.25

Eggs with dead embryos (B) % of eggs with dead embryos	32 11.94	36 13.23	27 10.23	28 10.69	23 12.71	18 9.63	19 10.61	19 10.80	22 12.64	22 13.02	123 11.54
Goosling hatched (A) % of goosling hatched	236 78.67	236 78.67	237 79.00	234 78.00	158 79.00	169 84.50	160 80.00	157 78.50	152 76.00	147 73.50	943 78.58
Goosling hatched (A) % of goosling hatched	236 88.06	236 86.76	237 89.77	234 89.31	158 87.29	169 90.37	160 89.39	157 89.20	152 87.36	147 86.98	943 88.46

(A) – of incubated eggs; (B) – of fertilized eggs.

The hatchability of goose eggs, observed by production cycles, was also on a satisfactory level, the hatchability out of the nubmer of incubated eggs being the highest in the third year (79.00%), and out of the nubmer of fertilized eggs in the second year of the production cycle (86.76%). For the total of four production cycles, the hatchability out of the number of incubated eggs was 78.58%, and out of fertililzed eggs was 88.46% (Table 1).

For the whole analyzed period, it is noticeable that the phase (month) during the season had impact on the observed indicators (Table 1). The best fertilization was achieved in March (187 eggs - 93.5%), and the poorest in July (169 eggs – 84.5%). The hatchability of goslings out of incubated eggs was between 84.5% (March) and 73.5% (July), and out of fertilized eggs between 90.37% (March) and 86.98% (July).

The results presented in the table show that the total fertilization of eggs was on average 88.83% (11.17% of unfertilized eggs), 10.25% of eggs with dead embryo out of the total number of incubated eggs, i.e. 11.54% out of the number of fertilized eggs, 78.58% of hatched goslings out of the nubmer of incubated eggs and 88.46% out of the number of fertilized eggs.

The presented results bring us to the conclusion that the age of geese and phase (month) during season (February-July) have an impact on fertilization and hatchability. This is confirmed by research done by Kent and Murphy (2003) who determined that egg production and hatchability gradually increase with age starting from age one until a certain limit, depending on the breed and type of geese. Bednarczyk and Rosiński (1999) discovered that in both types of Italian white goose (WD1 and WD3) the greatest hatchability out of fertilized eggs happened at the beginning of the season of laying 84.2% (WD1) abd 80.00% (WD3), which gradually declined until July, when it was 60.5% and 56.9%. The growth trend regarding the percent of hatchability during the season of egg laying, that the mentioned authors observed, is quite similar to our results. The difference is in the fact that the percent of hatchabililty out of fertilized eggs in our research was significantly more favourable (for each of the four production cycles (years) and for the total of four seasons 88.46%, Table 1).

Depending on the egg treatment (pre-heating of eggs before incubation) Kucharska-Gaca et al. (2016a) in the White Koluda goose eggs in the second and third season of laying found the egg fertilization that was between 79.3% (the control group eggs) and 82.8% (JI group- 6h pre-heated eggs), and the hatchability out of incubated and fertilized eggs was respectively between 66.8% and 80% and between 60.1% and 75%, which is significantly less in comparison to our results for the egg fertilization and hatchability in the Italian White goose. Even lower production of goslings out of fertilized eggs (62.2% - 61.1%) was found by KRD-IG (2013), Pakulska et al. (2003), and the poorest hatchability was found by Kucharska-Gaca et al. (2016b) in various weight groups, more specifically in the weight group of eggs which weighed between 181g and

200g (48.2% - out of incubated eggs; 73.7% - out of fertilized eggs). Kucharska-Gaca et al. (2016b), Bobko and Svetlik (2002), regardless of the weight group, came to the significantly higher embryo mortality than in invested i.e. fertilized eggs during the incubation period (11.3% - 20.9%) in comparison to our results (10.25% and 11.54% Table 1). Similarly, Rachwal (2008) finds that the egg mass has an impact on the embryo mortality and argues that eggs of smaller mass have lower embryo mortality and vice versa, which to a certain extent differs from our results. In addition, Pécsi et al. (2010) point out that the hatchability does not go over 70% because goose eggs are very difficult for hatching since they are quite big, have very hard shell and need regular cooling and bedewing. The similar fertilization of the Italian White Goose, hatchability and embryo mortality was found by Mitrovic et al. (2016), Mitrović et al. (2018), and Von Luttitz (2003). They emphasize that a phase during the production (season) of egg laying has an impact on the mentioned indicators and the average egg mass, i.e. the mass of hatched goslings.

Mazanowski and Chelmonska (2000), Mazanowski and Adamski (2002), Mazanowski and Bernacki (2006), Đermanović et al. (2008) examined the reproductive characteristics of goose crossbreeds that were created by the reciprocal crossing of typically three goose breeds, one of which was the White Italian (White Italian x Slovakian x Graylag), or two breeds (Chinese Knob Goose and domestic goose). Their results were similar or slightly worse than ours concerning the fertilization and hatchability. Golze (1991), Shalev et al. (1991), Vognivenko and Debrov (1997), Shalev (1998), Kirmizibayrak and Altinel (2001), Von Luttitz (2003), Shi et al. (2008), Scripnic and Modvala (2010) confirm that, in addition to the mentioned factors, genotype, the system of keeping, photoperiod and egg bedewing also have a significant effect on the incubation values (fertilization, hatchability and embryo mortality) and egg and gosling characteristics (egg mass, gosling mass on the first day, etc.).

A great number of authors did research on reproductive characteristics of other poultry species, mostly hens and turkeys, in a somewhat larger volume and they came to the similar conclusion that genetics and paragenetics have effect on their reproductive characteristics (fertilization, hatchability, chicken and turkey egg mass, egg length, egg width and egg shape index), to a certain extent similarly to geese (goose eggs).

Conclusion

Egg fertilization and hatchability are the most significant factors in the reproduction of all poultry species, including geese, since geese produce significantly lower number of eggs during the production cycle. The best egg fertilization (90.67%) was achieved in the second production cycle, then in the first cycle (89.33%) and the third (88%), while the worst was in the fourth cycle (87.33%). The fertilization for the four years in total was on average 88.83%. Therefore, the goose age had an impact on the number and percentage of fertilized eggs, the highest fertilization being achieved in the second and first cycle, then slightly decreasing in the third and fourth production cycle.

The egg hatchability, observed by production cycles, was also on a satisfactory level, the highest hatchability out of incubated eggs happening in the third production cycle (79%) and out of fertilized eggs in the second production cycle (86.76%). The hatchability for the total of production cycles was 78.58% for incubated eggs and 88.46% for fertilized eggs.

In all production cycles, it was in March that the best fertilization was achieved and it was 92% in the first cycle (year), and 94% in the second, third and fourth cycle. At the end of the season

(July), the fertilization was the lowest, going between 86% (first and second year) and 82% (fourth year).

In all production cycles (years), the most favourable hatchability in fertilized eggs happened in February and March (around 90% and more). Observing by months, the fertilization and hatchability during each production cycle, it can be noted the phase (month) during the season of egg production from February to July had effect on the measured indicators.

In the four-year period, the total of 943 goslings were hatched out of 1 200 incubated eggs. This egg category (the eggs out of which goslings came) was particularly examined because it is the most important link in the goose reproduction chain and goose meat production. This also goes for all other poultry.

The conclusion can be drawn that organic livestock production is not a typical extensive production (although it does have certain characteristics of that system). It is intensive with the acceptance of limitations set by the habitat. It limits the pollution in the habitat itself, which results in the preservation of the whole biological community, the satisfactory income and possibilities for the development of additional activities such as tourism (Council Directive 98/58/EC). In addition, organic production provides high value products certified as organic food, which increases the price of a unit product, reduces consumer health risks and enables the entrance on the global market. Of course, this production requires more work force, which is considered as very positive in the contemporary global trend of rural communities depopulation.

Finally, these activities prove that the standards of organic agriculture prescribed by the Common Agricultural Policy of the EU can be very successfully implemented in our region and that it is very desirable to apply them to the states who are not members or signatory states of the EU, such as our country, due to the goals achieved by this way of production, both concerning the production results and environmental protection.

Abstract

Holstein populations around the world are facing an increasing inbreeding rate. Despite being the most numerous dairy breed worldwide, Holstein effective population sizes are quite small. This is a result of intensive use of artificial insemination and high selection pressure. Recent data show that after the introduction of genomic selection, the inbreeding rate started increasing even faster. Results of inbreeding are well described in dairy cattle. Inbred cows have lower milk yield, worse reproduction parameters, and shorter survival in production. The objective of this study was to examine the inbreeding rate and population size of the Holstein population registered with the cattle breeding organization in Vojvodina province, Serbia. The pedigree file was formed for 36,733 animals born between 2013 and 2017. Inbreeding coefficients and effective population sizes were calculated using PopRep software (FLI). The average inbreeding coefficient steadily increased from 0.51% to 1.08% during the period observed. Effective population size was stabile when calculated according to a number of parents, with an average of 4,643 animals. Effective population size, obtained by the method of computing the relationship matrix with uncertain parentage, which was method proposed by software, was small and decreasing, ranging from 120 to just 65 in the period observed.

Key words: *Effective population size, inbreeding, Holstein cattle.*

Introduction

Inbreeding is mating of animals that are related by ancestry, i.e., animals that have a known common ancestor. Inbreeding increases homozygosity. One consequence of that is the occurrence of rare genetic disorders in progeny due to increased chance of detrimental recessive alleles to meet and be expressed (VanRaden and Miller, 2006). Another consequence is the overall reduction of birth size, growth rate, reproductive performance etc. This effect is known as inbreeding depression. Inbreeding depression is also probably mainly caused by recessive mutations (dominance theory) and recessive mutations at closely positioned loci on the same chromosome (pseudo-overdominance), while heterozygote advantage (overdominance theory) and epistasis playing a lesser role (Charlesworth and Willis, 2009).
Despite being the most numerous dairy breed worldwide, Holstein effective population sizes are small (Brotherstone and Goddard, 2005). This is a result of a combination of high selection pressure and artificial insemination (AI) that made possible for selected bulls to have a huge number of offspring. This combination resulted in an unprecedented spread of genetic material from small number of superior animals, and complete removal of all others from breeding population. More than 99% of USA AI bulls are direct descendants, by male lineage, of just two bulls born in 1950s (Yue *et al.*, 2015). Two additional male lineages were reconstructed at Penn

State University in 2017. by using stored semen of bulls belonging to lost lines, and modernized by mating with oocytes from today's elite females (Dechow *et al*., 2020), but question remains whether this lineages will find commercial interest and have any chance to bring diversity to current Holstein population.

Inbreeding is traditionally calculated based on pedigree data and expressed as a coefficient of inbreeding (F), as proposed by Wright (1922). It is equal to a chance that two alleles in a given animal are of the same origin, assuming an equal probability of every allele to be passed from one generation to another. When genomic data become available, new measures of inbreeding emerged. Bjelland *et al*. (2013) have used three measures to express inbreeding using single nucleotide polymorphism markers (SNP): percent homozygosity, runs of homozygosity (ROH) and genomic relationship matrix. These measures have advantage of not being dependent on pedigree data and not relying on the theoretical probability of alleles passing. Consequently, it can be expected that genomic measures of inbreeding will be better predictors of inbreeding depression. This is proven by simulation (Kardos *et al*., 2015). However, Nietlisbach *et al*. (2017) found, studying wild bird population, than genomic measure they used - homozygosity measured at microsatellites, is less well correlated with phenotype fitness than pedigree-based inbreeding coefficient. Pryce *et al*. (2014) have found low to moderate (0.26-0.53) correlations between pedigree-based inbreeding coefficient and genomic measures of inbreeding in Holstein and Jersey cows, but much stronger correlations (0.67-0.87) in research on Holstein bulls (Pryce *et al*., 2012). Authors explained this with worse pedigree recording for females than for males (Pryce *et al*., 2014).

The average inbreeding coefficient for Holstein breed increased from 0.4% in 1970 to 9% in 2021 in USA Holstein population (CDCB, 2021). It was estimated to be 3.5% in Australian Holstein population in 2007 (Pryce *et al*., 2014) and 5% in Dutch-Flemish Holstein-Friesian population in 2012 to 2016 (Doekes *et al*., 2018). It increased from 4% in 1990 to more than 9% in 2018 in Canada (Makanjuola *et al*., 2020). Inbreeding is also rising in small, importing Holstein populations like in Luxemburg and Tunisia, reaching 2-3% in 2000 (Hammami *et al*., 2007). It was predicted that genomic selection can reduce inbreeding (Daetwyler *et al*., 2007), but contrary to that, after introduction of genomic selection, average inbreeding coefficient started increasing even faster than before. During the last decade, average growth of the inbreeding coefficient in USA Holstein population was 0.3% per year, compared to 0.1% per year a decade before (CDCB, 2021). Same is true in Dutch-Flemish Holstein-Friesian population (Doekes *et al*., 2018), and Canadian Holstein population (Makanjuola *et al*., 2020).

The objective of this study was to examine the inbreeding rate and population size of the Holstein population registered with the cattle breeding organization in Vojvodina province, Serbia.

Materials and methods

The pedigree file was formed for 36,733 animals born between 2013 and 2017, registered as purebred Holstein with the cattle breeding organization in Vojvodina province, Serbia. Together with the ancestors, data file included 82,342 animals, and reached as far back as data was available. Pedigree completeness for animals observed, as calculated according to MacCluer *et al*. (1983), was fair, being 90% for 2 generations deep, 74% for 4 generations deep and 62% for six generations deep. It was somewhat lower for the first years of period observed and increased toward the end (Table 1).

Coefficients of inbreeding were calculated according to Wright (1922), while effective population sizes were calculated using six different methods: N_e-Cens (Wright, 1923), N_e-Ln (Pérez-Enciso, 1995), N_e-Ecg (Gutiérrez *et al*., 2009), N_e-ΔFp, N_e-ΔFg and N_e-Coan (Falconer and Mackay, 1996). All calculations were done using PopRep software of Friedrich Loeffler Institute (Groeneveld *et al*., 2009), and best method for estimating effective population size was chosen according to algorithm proposed by the same software.

Table 1. Pedigree completeness (%) for animals born between 2013 and 2017.

Year	Number of animals	Gen. 1	Gen. 2	Gen. 3	Gen. 4	Gen. 5	Gen. 6
2013	8430	99.4	82.2	70.4	62.3	55.7	49.9
2014	7954	99.8	87.6	77.6	70.5	64.3	58.5
2015	8872	99.9	91.8	83.5	77.1	71.2	65.5
2016	7632	100.0	94.6	87.7	82.0	76.4	70.9
2017	3845	100.0	96.1	90.4	85.2	79.9	74.5
Total	36733	99.8	89.7	80.8	74.1	68.1	62.5

Results and discussion

The average inbreeding coefficient increased steadily from 0.51% to 1.08% during the period observed (Table 2). It increased at the similar rate like in USA Holstein population before introduction of genomic selection (CDCB, 2021). In the same time, percentage of inbred animals also increased steadily, reaching 87% in 2017. This is probably a result, in part, of better pedigree completeness. Cassell *et al*. (2005) have shown that average inbreeding coefficient was 0.04 for Holstein animals with pedigree completeness less than 31% up to 5 generations, 1.65 for animals with pedigree completeness between 31 and 70%, and 2.06 for animals with pedigree completeness greater than 70%. However, even when taking imperfect completeness of pedigree data into account, observed inbreeding level of Holstein population in Vojvodina province during the period observed was very low. Reported inbreeding coefficients for other Holstein populations are usually much higher, ranging from 2-4% in Luxemburg, Tunisia and Australia (Hammami *et al*., 2007, Pryce *et al*., 2014), 5% in Denmark and Belgium (Doekes *et al*., 2018) and 9% in Canada and USA (Makanjuola *et al*., 2020, CDCB, 2021). This can be explained with the implementation of the breeding plan for Holsten population in Vojvodina province (BOTV, 2019), that culls out animals with high inbreeding coefficient. This measure reduces the number of animals that are suitable for the breeding population, but results in a lower inbreeding level in the population. Contrary to the average inbreeding, maximum levels of inbreeding decreased during the period observed (Table 2), probably as a result of culling animals with high inbreeding coefficient from breeding population.

Table 2. Number of inbred animals and inbreeding coefficients for animals born between 2013 and 2017.

Year	Number of animal		Inbred, % of total	Inbreeding coefficient		
	Total	Inbred		Average	SD	Maximum
2013	8430	4038	48%	0.0051	0.013	0.2581
2014	7954	4881	61%	0.0065	0.012	0.2586

2015	8872	6544	74%	0.0081	0.010	0.1333
2016	7632	6290	82%	0.0096	0.011	0.1262
2017	3845	3353	87%	0.0108	0.011	0.1366

Effective population size was stabile when calculated according to a number of parents (N_e-Cens), with an average of 4,643 animals. Out of six methods used for estimation of effective population size, N_e-Ln was chosen using the algorithm of PopRep software. In this method, effective population size is estimated by computing the relationship matrix with uncertain parentage (Perez-Enciso, 1995). When estimated by this method, effective population of Holstein breed in Vojvodina province was small and decreasing, ranging from 120 to just 65 in the period observed. This is similar to the estimate for the Spanish Holstein population of 66 to 79 (Rodríguez-Ramilo *et al*., 2015), 69 to 102 for Dutch-Flemish Holstein-Friesian population (Doekes *et al*., 2018) and 43 to 66 for Canadian Holstein population (Makanjuola *et al*., 2020). These populations, despite beeing numericaly much larger, also have simmilary small effective population size due to high and increasing inbreeding rate.

Table 3. Effective population size of Holstein breed in Vojvodina province as estimated using 6 different methods.

Year	N_e-Cens	N_e-ΔFp	N_e-ΔFg	N_e-Coan	**N_e-Ln**	N_e-Ecg
2013	4605	-122	273	134	**120**	420
2014	4645	-140	191	128	**104**	396
2015	4724	-159	139	109	**84**	363
2016	4785	-195	117	107	**72**	336
2017	4456	-225	109	102	**65**	323

Holstein populations around the world are a good example how intensive selection, especially genomic, and reproductive technologies, primarily AI, are drastically reducing effective population size and unavoidably increasing the inbreeding rate. Even when measures to control inbreeding temporarily increased the effective population size (Stachowicz *et al*., 2011), subsequent introduction of new technologies have reduced it back rapidly (Makanjuola *et al*., 2020). Inbreeding coefficients are even higher for AI bulls compared to the rest of population (CDCB, 2021). Question remains whether breeding plans should balance a need for intensive selection with measures to keep the inbreeding level low. However, Doekes *et al.* (2019) shows, on Dutch Holstein-Friesian population, that only the new inbreeding results in inbreeding depression, while ancient inbreeding even can have slightly favorable effects. This can be explained with purging effect (Gulisija and Crow, 2007, Mc Parland *et al*., 2009). Also, Doekes *et al.* (2019) argues that increase of inbreeding level that occurred in Dutch Holstein-Friesian population resulted in milk reduction of just 150 kg per lactation, while the realized genetic progress resulted in milk increase of 2,200 kg per lactation.

Conclusion

It can be concluded that Holstein population of Vojvodina province has low, but increasing inbreeding rate, that is currently around 1%, and small effective population size that is less than 100. It can be expected that the rate at which inbreeding level is rising will increase in the future, since similar trends are observed in worlds leading Holstein populations, especially with widespread use of the genomic selection. This will have to be addressed in new breeding plans.

Abstract

Meat and meat products are an important part of daily nutrition of human population. They are an important source of minerals and nutrients essential for human nutrition. Heavy metals are pollutants that, in some cases, can be found in meat and meat products. Lead (Pb) and cadmium (Cd) are heavy metals without any functions in animal organism. Their concentration is regulated through the legislation. The edible offal, like liver, is at the higher risk of the increased amount of Pb and Cd. The allowed concentration for Pb and Cd in liver is 0.5 mg/kg in the Republic of Serbia. The aim of the study was to determine the concentration of Pb and Cd in the liver of fattening pigs (22) and Mangulica (6) from different locations in Autonomous Province Vojvodina, Serbia. Fattening pigs (three breed hybrids) were reared in intensive condition on the formulated feed on sixteen different farms in Vojvodina. They were slaughtered at the age of six months, approximately at 105-110 kg of live weight. Mangulica were from two different locations, reared extensively without any formulated feed. They were slaughtered at the age of two years and at about 100 kg live weight. In all analyzed liver samples, the concentration of cadmium was in the allowed range. However, Pb concentrations in 10 liver samples of fattening pigs and in 4 liver samples of Mangulica exceed the allowed concentration.

Key words: *Lead (Pb), Cadmium (Cd), Fattening pigs, Mangulica pigs.*

Introduction

The pork is one of the most commonly consumed meats in the Republic of Serbia. The annual production is about 300 thousands of tones (Statistical Yearbook, Republic of Serbia 2018). The quality of meat and meat products (as edible offals) are from the great importance for the end consumers. The presence of some of the heavy metals in modern condition of production is almost infeasible. Lead (Pb) and Cadmium (Cd) are trace elements without any biological function in the body of the animals or humans. The elevated level of heavy metals such as lead and cadmium in the environment and food can be a serious problem so the levels of these heavy metals are regulated through the legislation. Usually the elevated levels of trace elements are in the proximity of industrial areas.

The fattening period in the condition on the commercial farms in Serbia usually take from 3-4 months, until the pigs reach 105-110 kg of the end live weight. During this period pigs are fed with formulated feed for the starting, growing and finishing period. Mangulica is an autochthonous breed in Serbia, the life span of the pigs is much longer than the life span of the fattening pigs. Mangulica are pigs reared in free range condition; their nutrition is not based on the concentrated food with added premix.

Lead can be naturally found in the nature however, due to the anthropogenic impact it can be pollutant and enter the human food chain. The human population is exposed to heavy metals via food, water air and soil. However, the food is the major source of exposure (EFSA, 2012). The primary place of accumulation of lead in animals are skeleton, the half- live for lead is about 30 days in blood, and in bones from 10-30 years. The maximum residue level for the lead (Pb) in the meat of bovine, pigs, sheep and poultry is 0.1mg/kg, and for edible offal is 0.5 mg/kg by the EU regulation (Andrée et al., 2010). The Serbian regulation is in accordance with the EU regulation (RS Pravilnik 2011). In the last decades the concentration of lead in food in the majority of EU countries had been reduced due to the effort to reduce emission of lead in the environment and ban of gasoline with lead (Bilandžić et al., 2010; EFSA, 2010; Andrée et al., 2010). However, there is not an abundance of data regarding the occurrence of lead in the meat and meat products in the Republic of Serbia. Some studies appoint that the increased level of lead in local environment is due to the vicinity of lead battery smelters (Mandić-Rajčević et al. 2018). In 4 years long study about heavy metal occurrence in the locally produced vegetables in the Vojvodina in some cases more than 40% of samples had the elevated level of lead (Pajević et al. 2018). Higher concentrations then the recommended by the International Dairy Federation of heavy metals including lead have been found in the milk in Serbia (Davidov et al., 2019). However, the analyzed samples of edible offal of fattening pigs in three different studies done in Serbia did not showed any indications of the increased lead concentration (Milićević et al., 2010; Mitić et al., 2012; Nikolic et al., 2017).
Cadmium does not have any biological function in animal organism. The main source of possible contamination of cadmium is food in non smoking population (Andrée et al. 2010). The allowed concentration of cadmium in liver of animal is 0.5 mg/kg, while in the kidneys is 1 mg/kg (RS Pravilnik 2011). Cadmium have very long half life from 10 to 30 years (Andrée et al. 2010). Some data suggested that in extensively reared pigs cadmium can have higher values than allowed by legislation of the Republic of Serbia (Nikolić, 2018). In the another study the levels of cadmium in the fattening pigs livers were in the allowed range but in the higher concentration than reported in some developed countries (Tomović et al., 2011).
The purpose of this research was to estimate the occurrence of heavy metals in the liver of two type pigs reared in the Autonomous Province Vojvodina, Serbia. Fattening pigs produced in the intensive condition on the commercial farms with the nutrition based on the formulated feed. Mangulice are extensive breed pigs with the nutrition which are not based on the formulated feed and with much longer life span

Material and method

Fattening pigs

Samples of liver were taken from random choice fattening pigs (three breed hybrids) on the slaughter line of three different slaughterhouses in the 2019-2020. The fattening pigs were approximately six months old, weighing from 100-110 kg and originating from sixteen different commercial pig farms located in Autonomous Province Vojvodina, Serbia. The fattening pigs' diet was based on the locally produced corn and soybean meals and was formulated to meet the animals' nutritional needs. The fattening of the pigs was divided in three phases: the starting, growing and finishing periods.

Mangulica
Six samples of liver of Mangulica were taken from two locations in Vojvodina. The Mangulica were reared in free range condition. The pigs were slaughter at the weighing 100-105 kg at the age of almost two years old.

Sampling preparation
Upon homogenization, all the samples were frozen at -20 °C until further analysis. Analytical methods lead and cadmium concentrations were determined after the wet sample digestion in concentrated nitric and hydrochloric acid (3:1, v/v) using a Reacti-ThermTM Heating/Stirring module Thermo Scientific (Rockford, USA). The analysis was performed using a Perkin-Elmer PinAAcle 900T THGA/FL atomic absorption spectrometer, a longitudinal Zeeman-effect background correction system, equipped with a transversely heated graphite atomizer (THGA) and an AS900 auto sampler. Hollow cathode lamps (HCL) were used for lead and cadmium detection. The analysis was carried out according to the method described by Beuković et al. (2015). The basic descriptive statistical data were done by processing the obtain data in the program Statistica 16.

Results and discussion

The results of the occurrence of lead (Pb) and cadmium (Cd) in the liver of the fattening pigs and Mangulica in mg/kg are showed in the Table 1. The average concentration of cadmium (Cd) in the liver of fattening pigs was 0.108 mg/kg, while in the liver in Mangulica was 0.209 mg/kg. Albeit the concentration of cadmium in the liver of Mangulica was higher than in the liver of the fattening pigs, it was in the allowed concentration of 0.5 mg/kg. However, the concentration of lead (Pb) in the liver in the both types of pigs was higher in more than several samples than it is allowed by current legislation in the Republic of Serbia. In ten (45.45%) out of 22 samples of the liver of the fattening pigs the found concentration of lead was higher than allowed. Moreover, in four out of six samples of the liver of Mangulica pigs the concentration of lead was also higher (66.67%) than allowed. The maximum found value for lead in the liver of fattening pigs was 1.890 mg/kg, while for the liver of Mangulica was 1.955mg/kg.

Tabela 1. Lead (Pb) and Cadmium (Cd) concentration (mg/kg) in the liver of fattening pigs and Manuglica from the region of Autonomous Province Vojvodina, Serbia

	Lead (Pb)		Cadmium (Cd)	
	Fattening pigs	Mangulica	Fattening pigs	Mangulica
average	0.703	1.142	0.106	0.209
N	22	6	22	6
SD	0.511	0.745	0.088	0.050
Min	0.212	0.379	0.060	0.137
Max	1.890	1.955	0.483	0.262
Permitted value	0.500	0.500	0.500	0.500
> 0.500	45.45	66.67	0	0

The concentration of cadmium in liver of fattening pigs in our study was in accordance with some other studies done in Serbia, where the average found concentration of cadmium in was 0.13 mg/kg (Tomović et al. 2011). In another study done in Serbia the concentration of cadmium was somewhat lower than in our and was in the range from 0.005-0.085 mg/kg for the period of five years (Nikolic et al. 2019). The cadmium concentration was higher in the liver of Mangulica than in the liver of fattening pigs. Most possible because of the almost four times longer life span of Mangulica and longer possible period of accumulation. The similar observation was found in another study where the concentration of cadmium was higher in Mangulica than in commercially produced pig. However, concentration was much higher with the average value of 1,612±0,229 mg/kg (Nikolić et al., 2018). The concentration of the lead found in the liver of fattening pigs and Mangulica in our study are rather surprising. Even the average concentrations of lead in fattening pigs and Mangulica 0.703 mg/kg and 1.142 mg/kg are above the legislation limit, with the range from 0.212-1.890 and 0.379-1.955 mg/kg in fattening pigs and Mangulica respectively. It is very hard to explain our results. In previous studies there were no any indications regarding the increased level of lead in edible tissue of pigs (Milićević et al. 2010; Nikolic et al. 2017b). Samples of liver of fattening pigs are from sixteen different farms and by that from the sixteen different locations in Vojvodina. Each farm has its own management and on each farm there were numerous possibilities for the source of contamination through food, water or soil. However, food is very different for the Mangulica and fattening pigs. Fattening pigs are fed with the formulated feed in which is incorporated premix. Premix and some feed additives can in some cases be the source of contamination. In the liver of fattening pigs 2008 in Australia the lead as high as 3.3 mg/kg for fresh weight was detected. Trace back investigation revealed the source. Zinc oxide feed additive which is used early in post weaning period, had contained in excess 8% of lead (Maclachlan et al., 2015). However, mangulice are fed only with the basics without the formulated food and premix in it. There are data which are indicating that the occurrences of lead in the environment in the region of Serbia are sometimes increased which resulted in increased level in the milk (Davidov et al. 2019) or the vegetables (Pajević et al. 2018). However, in the s observation done in period between 2007- 2017 in the two suburban areas of Belgrade heavy metals did not pose any risk in animal feed (Mitrovic et al. 2019). Lead in the environment is the effect of the androgenic influence. Our samples are from the sixteen different locations in Vojvodina and possible that the increased level of lead is the effect of environmental pollutant and local industry. Majority of farms previously state owned were built in the 1970s and 1980s and then privatized. Some of them are renovated and some of them are still with the old objects and infrastructure, so there are many possible sources of lead.

Conclusion

From the results of our work it seems that the occurrence of cadmium in the liver of the fattening pigs and Mangulica are in the allowed range and do not pose any health risks. However, the occurrence of lead in the liver of the both fattening pigs and Mangulica are increased and pose a possible health risk. There is a need for the further investigation of the origin of the lead exposure. The Mangulica and fattening pigs are reared completely different and in the different condition, with the different life span and yet in the liver of the both type the occurrence of lead was increased in some samples (45.45% for the fattening pigs, 66.67% for mangulice). It is possible that there is multiple source of lead.

Abstract

The overview of domestic and foreign investigations was given in the paper about the influence of forage and concentrate ratio in the diet on production and chemical composition of milk, and on the polyunsaturated fatty acid (PUFA) content in cows milk fat. Special attention was given to conjugated linoleic acid (CLA) because of its proved antidiabetic and anticarcinogenic properties. Green forages like pasture has positive effect on PUFA content, but significantly decreases milk synthesis. Increase in milk yield can be achieved with the increase in quality forage and/or with the increase of concentrates in the diet. There are differences between various forages, so that grass and legume silages have more favorable effects on milk fat synthesis and fatty acid profile compared to maize silage. The increase of energy in the diet with the aim to increase milk yield can be achieved with the use of carbohydrate (starch) and feeds high in oil. High starch content in the diet provides lower production of volatile fatty acids (acetic and β-hydroxibutyric), which are used for *de novo* synthesis of fatty acids (<16:0) in the udder. The result of such feeding regime is decrease of PUFA and CLA content in milk fat. The use of some high oil feeds in the concentrates increased PUFA content significantly. Among the investigated species (soybeans, sunflower, linseed, cotton see, peanuts) the highest increase in CLA content (by 60%) was obtained with heat processed soybeans, compared to control ($p<0.01$).

Key words: *feeding, cows, milk, fatty acids.*

Introduction

Unlike other animals ruminants largely use structural carbohydrates to satisfy their energy needs (due to activity of cellulolytic mikroflora in the rumen), which decreases the cost of their production. However, the use of large quantities of forage feeds (fresh or conserved) is limiting the meat or milk production. That is the reason why it is very important to produce high quality forages (Đorđević et al., 2010, 2011) and to supplement the diet with concentrates (Grubić and Đorđević, 2005; Đorđević et al., 2014; Khan et al., 2012; Rego et al., 2016). Low quality of forages is decreasing their intake which is forcing the increase in concentrates in the diet. Byström et al. (2002) conclude that due to low quality of forages (late cut, low energy and protein, high cellulose content) the voluntary intake of forages was lower (1,6 kg SM/100 kg TM) than expected (2-2,5 kg SM/100 kg TM). Intensive dairy production demands maximal use of concentrates in the amount of up to 60% of dry matter in the diet. With the decrease in milk fat content, the fatty acid ratio is changed so that there is an increase i saturated fatty acid (SFA) content, which are considered responsible for cardiovascular problems. Contrary to that, the amount of polyunsaturated fatty acids (PUFA) is decreased which are considered as healthy for humans (Đorđević et al., 2003; 2010; 2016; 2020b). Some of the PUFA are precursors for biologically active eicosanoids, which are important in immunological and inflammatory response (McDonald et al., 2011). Especially important is conjugated linoleic acid (CLA) because it has anticarcinogenic effect, it is also helpful against diabetes and has anti-inflammatory effects (Collomb et al., 2008).

Ruminant milk and meat are the most important source of CLA in human nutrition since they provide about 70% of total CLA requirements and that is the reason why that area is investigated in recent times, with the aim to modify content and ratio of PUFA (Đorđević et al.,2020a,b). Many genetic and nongenetic factors contribute to variations in amount of produced milk fat and fatty acid (FA) content in milk. Amount the nongenetic factors the most important is nutrition, through used feeds and forage to concentrate ratio (Radonjic et al., 2019; Đorđević et al., 2021).

The influence of concentration and type of diet on milk fat content

Milk fat is traditionally highly priced product in animal production, because it is obtained from living animals fed with forages. The milk price was until recently formed based on fat content. In recent years the consumers changed their regard for milk fat considering the health problems that it may induce. However, those effect are result of the presence of some FA. Modern investigations showed that human nutrition with fats rich in lauric (C12:0), myristic (C14:0) and palmitic acid (C16:0) increase incidence of obesity and coronary conditions (Arnould and Soyeurt, 2009). In spite of that the goal of every milk producer is to obtain product with maximal fat content.

Milk fat is the most variable ingredient, depending on numerous factors, of which feeding is especially important. According to Bauman and Griinari (2001) there are two main theories to explain milk fat depression (MFD): 1. Lack of precursors for milk fat synthesis in the udder and 2. Problems in milk fat synthesis. One of the most mentioned reasons is insufficient amount of acetic acid (the main precursor for milk fat synthesis) that is supplied to udder. Acetic acid is the product of microbial degradation of fiber in the rumen. When high concentrate diets are used the amount of produced acetic acid in decreased and the amount of propionic acid is increased. Similar problem occurs if the forage feeds are too finely ground (silage, total mixed ration – TMR). Bauman and Griinari (2003) showed that in cows fed standard and high concentrate diets similar amount of acetic acid is produced but the amount of propionic is increased, which is changing their relative ratio. However, the absolute amount of acetic acid that is reaching the udder is little changed. Some researchers showed that there is no significant change in milk fat content with the increased amounts of concentrates. Machado et al. (2014) fed cows with various concentrate to forage ratio (35:65, 45:55 i 55:45% in dietary dry matter) and they found that with the increase of concentrates there is linear response in higher production of fat corrected milk (FCM) with the non-significant decrease in milk fat percent and lactose. Mendosa et al. (2016) fed cows with TMR in control group and in experimental groups I and II there were fed with cut green mass 4 or 8 hours per day. They found that with the increase of green mass intake there is significant decrease in milk yield (from 34.4 to 32.7 kg/day; $p<0.05$), FCM (from 37,6 to 35.1 kg/day; $p<0.05$)) and milk fat (from 1,40 to 1,29 kg/day; $p<0.10$), while decrease in milk fat percent (from 4.10 to 3.99 %) was not significant. Their conclusion was that with the increase in concentrates in the diet there was increase in milk and milk fat yield (absolute value) and the decrease in milk fat percentage (relative value).

If low quality forage is used the intake is decreased but the time for digestion is increased which as a result has lower supply of acetic acid to the udder and the MFD occurs. This is why it is very important to pay maximal attention to the quality of forage feeds. One of the ways to produce quality forages is to choose the optimal time for harvesting (Božičković et al., 2016), but also the appropriate manipulations when forages are conserved (Đorđević et al., 2012a,b). Aside from that, the use of high quality forages is enabling the lower use of concentrates, which is reducing the feeding cost and has good effects on health and reproduction.
The significant problem with the use of larger quantities of concentrates is the decrease in ruminal pH value, acidosis, which has negative effects on cellulolytic bacteria in the rumen and acetic acid synthesis (Mendoza et al., 2016). That is why the buffering compounds are added to high concentrate diets and special attention is paid to effective fibre. The correct amount of effective fibre is enabling optimal rumination time and acid neutralization in the rumen (Stojanović et al., 2012). By preserving the optimal pH value on the rumen the maximal activity of cellulolytic bacteria in the rumen is achieved, which as a result has appropriate supply of acetic acid to the udder.

The influence of concentration and composition of the diet on fatty acid content

Milk fat consists of triglycerides (about 98%), with about 400 different FA (Jensen, 2002). FA with C chain of 4-14 C atoms and part of C16 is created in de novo synthesis in the udder using acetic and β-hidroxybutyric acid (products of microbial digestion in the rumen). The rest of C16 and longer chain FA are taken from the blood after being transferred from the intestines (Kęsek et al., 2014), or came from body reserves (Parodi, 2004). The content of fatty acid that are produced from fatty reserves varies from about 5% in well fed animals to ore that 20% in early lactation when cows are in negative energy balance (Lake et al., 2005). Bacterial flora in the rumen is producing also odd numbered FA (C 15:0 and C 17:0) (German and Dillard, 2006). Conversion of FA C10:0-C18:0 into monounsaturated fatty acids (MUFA) is also happening in the udder. Animal cells cannot synthesize FA with several double bonds (linoleic acid with two and linolenic acid with three double bonds), which is why they are essential and must be supplied with food. Linoleic and linolenic acids from feeds and with incomplete biohydrogenisation in the rumen are main precursors for CLA. Bacterial biohydrogenisation of linoleic acid the CLA is formed but it is rapidly converted into trans-11 oleic acid (18:1), which is why concentration of cis-9 trans-11 CLA isomer is very low in the rumen and milk. CLA is also formed endogenously in tissues. Biohydrogenisation has large physiological significance since unsaturated FA ate toxic for ruminal microorganisms. Since the lipid degradation intensity in the rumen is larger than the speed of biohydrogenisation it is very important that ruminant diets do not contain larger amounts of fats (up to 7% of dry matter). The higher amount can have negative effects on cellulolytic bacteria and decreased production of acetates, which can depress milk fat. (Grubić et al., 2007). The use of high oil feeds in dairy cow nutrition can produce such problem but also have positive effects on PUFA and CLA content. Several experiments showed that heat processed soybeans have best effects on PUFA and CLA content compared to other high oil feeds. According to Liu et al. (2008), the use of whole soybean grain increased CLA content by 60% ($p<0.01$) compared to control group.
Among all genetic and nongenetic factors, the key role in fat modification is played by nutrition and specially with fresh green forage like pasture or cut green mass (Đorđević et al., 2017), through botanical composition and development phase (Radonjić et al., 2019). Dhiman et al.

(1999) showed that pasture fed cows had 5.7 times more CLA in their milk compared with those fed with conserved feeds (hay, silage). During drying (for hay) or wilting (for silage) there are significant losses in FA. On the other side, feeding mostly with forages do not provide enough dry matter intake for maximal milk yield. The optimal dry matter intake is achieved with the use of concentrates or TMR. However, the large amounts of concentrates influences biohydrogenisation of linoleic acid to trans-10, cis-12 CLA isomer which has strong inhibitory influence on milk fat synthesis (Grubić et al., 2007). It is shown that addition of trans-10, cis-12 CLA decreases milk fat content, which is not happening with cis-9, trans-11 CLA (Bauman, 2001). Since many countries have limited pasture areas the most likely solution is the use of TMR, combined with the green forages produced as crops. Mendosa et al. (2016) in mentioned example, while feeding cows with TMR (T_0) and cut green forage (*Lolium multiflorum*) fed *ad lib* for 4 (T_4) or 8 (T_8) hours determined significant increase of cis-9, trans-11 CLA and MUFA, and decrease in SFA. They also observed linear but not significant increase in PUFA content (table 1).

Table 1. Milk yield and fetty acid profile (Mendosa et al., 2016)

Parameters	T_0	T_4	T_8	P - value
Milk, kg/d	34.4^{a}	34.9^{a}	32.7^{b}	0.027
3,5% FCM, kg/d	37.6^{a}	37.3^{a}	35.1^{b}	0.012
Fat, kg/d	1.40^{x}	1.37^{xy}	1.29^{y}	0.068
Fat, %	4.10	3.95	3.99	0.604
Cis-9, trans-11 CLA	0.49^{a}	0.65^{ab}	0.77^{b}	0.062
SFA	72.16^{a}	70.90^{ab}	68.71^{b}	0.020
MUFA	24.39^{a}	25.36^{ab}	27.29^{b}	0.025
PUFA	3.46	3.74	3.90	0.133
n6:n3 ratio	8.03^{a}	6.77^{ab}	5.64^{b}	0.035

a,b - Within a row, means with different superscripts are different ($P < 0.05$).
x,y - Within a row, means with different superscripts are different ($P < 0.10$).

Conclusion (and suggestions)

Nutrition is one of the most important factors that influence production and quality of milk. In order to obtain maximal milk yield, with the highest percent of fats and PUFA it is necessary to: provide the best possible quality of forage feeds; use hay in all diets (minimal amount 2.5 kg per cow in long form); optimally balance diet using latest recommendations, normative and models; provide appropriate physical effectivity of diet; mix properly TMR; carefully use feeds with high oil content and provide optimal pH value in the rumen.

Abstract

In this paper we examined the effects of usage of organic selenium in the nutrition of pheasants on breast meat quality in the experiment that lasted for two months. Forty five pheasants were divided into three groups of 15 pheasants, and were fed with mixtures of organic selenium supplementation in concentrations of 0.2 mg/kg (I group) and 0.3 mg/kg (II group), while the food of the control group was without selenium supplementation. The obtained results showed that the introduction of organic selenium into pheasant mixtures did not have statistically significant effect ($p>0.05$) on the average breast meat weight and chemical composition of meat: water, fat, protein, pH and ash content. Organic selenium in a concentration of 0.3 mg/kg of the mixture had a positive effect on increasing the water holding capacity of the breast meat and on sensory traits compared to meat of the control group and the I group which was fed with 0.2 mg/kg of organic selenium in the mixture. The ability of water retention in breast meat of the II group of pheasants was higher than in control group by 0.75% i.e. 0.58% in comparison to I group. Sensory traits of breast meat of the II group of pheasants were for 15 points better than sensory traits of meat of the control group, that is for 7 points better than the I group of pheasants. Statistically significant differences were determined among the average values of selenium concentration in white breast meat of II group pheasants ($p<0.05$) and the control group of the pheasants which are fed without selenium supplementation.

Keywords: *organic selenium, meat quality, pheasant.*

Introduction

The common pheasant is one of the most widespread birds on the planet earth. Thanks to artificial breeding in pheasantries the number of this feathered game, which is a favorite prey for hunting, as well as an alternative to poultry farming in the production of quality meat, has increased. During the last few years, pheasant farms have been developed around the world as a new branch of agriculture for commercial meat production.

Organically bound selenium in the form of selenomethionine manifests a strong antioxidant effect in poultry organism, directly affecting the increase in the concentration of the enzymes of glutathione peroxidase (GPx) in the liver and the reduction in the concentration of lipid peroxidase and hydrogen peroxide produced during normal metabolic activity, thus gaining meat of exceptional quality high in selenium content. Selenium deficiency and loss of GPx enzyme activity cause cell membrane damage, free radical accumulation, and cell decay. The antioxidant effect of selenium protects poultry from atherosclerosis, degenerative processes of the pancreas and kidneys, reproductive disorders, tumorigenesis and at the same time selenium also has an immunostimulatory effect (Dukes, 1993; Kang *et al*., 2000; Dlouha *et al*., 2008).Oral intake of selenium by food results in increased content of its concentration in tissues and eggs (Edens, 1997; Surai *et al*., 2002; Edens *et al*., 2004). Selenium deficiency in the organism of poultry causes numerous pathological changes and diseases such as: atrophy of the pancreas, kidney damage, exudative diathesis, reduced fertilization and immunity. Selenium is also an activator of thyroid hormones, which among other things, participate in the thermogenesis of poultry, so for that reason, the concentration of selenium in the organism of birds under heat stress can be significantly reduced. (Silva *et al*., 2002).

The poultry and birds' production depends on numerous stress factors (overpopulation, heat stress, diseases), which is why selenium, as an integral part of many selenoproteins, actively participates in their prevention by activating antioxidant mechanisms. The accumulation of selenium in the organism of poultry is the highest in the kidneys, followed by the liver and pancreas, while the lowest concentrations are in adipose tissue and feathers. In the case of surplus, selenium is predominantly deposited in the liver and muscles (Surai, 2000; Surai *et al*., 2002).

Meat quality is the sum of the traits and characteristics of a product based on its ability to satisfy the consumer. Meat quality primarily depends on its nutritive value i.e. chemical composition and sensory traits. Poultry and bird meat are of great importance due to high content of biologically valuable proteins, fats, vitamins, minerals and essential fatty acids (Franco *et al*., 2013). The breast meat of poultry and birds is high in protein, low on fat and cholesterol compared to meat of other domestic animals which makes it a dietary product (Barroeta, 2006).

There is a significant number of papers in the literature engaged in the nutritional effect of selenium on poultry, but a very small number of available researches explain the effect of organic selenium on the quality of pheasant breast meat. The aim of this paper was to determine the effect of adding organic selenium in pheasant feed on the quality of breast meat, its chemical composition, sensory traits meat acceptability and selenium content.

Material and Methods

The experiment was conducted with 45 common pheasants, both male and female, of average body weight of 385 ± 75 g and age of 42 days. They were divided into three groups with 15 pheasants in each group. The experiment lasted for 60 days and during that period accomodation and nutrition of pheasants were adjusted to the floor way of raising.

We used a pelleted mixture for pheasant nutrition and it was formulated according to the nutritional needs of pheasants (NRC, 1994). The organic selenium contained in *Alkosel®* preparation (Lallemand, Fra) was added to the premixes, and after appropriate mixing, the premix with selenium was applied to the complete mixtures and mixed again with the complete mixture. The control group was fed with food without selenium supplementation, while the food of experimental I group contained organic selenium in a concentration of 0.2 mg/kg, and the food of experimental II group contained organic selenium in a concentration of 0.3 mg/kg. The raw material and chemical composition of pheasant food is shown in Table 1.

Throughout the entire duration of the experiment, the consumption of food and water was at will. The average sample of complete mixtures for pheasant nutrition was analyzed for the basic chemical composition at the beginning of the experiment (content of air dry matter, ash, crude proteins, fats and cellulose), by applying standard analytical methods of chemical food examination (AOAC, 1990). Calcium and phosphorus content was determined by the colorimetric method on the Tecator system (SRPS ISO 6490-1/2001; SRPS ISO 6491/2002),

while the content of metabolic energy and amino acids was obtained by calculation based on their content in nutrients (INRA-AFZ, 2004).
Control measurements of pheasant body weight were performed on an electronic scale with an accuracy of ± 0.5 grams, both at the beginning and the end of the experiment, based on which the average body weight was calculated. Throughout the experiment, the health condition of pheasants and their mortality were monitored. By the method of random sampling at the end of 60 days experiment, seven pheasants were taken from each group, they were individually measured before slaughter, and after primary slaughter processing and water cooling, chilled carcasses were cut into basic pieces in a manner regulated by Ordinance on the quality of poultry meat (Official Gazette SFRY No. 1/81 and 51/88). During the cutting the brest muscle was separated and measured on an automatic scale with an accuracy of ± 0.5 grams.

Table 1. Ingredients and nutrient content of complete feed mixture for pheasants

Component (%)	Group Control (K), I and II
Maize	40
Wheat bran	3
Soybean meal	24
Sunflower meal 33%	4.3
Alfalfa meal	3
Yeast	3.5
Soybean grits	12
Sunflower meal 42%	5
Lysine	0.1
Methionine	0.2
Limestone	1.6
Mono-Ca-phosphate	1.5
Salt	0.3
Additive Peletin	0.5
Premix	1

The chemical feed composition of all three groups (%): Proteins 24.25; Cellulose 6.05; Fats 4.63 Ash 7.35; Dry matter 88.20; Calcium 1.02; Total phosphorus 0.82; ME 12.75 MJ/kg; Lysine 1.35; Methionine + Cystine 0.90. *Composition of premix in 1kg of complete mixture:*Vitamin A (IU/kg) 15000;Vitamin D_3 (IU/kg) 3000; Vitamin E (mg/kg) 32; Biotin (mg/kg) 0.20; Vitamin C (mg/kg) 15; Folicacid (mg/kg) 1.20; Niacin (mg/kg) 30; Pantothenicacid (mg/kg) 15; Vitamin B_6 (mg/kg) 3.20; Vitamin B_2 (mg/kg) 7; Vitamin B_1 (mg/kg) 2.10; Vitamin B_{12} (mg/kg) 0.03; Cholinechloride (mg/kg) 500; Fe (mg/kg) 40; Mn (mg/kg) 80; Cu (mg/kg) 8; Zn (mg/kg) 60; J (mg/kg) 0.80; Co (mg/kg) 0.45; Antioxidant BHT (mg/kg) 100.

The chemical composition of breast meat was analyzed by using standard methods. The total water content was determined by drying the samples to constant weight (SRPS ISO 1442/1998), the total ash by burning and annealing the sample at a temperature of 500°C to 600°C (SRPS ISO 936/1999), pH of the meat with a pH meter (SRPS ISO 2917 : 2004), total proteins by the Kjedahl method based on nitrogen content (SRPS ISO 937/1992), total fat by Soxlett extraction with pre-drying of the sample (SRPS ISO 1443/1992). The content of selenium in white breast

meat of pheasants was determined by atomic absorption spectrophotometry with the hydride technique (SRPS EN 16159 : 2012).
The ability to retain water in the breast meat was specified by measuring the content of total moisture in it, after 24 and 48 hours from the time of cooling the meat to 4°C. The quality of sensory traits of meat was examined by the method of determining the difference in meat acceptability – by Rank test, assessed by 7 evaluators (Baltić, 1993; Baltić *et al*., 1997; SRPS EN ISO 8587/2006) The evaluators assessed the characteristics of the meat that can be registered by the senses (smell, taste, juiciness, softness and appearance), whereby the obtained differences in the acceptability of the meat represent differences in the overall impression of all evaluators. Before starting the examination, all the samples were thermally processed on the grill for about 15 minutes and after that the evaluators rated the samples with the grades the most acceptable, less acceptable and the least acceptable. Within the statistical analysis of the obtained results, the analysis of variance was performed by a standard procedure with testing of the statistical significance of the differences between certain groups and examined parameters by applying LSD test.

Results and Discussion

The chemical composition of complete feed mixtures for pheasants' nutrition completely met the nutritional needs of pheasants in fattening and was in accordance with the recommended norms of the NRC (1994). There were no health issues or pheasant deaths throughout the duration of this experiment.

Table 2. Chemical composition of the breast muscle and selenium content in meat

Chemical composition	Control group	I group	II group
Mass (g)	221.50±28	224.60 ± 18	229.42±32
pH meat	6.10±16	6.02±32	6.19±42
Moisture (%)	72.63±23	72.38 ± 52	72.49±55
Fat (%)	1.08±56	1.10 ± 23	1.11±36
Total protein (%)	25.14±14	25.15 ± 11	25.11±87
Ash (%)	1.18±41	1.20 ± 09	1.20±23
Selenium (mg/kg)	0.121±13	0.129±03	0.135±33*

*p<0.05 (Control group and II group pheasants)

By the reviewing of the obtained results of the chemical composition of breast meat (Table 2), it can be concluded that the presence of organic selenium in pheasant feeding mixtures caused relative raising of higher values of breast muscle mass, electrochemical reaction of meat, water and fat content but without determined statistically significant differences between treatments (p>0.05). In the analysis of the obtained results of the breast weight we noticed that its weight was the lowest in pheasants of the control group with 221.50 grams, and the highest was in pheasants of II group with 229.32 grams. The relative uniformity of the chemical composition of breast meat in terms of the content of the analyzed parameters between the examined groups of pheasants is in accordance with the research of Cvrtila *et al*., (2007). In our experiments, no statistically significant differences were determined between the treatments (p>0.05) of examined basic chemical parameters of meat. Tucak *et al*., (2008) state that the breast weight of

adult pheasants raised in an aviary ranged from 248 to 295 grams. In comparison to our results, the authors determined higher values of proteins, fat and ash in pheasant breast meat. In our experiment, the protein and fat concentration in pheasant meat were uniform, whereas the protein content was higher than the fat content. The explanation for this phenomenon is the age of the pheasants, because in our research we dealt with young, not adult pheasants.
Results of selenium content in breast meat samples shown in Table 2, indicate that the average selenium content was the lowest in the control group 0.121 mg/kg, slightly higher was in the I group 0.129 mg/kg and the highest was in the II group of pheasants 0.135 mg/kg. Statistically data processing on selenium content in breast meat we determined a statistically significant difference ($p<0.05$) among control group that did not receive selenium in food and the II group of pheasants that received organic selenium with food in concentracion of 0.3 mg/kg. Several researchers have confirmed, in their experiments, that the positive effect of increasing the concentration of selenium in the musculature of broilers whose food was treated with organic selenium compared to the control group without supplement or with inorganic selenium supplementation in food (Edens *et al*., 2004; Payne *et al*., 2005; Dlouha *et al*., 2008).

Water loss in meat	Control group		I group		II group	
	g	%	g	%	g	%
Water loss after 24 h	1.30	1.79	1.10	1.52	0.85	1.17
Water loss after 48 h	1.95	2.68	1.70	2.10	1.40	1.93
Difference, %	-	-	-	0.58	-	0.75

The results of white breast meat moister loss are shown in Table 3. The best relative values of water retention in white breast meat was achieved by II group both after 24h (1.17%) and after 48h (1.93%) from the time of meat cooling, so in comparison to control group it had better efficiency by 0.75%. Similar results were achieved by I group, which in comparison to control group had better water retention in meat by 0.58%. The worst results were recorded in the control group which had relative value of water retention of 1.79% after 24h, and 2.68% after 48h. Our research confirmed the positive antioxidant effect of selenium on the musculature of the breast meat because I group and II group of pheasants achieved less water loss during storage. Meat quality can successfully be maintained during storage by adding selenium antioxidants to the feeding of domestic animals, because selenium is deposited in musculature cells, which improves the ability of the cells to retain water (Surai, 2000). According to Edens (2001), selenium in the muscle tissue reduces fat peroxidation during meat storage and thus affects the preservation of meat quality. Organic selenium in form of selenomethionine has a positive effect on meat quality because it increases the activity of glutathione peroxidase (GSH-Pk) and maintains a low level of lipid peroxidase which results in cell membrane stability and the ability to bind water (Edens *et al*., 2000; Edens *et al*., 2004).

Table 4. The assessment of the overall acceptability of broiler breast meat samples

Groups	Groups		
	Control group	I group	II group
The sum of ranks	47	39	32
Control group	-	8	15
I group	-	-	7
II group	-	-	-

A very important indicator of meat quality, besides chemical composition, is its sensory traits which were examined by the Rank test method in this experiment, or meat acceptability by consumers, whereby lower sum of ranks represent better meat acceptability. In Table 4 we displayed the differences in assessment of the breast meat acceptability of the examined broilers. By ranking of the breast meat samples, the samples of II group (32 points) were evaluated as the most acceptable, which at the same time had the highest difference in the sum of ranks of 15 points, then I group of pheasants (39 points) with the difference in the sum of ranks of 7 points in comparison to the control group, and as the least acceptable were the breast meat samples of the control group (47 points). Based on the Rang test results obtained in these researches, we can conclude that the appliance of organic selenium in food had a positive effect on acceptability of meat of examined pheasants. According to many authors, the highest effect on food acceptability has compounds that are carriers of smell and taste. (Baltić, 1993: Ivanović *et al*., 2012). The appliance of organic selenium in food has a positive effect on the appearance, juiciness, smell and colour of meat (Surai *et al*., 2002), while the increased juiciness is the result of better water retention in meat (Džinić *et al*., 2006).

Conclusions

Based on the results obtained in the conducted experiments, it can be concluded that the addition of organically bound selenium to pheasant food in a concentration of 0.3 mg/kg had a stimulating effect on selenium content in breast meat (p>0.05). Organic selenium added in the food of II group in a concentration of 0.3 mg/kg had a positive effect on sensory traits of breast meat by 0.75% and the ability to retain water in breast meat by 15 points compared to control group which was fed without selenium supplementation. The general conclusion is that the appliance of selenium in increased concentrations has its significance in production of pheasant meat with high content of selenium for human consumption.

Abstract

The aim of this study was to examine the influence of different starter cultures on the composition and sensory characteristics of white-brined goat cheeses. Four varieties of cheese (A, B, C, D) were produced according to the same technological procedure. Quality parameters, with special emphasis on the dynamics of ripening, were determined after production, on the 10th, 20th and 30th day of ripening. Since the cheeses were produced from full-fat goat's milk, after the ripening period, they belonged to the group of full-fat cheeses (with a fat content in the dry matter higher than 45%). As a result of different starter cultures, in variants A and B intensive proteolysis occurred after 20 days of ripening, while in variant C increase of Ripening Index was observed after 10 days. The most intense proteolytic changes were found in variant A at the end of ripening period, where the soluble nitrogen (SN) content in 12% TCA was 154.9 mg%, while the lowest intensity of proteolytic changes was determined in variant B with the average SN content in 12% TCA of 116.3 mg%. The best sensory evaluations were given to cheese variants B and C, which were evaluated with excellent quality (4.92 and 4.56), while cheese variants A and D had very good quality (4.47 and 4.36).

Key words: *goat milk, cheese in brine, sensory quality.*

Introduction

Production and processing of goat's milk is characteristic for the Mediterranean and the Balkan Peninsula, and highly developed and organized goat breeding is specific for France. The processing of goat's milk into cheese has a very long tradition, especially in some countries such as France, where there are over 90 different types of goat's cheese (Alichanidis and Abd El-Salam, 2004; Alichanidis and Polychroniadou, 2008). In the last two decades, the upward trend in production and processing of goat milk into various milk products, especially white cheeses in brine, was observed in Serbia. A shorter period of lactation is the reason why goat milk products have seasonal character. Therefore, freezing of milk or curd could be the way to overcome this problem (Kljajevic et al., 2017). Technological characteristics of goat milk are significantly different compared to cow's milk, resulting in a softer curd and a smaller cheese yield. Also, the sensory characteristics are different, given the specific composition of milk fat in goat's milk due to the presence of capric, caprylic and caproic fatty acids (Dozet et al., 2000, 2004, 2005). The aim of this work was to investigate the influence of different starter cultures on the composition and sensory characteristics of white-brined goat cheeses.

Material and method

All studies were conducted in the Milk Technology laboratory at Faculty of Agriculture, Belgrade, during the months of June and July. Goat's milk from the farm "Beocarpa" Kukujevci, Serbia, was used for the production of white cheese in brine. Depending on the various strains of microorganisms and their share in the starter culture 4 variants of white-brined goat cheese were produced:

- A: *Lb. plantarum* BGVLS2-18 - 33%, *Lc. lactis* subsp. *lactis* BGVL3-8 - 33%, *Leu. pseudomesenteroides* BGVL3-29 - 17%, *Leu. pseudomesenteroides* BGVL3-63 - 17%;
- B: *Lb. plantarum* BGVLS2-18 - 50%, *Lc. lactis* subsp. *lactis* BGVL3-8 - 50%;
- C: *Lb. plantarum* BGVLS2-18 - 33%, *Lc. lactis subsp. lactis* BGVL3-8 - 33%, *Leu. pseudomesenteroides* BGVL3-29 - 34%;
- D: *Lb. plantarum* BGVLS2-18 - 33%, *Lc. lactis subsp. lactis* BGVL3-8 - 33%, *Leu. pseudomesenteroides* BGVL3-63 - 34%.

The average content of fat and protein of the raw goat milk used was 2.50±0.71 and 2.62±0.36, respectively and the pH was 6.24±0.47. Raw goat milk was pasteurized (65°C/30 min), cooled to 33°C, and starter cultures and $CaCl_2$ were added. After 30 min, rennet (Caglificio, Clarici Italy) was added in concentration of 0.0325 g/L. Coagulation took place within 40 min at 32-33°C. The curd was cut crossways in cubes of 1 cm^3 and left for 5 min. Then, it was gently agitated for another 5 min to facilitate whey expulsion and carefully transferred into the mold. After that, the curd was left for 30 min to self-press, and then pressed for 20 min at 2 kg/kg, followed by pressing at 4 kg/kg during 40-60 min. After that, the cheese curd was cut into pieces of 10×10×4 cm, dry salted with 3.0% NaCl and left overnight. The next day, cheese slices were placed into plastic containers and covered with 6% NaCl brine. Ripening was conducted at 14°C during 30 days. The cheeses were sampled at 1, 10, 20 and 30 days of ripening.

The chemical composition of cheese samples was determined using standard methods: dry matter (IDF 4A:1982), fat (IDF 5B:1986), total nitrogen (IDF 20B:1993) and NaCl content (IDF 88A:1988).The protein content was calculated as the nitrogen content multiplied by 6.38. Using these parameters fat in dry matter (FDM) and moisture in non-fat solids (MNFS) were calculated. The pH of cheeses was measured using a pH meter (Consort, Belgium). Each analysis was done in triplicate. Proteolysis was monitored by measuring the contents of water-soluble nitrogen (WSN) and 12% trichloroacetic acid-soluble nitrogen (TCA-SN) according to Kuchroo and Fox (1982). After 30 days of ripening, the overall sensory quality was determined by point rating scale method (Radovanović and Popov-Raljić, 2001) by trained judges.

Data were subjected to one-way analysis of variance (ANOVA) with Statistica 6.0 software (Stat Soft. Inc., Tulsa, USA), and comparisons of means was done by t-test at $p<0.05$.

Results and discussion

Physico-chemical characteristics of four cheese variants are presented in Table 1. According to the fat in dry matter content (FDM) and the Codex standard 208 (1999), after the ripening period, all cheeses belonged to the group of full-fat cheeses. Variant D had significantly lower ($p<0.05$) FDM. Cheese B was the only one having similar FDM content as goat cheeses reported by Barać et al. (2016) and traditional Serbian white-brined cheeses produced from cow and sheep milk (Barać et al., 2019). Regarding moisture in nonfat solids (MNFS), all cheese variants were classified as soft cheeses. After 30 days of ripening no significant differences ($p>0.05$) in salt content and pH values were found.

Table 1. Physico-chemical characteristics of cheeses

Cheese variant	Time of ripening (days)	Parameter					
		DM (%)	FDM (%)	MNFS (%)	Proteins (%)	NaCl (%)	pH

DM - dry matter, FDM - fat in dry matter, MNFS - moisture in nonfat solid. Data within the same column marked with different lowercase letters are significantly different at $p<0.05$

Proteolytic activity is measured by the water soluble nitrogen per total nitrogen (WSN/TN) ratio known as the Ripening Index (RI). The higher RI values suggest more intensive initial proteolysis in brined cheese. The WSN fraction mainly consists of the whey proteins, proteose-peptone, low molecular weight peptides derived from casein hydrolysis, free amino acids and weakly bounded caseins (Mallatou et al., 2004). According to Terzić-Vidojević et al. (2013) *Lc. lactis* ssp. *lactis* BGVL2-8 has good acidification ability and antimicrobial activity, while *Lb. plantarum* BGVL2a-18 has good proteolytic activity and ability to form exopolysaccharides.

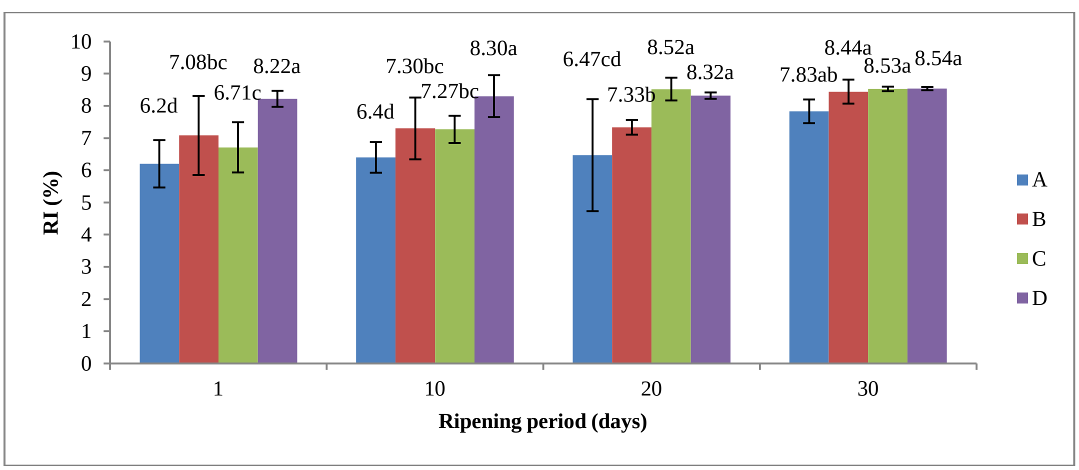

Figure 1. The change of ripening index

* Data marked with different lowercase letters are significantly different at $p<0.05$

As shown in Fig. 1. as a result of different starter cultures, in variants A and B intensive proteolysis occurred after 20 days of ripening, while in variant C increase of RI was observed after 10 days. The highest RI was found in variant D and did not change significantly ($p>0.05$) throughout whole ripening period. High levels of RI in cheese D at the beginning of ripening are probably the result of the proteolysis during curd processing. Significant reduce of pH value (Table 1) during the first 10 days of ripening may have contributed to bacterial activity which explains the absence of RI changes during ripening. Nevertheless, obtained results are in agreement with data presented by Barać et al. (2013) for 30-days-old white-brined goat cheese.

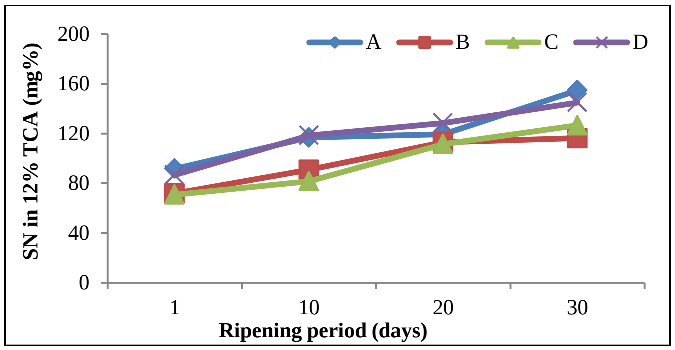

Figure 2. The change of TCA-SN during ripening

TCA-soluble nitrogen is traditionally considered as an index of "ripening depth" since it indicates progress of secondary proteolysis and the degree of formation of low-molecular-mass peptides (<15 000 Da) (Ardö et al., 1999; Tejada et al., 2008). As presented in Fig. 2. the level of TCA-SN increased during ripening. After 30 days values of TCA-SN were in the range 116.3-154.9 mg% and significantly higher ($p<0.05$) comparing to the first day of ripening in all cheese variants (70.9-91.7 mg%). However, those values were much lower than values reported for traditional Serbian white cheeses in brine (Barać et al., 2019). Variants B and C had less pronounced secondary proteolysis which can indicate slightly slower bacterial activity of those starter cultures. In the overall quality of food products, in addition to hygienic-toxicological, technological and nutritional factors, a significant place belongs to the sensory characteristics of the product. Sensory quality parameters usually include: appearance, color, flavor, taste, softness, structure, consistency and texture, where each group of products has specific sensory elements of quality, and thus specific sensory properties of quality (Radovanović and et al., 2001). The results of sensory analysis of white-brined goat cheese after 30 days of ripening are shown in Fig. 3. Taste is one of the most important sensory attributes in overall sensory quality of dairy products, including cheeses. Since cheese variant B had flavor, taste and consistency typical for goat white cheeses in brine, it was evaluated with the highest scores for those parameters. Furthermore, those scores were significantly higher ($p<0.05$) for variant B comparing to the other investigated cheese variants. Slices of cheese B also had uniform white color, unlike other cheese variants, especially variant D, in which slightly darker and more uneven color was observed. However, differences in color of cheese slices were not significant ($p>0.05$). Regarding taste, significant difference ($p<0.05$) was also established between variant A and variants C and D since they were slightly more acidic than the other cheese variants. Furthermore, cheese D had undefined and unexpressed taste. As a result pondered mean value of variant D was the lowest (4.36).

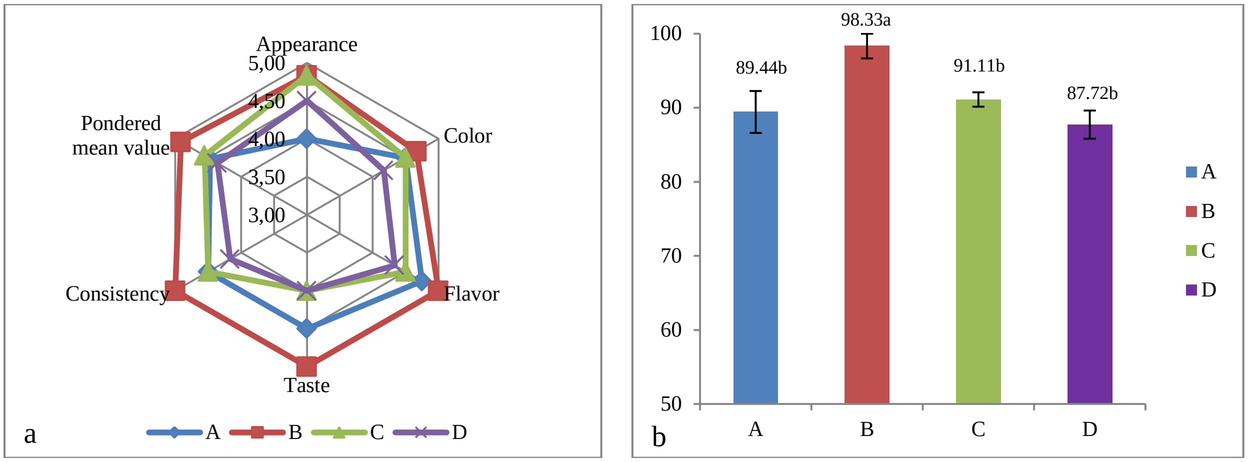

Figure 3. Sensory evaluation of white-brined goat cheese (a – Sensory quality parameters; b – Percentage of maximum quality)

* Data marked with different lowercase letters are significantly different at $p<0.05$

Percentage of maximum quality for investigated cheese varieties was in the range 87.72-98.33% (Fig. 3b). Due to the highest scores for all investigated sensory parameters, cheese variant B had significantly higher ($p<0.05$) percentage of maximum quality and was evaluated as the best among investigated variants of white-brined goat cheese.

Conclusion

Four variants of goat white-brined cheese were produced according to the same technological procedure using different starter cultures (A, B, C, D). All variants were classified as full-fat and soft cheeses. As a result of different starter cultures, different trends and rates of proteolysis were observed. According to sensory evaluation, both variants B and C were rated as excellent with the average pondered mean values 4.92 and 4.56, respectively. Since variants A and D had slightly lower overall scores (4.47 and 4.36), their quality was evaluated as very good.

*Corresponding author: taygun@bingol.edu.tr

Abstract

Livestock sector in Van province of Eastern Anatolia is an important source of income for the local people. The objective of this survey is to present the current situation and the potential of buffalo husbandry and breeding opportunities in Van province of Eastern Anatolia in Turkey. However, it is possible to say that water buffalo breeding has decreased considerably for last years. Even though this is the case, especially buffalo husbandry is indispensable for indigenous people. Van province is one of the most prominent cities of this area in which its public sustain themselves by animal production, because there are many wetlands in Van province. For this reason, buffalo husbandry should be expanded in Van province. According to the results of research, the dilemma as such as low yield in buffalo, low number of animals raised, limited marketing opportunity, insufficient reproductive cycle of the animal, insufficient technical knowledge, inadequate cooperatives, inadequate and expensive veterinary service are most problems to create efficient breeding programs. According to the data of 2020, there are a total of 1001 head buffalo in Van province. In Van province of Eastern Anatolia, buffalo husbandry participates with 0.71% in general livestock production in Turkey with very low share. Anatolian buffalo breed is more common in this region. Anatolian buffalo, among Mediterranean water buffalo which are subgroup of river buffalos, is raised in Turkey. Milk yield, lactation period, birth weight of calves, and daily live weight gain during feeding in Anatolian buffaloes are 800-1000 kg, 200-250 days, 30 kg, and 550-600 g, respectively. The buffalo milk from this breed is consumed by the household as raw milk. As a result, the preservation and the development of Anatolian buffalo breed as a genetic source is very important. Water buffalo breeding needs to be developed in Van province.

Keywords: *Buffalo milk, Husbandry, Improvement, Van province, Water buffalo.*

Introduction

Water buffaloes in Turkey are believed to have originated from Mediterranean water buffaloes, which are a sub-group of river water buffaloes, and are called Anatolian water buffaloes (Soysal, 2006). Water buffalo farming has advantages related to the resistance of water buffaloes to natural conditions and diseases, their ability to benefit from feed and to turn poor feed into meat and milk, and finally, their low cost compared with cows (Canbolat, 2012). The number of animals in Turkey has decreased significantly in the last thirty years. The decrease in the number of buffaloes is more serious. In particular, the support given to livestock in recent years has led to an increase in the number of animals in Turkey. This increase was also reflected in buffalo breeding.

Water buffalo husbandry in Anatolia has been adapted to regional differences and has been characterized by the prominence of different applications. With the inquiry works, results are determined as yield of buffalo is low, the number of animals raised are very small, possibility of marketing is restricted, breeding condition of animal is inconvenient, technical knowledge is insufficient, membership at the cooperative is incapable, veterinarian service is expensive. Genetic improvement offers solutions for satisfaction of needs in livestock husbandry.

Livestock in Eastern Anatolia province are mostly carried out with traditional methods. Therefore, it will provide contribution to knowledge of the current problems of the industry in the province the current situation of the livestock sector and needs to be determined and the current situation to the steps taken to improve (Şeker and Köseman, 2015). The first practices that should be done to increase the profitability in livestock enterprises should be directed to environmental regulations. As the environmental factors improve, the genotype needs to be improved accordingly (Öztürk, 2009).

Muş province was chosen as the research area in this study as one of the important provinces for water buffalo farming in the East Anatolia region in Turkey. Few studies of water buffalo farming have been found as a result of a literature review. There are no studies on water buffalo farming in Muş province. Agriculture is the major source of income in the province, and the pasture and meadow areas suitable for livestock have a high potential for new investments. The number of water buffaloes was 13749 head in 1991, and declined sharply to 3296 head in 2009. After this year, it started to increase with animal husbandry support by the government (Işık and Gül, 2016).

The most common diseases in buffalo husbandry enterprises of Van province are foot and mouth disease, brucellosis, mastitis. Farmers are generally evaluating their milk themselves. Mostly, farmers are milking by hand.

Livestock activities in Van province of Eastern Anatolia are an important source of income for the local people. Van province is one of the most prominent cities of this area in which its public sustain themselves by animal production. For this reason, it is very important to define the condition, potential, and problems of breeding sector especially with respect to the water buffalo stock in this province. The aim of this survey is to put forward the current situation and the potential of water buffalo husbandry and breeding opportunities in Van province of Eastern Anatolia in Turkey.

Demographic Structure of Van Province

Van province is located in Lake Van in Eastern Anatolia Region Chapter of the Upper Murat-Van in a closed basin on Turkey. The border with the Iranian State lies to the east of Van. Van is surrounded by Van Lake from west. It is also surrounded by cities such as Ağrı from north and Bitlis from west, Siirt, Şırnak, Hakkari from south and Iran from east. Van city is nineteenth the most crowded city in Turkey. As of the end of 2019, its population is 1.136.757 people. Van is the fifth largest province in terms of surface area in Turkey. Its area is 21.334 km^2. Although Van Lake and its valleys are covered with rich vegetation, the mountains are generally barren (Anonymous, 2021). Economy of Van province is an economy mainly based on agriculture and animal husbandry, aquaculture, and tourism. The livestock sector in Van province has been developing and gaining importance day by day.

As Van province is in the lower status in terms of socio-economic development (in the 5th level), its unemployment rate high and employment rate low, and more than half of the working population in different sectors is concentrated on the agriculture sector significant migrations occurred in the province (Elmastaş and Yılmaz, 2015). The educational status of the buffalo farmers and families of Van province is low. This will have a negative impact on the care and feeding of animals and the productivity of the products to be obtained. For this purpose, meetings where business owners can get technical information can be organized and small units can be created and information can be transferred from village to village. Thus, it will be contributed both to the conscious raising of animal husbandry and the economy of the country.

The Importance of Water Buffalo Husbandry in Van Province

Buffalo production is an industrial sector that they transform the natural vegetation cover pasture and the pasture not used in the agriculture into the products such as meat and milk. Buffalo production is indispensable and an important source of income for farmers in Van province. Van province is suitable for both the small ruminant breeding and the cattle and the water buffalo husbandry in terms of large pasture areas, water resources, and climate characteristics.

The purpose of sheltering animals is to eliminate the negative effects of the environment on animals within economic limits and to provide comfortable living conditions suitable for their behavior. For this reason, when designing animal shelters, they should be dimensioned so as to provide sufficient space and internal detail for the movement, social, feed and water drinking behaviors of animals, and should be kept within economic and optimal limits in care management and hygienic conditions (Mutaf et al., 2001).

It can be said that the province is rich in terms of underground and surface irrigation sources as well as a suitable land structure for the production of forage crops. However, small ruminant husbandry is a major industrial sector in Van province in the Eastern Anatolia of Turkey (İnan and Aygün, 2018). Meanwhile, it is directly dependent on the involvement of the breeder to be successful in all studies to improve breeding and environmental factors at the breeder level.

It is important to understand the socio-economic characteristics of water buffalo farmers. This was done with the hope of identifying those characteristics that may impact and also help to explain the farming activities of the area. The characteristics considered were age, educational attainment, household size, land acquisition type, farming experience, agricultural land, and farm output sizes. Lack of information on benefits of water buffalo dairy products creates an important problem in the marketing of these products for farmers. Therefore, infrastructures required for promotion of water buffalo dairy products should be prepared and policies related to promotional advertisement should be implemented. To reach the desired level of water buffalo farming, incentives on water buffalo should be maintained, policies should be improved by using input subsidies, producers should be trained on water buffalo farming, and improvements in policies of promotion and benefits of water buffalo dairy products may be useful for establishing a water buffalo culture in Turkey. Maintaining traditional methods in water buffalo farming prevents targeted efficiency expectations. Therefore, transferring new modern husbandry techniques to producers is an important issue for policy makers. (Işık and Gül, 2016).

Number of Buffalo in Van Province

Characteristics of buffalo husbandry in Van province are small farms with 2 to 3 cows per farm (80-85% of total number of farms). The most common of buffalo breeds in Turkey is the Anatolian water buffalo breed. It is very important to define the condition, potential and

problems of breeding sector especially with respect to the water buffalo, the cattle, sheep, and goat stock in this province. Correspondingly, it could be possible to find short, average and long term solutions for the identified issues. The most important of these problems is roughage.
Inventory studies constitute the basis of all kinds of studies that are planned to be carried out at national or regional level. Therefore, important suggestions for the Van region will be presented with this study. Number of buffalo and cattle is presented in Table 1 in Turkey and in Table 2 in Van province.

Table 1. Number of buffalo and cattle in Turkey (head) (TOB, 2021).

Year	Buffalo	Cattle	Total
2015	133766	13994071	14127837
2016	142073	14080155	14222228
2017	161439	15943586	16105025
2018	178397	17042506	17220903
2019	180826	18070500	18251326
2020	188771	18626219	18614990

Table 2. Number of buffalo and cattle in Van province (head) (TOB, 2021).

Year	Buffalo	Cattle	Total
2015	264	166944	167208
2016	308	162172	162480
2017	394	185349	329688
2018	536	176438	176974
2019	490	179713	180203
2020	485	185240	185725

The numbers of indigenous water buffalo are low and there is need for conservation and spread of indigenous pure breeds on other suitable areas. In Van province of Eastern Anatolia in Turkey, the indigenous water buffaloes are found to be small in numbers. Therefore, the milk productivity of the indigenous buffalo is very low. Improvement in productive and reproductive performance is the key for increase the milk production. There is need to increase the milk production in relatively low performing dairy sates to achieve future milk demand and make dairy farming sustainable for farmers.
Since the farms in the region are small and the prices of inputs are high, water buffalo farming has not developed enough to reach the level of market-oriented production. Therefore, policies should be made according to the size of farms in the region and more economical production can be achieved by solving market-related problems. The milk productivity of water buffaloes in the region is low and it is more obvious especially on small farms. Thus, milk yield could be increased by animal improvements. In this way, milk yield could reach a desired level (Işık and Gül, 2016).

Buffalo Products in Van Province

It is considered that the size of the establishment has no effect on cattle and buffalo breeding practices (Özyürek et al., 2014). Unfortunately, in most of the enterprises studied in the region, there are no suitable environments for animal husbandry. The environmental conditions must be arranged so as to be suitable for animal husbandry. In accordance with the regulation of environmental conditions, breeders must be equipped as technical information. As a result, the profits of the breeders will increase with the livestock breeding in the region and will contribute to the country's economy. Meat and milk products from buffalo in Turkey are presented in Table 3. In Turkey, there are serious problems in the use of litter that provides dryness and softness in the sleeping and resting places of animal farms. In large-scale researches conducted in 2016, it is observed that the bodies of buffaloes and cows in milk processing are unacceptably dirty (up to 70%), thus causing frequent foot, breast and reproductive health and milking hygiene problems (TOB, 2021).

Table 3. Meat and milk products from buffaloes in Turkey (tons) (TOB, 2021).

Year	Meat	Milk
2015	326	62751
2016	351	63085
2017	1339	69401
2018	402	75742
2019	73	70341
2020	250	75300

It is extremely important that the breeders and the organizations engaged in animal husbandry have knowledge of occupational health and safety. The nature of livestock husbandry requires organization that is its own appropriate in accordance with local conditions for the occupational health and safety. These organizations should be units that are tried to be prevented by determining at the source of the danger. For this aim, the risks at work should firstly be determined. Then, solution suggestions should be presented to remove or minimize these risks.
Zoonotic diseases are one of the most important problems of workers in animal husbandry. Workers and animals must be vaccinated against various zoonotic diseases. The rules of order and hygiene must be taken into accounted during the milking and the shearing of the animals. Improved water supply should be combined with improved sanitation, special needs of workers, and a separate toilet in each household to facilitate personal hygiene. Taking precautions for occupational health and safety are very difficult, costly and time consuming. Also, not all agricultural activities carry the same risk, and, as noted above, there are many special populations that must be considered.

Conclusion

Like the Asian countries, buffalo breeding in Turkey has been performed by traditional methods and production per cow is low in comparison with intensive buffalo production systems such as Italy, but little is known about variation of production traits. All scientific research so far has shown that the water buffalo husbandry in this region is also done in the traditional production system. In addition we think that databases for Anatolian buffaloes have under developed, showing that they have a wider range of data because of problems in herd management system. Especially in some seasons, buffaloes have been hold at night outside, and therefore in these regions it is difficult to develop and pursue the effective data collect processes. Van province has ecological conditions suitable for animal production. In Van province of Eastern Anatolia, buffalo production participates with 0.71% in general livestock production in Turkey with very low share. The most common of buffalo breeds in Van province is the Anatolian buffalo breed. The milk from this buffalo breed is either consumed by the household as raw milk or in making cream and yoghurt. As a result, preservation and development of native buffalo breed as a genetic source is very important. If the current potential especially in the Eastern Anatolian Region and in Turkey is evaluated, it can become very important in this region. It can be said that Van province has an important place in terms of its features for buffalo presence and animal production.

OCCUPATIONAL HEALTH AND SAFETY CULTURE IN ANIMAL PRODUCTION IN TURKEY

Turgut AYGÜN*

Department of Animal Science and Animal Nutrition, Faculty of Veterinary Medicine, Bingöl University, Bingöl, Turkey
*Corresponding author: taygun@bingol.edu.tr

Abstract

Animal production has an important place in agricultural activities. The aim of this review is to provide sensitivity about occupational health and safety, accidents, diseases, and musculoskeletal disorders in animal production sector in Turkey. It is also aimed to provide suggestions for occupational health and safety that increase production in animal breeding. The livestock activities in Turkey have been characterized by the different regional applications. Animal production is associated with a variety of occupational illnesses and injuries. The issue of occupational health and safety in animal production is very important as it is in many other areas. In practical work related to crop and livestock production to ensure safety and to prevent accidents at work, it is important to take necessary precautions. In such an environment and in a certain direction, employees are exposed to occupational accidents. Farm workers can often experience unavoidable health problems and even death may occur. In addition, there is also a risk of contracting an occupational disease that may occur in the future in livestock farming. The most common hazards at the animal production in Turkey are the zoonotic diseases, the ergonomics, the noise, the air conditioning, the chemicals, the animal attacks, the bites, the injuries, the accidents in transport, the psychological stress, and the skin-borne diseases. Especially, the animal hitting and the zoonotic diseases are very important in animal husbandry. Therefore, the precautions related to the occupational health and safety must be taken for the workers at the livestock enterprises, the field, and the factories dealing with the feed, skin, and meat. In Turkey, preventive measures have started to be taken on occupational health and safety in livestock production. This information has been prepared based on the personal observations and the experiences directly in the local area.

Keywords: *Animal production, Occupational disease, OHS culture, Zoonotic disease.*

Introduction

The Occupational Health and Safety (OHS) has a vital importance in livestock production. It has also significant economic implication particularly in terms of medical costs and economic productivity losses. Occupational safety and accident risk factors of revealing awareness of breeders are not yet fully come to avoid. The livestock activities in Turkey have been characterized by the different regional applications. Animal production has an important place in agricultural activities. There are many factors which limit the economic efficiency for production. One of them is production losses due to the workplace accidents and the occupational illness. The issue of occupational health and safety in animal production is very important as it is in many other areas (Aygün et al., 2014; 2019a).

Occupational diseases and accidents that can be encountered by workers at business have caused the losses of very serious economic and the qualify person in animal production. In addition, the sustainability of production is negatively affected. The most common hazards at the animal production in Turkey are the zoonotic diseases, the ergonomics, the noise, the air conditioning, the chemicals, the animal attacks, the bites, the injuries, the accidents in transport, the psychological stress, and the skin-borne diseases etc. Especially, the animal hitting and the zoonotic diseases are very important in animal husbandry. Therefore, the precautions related to the occupational health and safety must be taken for the workers at the livestock enterprises, the field, and the factories such as the feed, the skin, and the meat (Aygün et al., 2019b).
The risk factors that the livestock workers faced vary according to the sector. In sheep-goat husbandry, the most important task in the care-feeding and management of animals falls into workers. Occupational Health and Safety (OHS) has significant economic implication particularly in terms of medical costs and economic productivity losses.
Sheep and goat breeding in Anatolia has been adapted to regional differences and has been characterized by the prominence of different applications (Aygün, 2017). It is true that more occupational health and safety intervention research focusing on preventing illness and injury needs to be conducted. Conducting this type of research is difficult and time-consuming; however, without increasing the number and methodological rigor of these studies, it will be difficult to identify effective intervention methods and confidently encourage their use (Goldenhar and Schulte, 1996). Animal production is associated with a variety of occupational illnesses and injuries.
The object of this review is to provide sensitivity about occupational health and safety, accidents, diseases, and musculoskeletal disorders in animal production sector. It is also aimed to provide suggestions for occupational health and safety that increase production in animal breeding. This information has been prepared based on the personal observations and the experiences directly in the local area.

The Place and Importance of Animal Production in Turkey

The livestock activities in Turkey have been characterized by the different regional applications. The activities of animal breeding sector are especially an important source of income for the indigenous people in Turkey.
Commonly, it was aimed to be offered some information about living culture and stockbreeding activities of nomadic tribes that they come from the south to east because of weather warming up with. Studies made by some researchers in order to achieve their political goals on political and ideological studies relating to a multi-ethnic structure and stockbreeding activities that is the main source of income of the politicized tribes were the main theme of this study. One of the most important issues to be taken into account for sustainable animal breeding sector in Turkey is no doubt farming culture. Some researchers have emphasized that culture of communities consisted of some narrow range cultures, and that national culture also consisted of many local, regional, or sub-cultural backgrounds (Aygün et al., 2013; İnan and Aygün, 2019).
In Turkey, livestock sector has a considerable potential and is an important part of agricultural sector and economy. The livestock products, including meat, milk, eggs, honey, wool, and hides, play a significant role in the Turkish economy. In general, animal production constituted approximately 25 % of agricultural production value. The sector's contribution to farm income is substantial, and activities related to livestock production and marketing are important to the

economic development of rural areas in Turkey.. In parts of country where agriculture and farming are limited because of land shape or limited land and high number of population, households make their living with animals, especially in Eastern and Southeastern Anatolia. However, in these regions, mostly traditional techniques are used, and the results are not much satisfactory when compared to developed countries.

Livestock products are an important source of household income for many farmers and households in rural areas. For small farmers, livestock products such as cattle, sheep and goat generate income and ensure food security for these households because an important amount of their incomes comes from the sales of animal and milk.

The Most Common Occupational Accidents in Animal Husbandry

The hazard is anything that has the potential to harm. Hazard can affect the person, the material and the process. Also, hazards can cause accidents, diseases, loss of product, and machine damage etc. The occupational risk refers to the combination of the likelihood and severity of an injury or illness resulting from exposure to a hazard.

Since livestock workers spend a great deal of time outdoors, they are at risk for physical stress from excessively cold and excessively hot environments. The magnitude of heat and cold stress problems in agriculture is not well documented. Tolerance to such environments varies among individuals and may be difficult to predict. Livestock workers should be provided the means to compensate for extremes of temperature. For example, adequate water supplies while working outdoors in hot climates are essential.

In animal husbandry sector, the most important task in the care-feeding and management of animals falls into workers.

Workers who are away from social habitats and who work in the hills may be exposed to allergies or poisoning caused by the attack of various wild animals, such as bee or insect bites, as well as plants grown in the spring, pollen of fungi or various flowers. Employees are camels exposed to the sun because the work area is mostly open space. Therefore, excessive exposure to sunlight can cause dermatological problems.

Since livestock workers spend a great deal of time outdoors, they are at risk for physical stress from excessively cold and excessively hot environments. The magnitude of heat and cold stress problems in agriculture is not well documented. Tolerance to such environments varies among individuals and may be difficult to predict. Livestock workers should be provided the means to compensate for extremes of temperature. For example, adequate water supplies while working outdoors in hot climates are essential.

Workers in animal husbandry have exposure to other hazards that may increase their risk of health problems: climate-dependent problems, such as heat stroke or cold shock, and occupationally caused infections such as *anthrax, ascariasis, encephalitis, leptospirosis, rabies, salmonellosis, tetanus, and coccidioidomycosis.* Sensory problems are common: eye problems, caused by irritation, infection, or injury from the wind, sun, dust or soil, agricultural chemicals, debris ejected from farm machinery, and allergic reactions to plants, and hearing problems due to noise from farm machinery and cannery work.

The Most Common Occupational Diseases in Animal Production

An "occupational disease" is any disease or disorder contracted primarily as a result of an exposure to risk factors arising from work activity. "Work-related diseases" have multiple causes, where factors in the work environment may play a role, together with other risk factors, in the development of such diseases. The World Health Organization emphasizes the following: Carrying our estimates of the global burden of disease from major occupational risks, such as injuries, airborne exposures, carcinogens, ergonomic stressors, noise and other specific risks. Working with ILO to develop diagnostic and exposure criteria for occupational diseases and to enable primary and secondary health care providers to detect and report such diseases (WHO, 2020).

The most common risk factors at animal production sector in Turkey are the ergonomics, the noise, the air conditioning, the chemicals, the occupational diseases, the zoonotic diseases, the animal attacks, the bites, the injuries, the accidents in transport, the psychological stress and, the skin-borne diseases etc. Occupational diseases and accidents that can be encountered by workers have caused the losses of very serious economic and the qualify persons in animal husbandry. Therefore, the precautions related to the occupational health and safety must be taken for workers at the husbandry and the field (Aygün, 2017).

Zoonotic disease is naturally called vertebrate animals to humans, and humans to animals to diseases or infections. Zoonoses are infections that are spread from animals to humans. The World Health Organization (WHO) defines zoonotic diseases as 'any diseases or infections that are naturally transmitted between vertebrate animals and humans.' Agents causing zoonotic diseases may be bacteria, fungi, viruses, parasites or any other communicable agents, for example prions. Currently there are over 200 recognized zoonoses, some of which have a worldwide distribution and others which are localized to specific regions. The situation is not static, and emerging zoonotic diseases are continually being recognized, both animal diseases which have spread to humans for the first time and existing zoonoses spreading to new geographical areas. Occupational zoonotic diseases are most common where there is close contact between animals and humans at work, for example in animal husbandry and agricultural occupations, although workers in a wide range of other occupations may also be exposed to zoonotic agents, including those employed in the outdoor leisure industry or the waste water industry and laboratory workers. There are many occupational zoonotic diseases in the world, many of which occur very rarely, although some do pose a significant health risk for workers in certain occupations. While the incidence of specific zoonoses varies from country to country, there are many occupational zoonoses that occur across Europe, although not every disease is present in every country. (Cook and Farrant, 2020)

Other health and safety risks include skin problems, hearing loss, stress, and mental well-being issues particular to farming and the rural way of life. Occupational skin disorders are common in livestock workers. The effects of sun exposure are an important cause of morbidity in animal breeders group. Farmers' lung is one of many forms of *hypersensitivity pneumonitis*. This problem is becoming rare, which is likely due to the reduction of exposure to organic dust from the increasing mechanization of agriculture and the effect of livestock health and safety programs (Von Essen and McCurdy, 1998). Another danger for farmers is the waste of animals. Animal wastes are frequently stored underground and are a source of toxic gases. Entering confined spaces used for manure storage can lead to fatalities, which are often caused by hydrogen sulfide exposures (Von Essen and McCurdy, 1998).

Some Suggestions and Possible Preventions

It is extremely important that the breeders and the organizations engaged in animal production have knowledge of occupational health and safety. The nature of animal production requires organization that is its own appropriate in accordance with local conditions for the occupational health and safety. These organizations should be units that are tried to be prevented by determining at the source of the danger. For this aim, the risks at work should firstly be determined. Then, solution suggestions should be presented to remove or minimize these risks.
Zoonotic diseases are one of the most important problems of farmers in animal production. Workers and animals must be vaccinated against various zoonotic diseases.
With regard to the control of occupational zoonoses, there are some general control measures which reduce the risk of infection for a wide range of zoonoses. These include the following:

- good personal hygiene practices, especially washing with soap and warm water;
- covering cuts and scratches with waterproof dressings;
- wearing of appropriate PPE, for example gloves, overalls, respiratory protection – this must provide relevant protection, while also being suitable for carrying out the required task;
- good hygiene practices for animal husbandry; and
- use of an appropriate disinfectant to clean potentially contaminated areas.

For certain zoonoses, there is an effective vaccine available and it may be appropriate to administer this to individuals in high risk occupations, for example laboratory workers handling infected animals. In many cases there are effective prophylaxis and treatments available. For these to be used to maximum advantage, it is necessary for workers to be aware of any diseases they may be at risk from and to be able to recognise early symptoms of these diseases. For certain occupations it may be required for workers to inform their employer if they have a weakened immune system (Cook and Farrant, 2020).
The rules of order and hygiene must be taken into accounted during the milking and the shearing of the animals. Improved water supply should be combined with improved sanitation, special needs of women workers, and a separate toilet in each household to facilitate personal hygiene.
These approaches are necessary to obtain the cooperation of nomadic workers and their employers so that occupational exposures and protection as well as health consequences are accurately and completely ascertained. In addition, information about health effects should be obtained in a way that is not only culturally sensitive but also meaningful to study participants and yet comparable to that obtained through standardized instruments. Undertaking studies of occupational health risks in this population with these considerations will not only contribute to the understanding of such risks but can also further preventive efforts and lead to better health in this high-risk population. Effective prevention can reduce suffering and death and contribute to enhanced productivity in the workplace. In this way, both the employers and the employees gain (Aygün and Demir, 2015).
Taking precautions for occupational health and safety are very difficult, costly and time consuming. Among the difficulties is the varied nature of agriculture, the many ethnic groups engaged in the activities, the traditionalist view of farming families, and rapidly changing technology. Also, not all agricultural activities carry the same risk, and, as noted above, there are many special populations that must be considered.
There are many factors which limit the economic efficiency for production. One of them is production losses due to the workplace accidents and the occupational illness. The issue of

occupational health and safety in animal production is very important as it is in many other areas. Occupational diseases and accidents that can be encountered by livestock workers at business have caused the losses of very serious economic and the qualify person in animal production (Aygün, 2015).

As a result, the work-related accidents encountered workers in the plateau have also been emphasized. This information has been prepared based on the personal observations and the experiences directly in the local area. There are many factors which limit the economic efficiency for production. One of them is production losses due to the workplace accidents and the occupational illness.

The issue of occupational health and safety in animal production is very important as it is in many other areas. In addition, the sustainability of production is negatively affected. Occupational accidents and diseases that can be encountered by workers have caused the losses of very serious economic and the qualify persons in animal husbandry sector. Therefore, the precautions related to the occupational health and safety must be taken for workers at the husbandry and the field. There are a number of characteristics of Turkish agriculture that need to be acknowledged for an effective occupational health and safety response to the farm injury or illness problem. In Turkey, preventive measures have started to be taken on occupational health and safety in livestock production.

NOMADIC ACTIVITIES OF SMALL RUMINANT HUSBANDRY IN MUŞ PROVINCE OF EASTERN ANATOLIA IN TURKEY

Turgut AYGÜN*

Department of Animal Science and Animal Nutrition, Faculty of Veterinary Medicine, Bingöl University, Bingöl, Turkey

*Corresponding author: taygun@bingol.edu.tr

Abstract

In this survey, the nomadic life culture and the nomadic small ruminant husbandry in Muş province of the Eastern Anatolia Region in Turkey have been discussed. Also, detailed information about nomadic families in Muş province dealing with stockbreeding activities has been given. This information has been prepared based on the personal observations and the experiences directly in local area. Stockbreeding activities of nomadic and semi-nomadic tribes have been examined. The migrants are mostly from Şırnak, Batman, Mardin, and Siirt provinces to the Muş highlands. These migrants make as pedestrian their arrival and return to the plateau. Shepherds in their family are responsible for maintenance and feeding of animals on the plateau. According to the data of 2020, there are a total of 1,235,552 head goats and sheep in Muş province. In the highland small ruminant husbandry towards the end of the spring, animal herds are taken to the plateaus which are cool and grassy as opposed to the drying of pastures and the start of heat. For a period of 3-5 months, sheep remain in control by shepherds in highland. After the weather cools down, highland breeders and sheep return to villages or to their settlements. Sheep herds usually consist of 300 to 500 heads. One of the most important issues to be taken into account for sustainable small ruminant husbandry in this region is no doubt the nomadic life culture. In order to get more abundant products such as milk, cheese, wool and so on, the people of the region have to go to highlands with the arrival of spring to find better grazing and water areas for animals. The results indicate that solving the problems of nomadic and semi-nomadic families is very important to sustain stockbreeding of sheep and goats, and to benefit Muş province economically.

Keywords: *Goat husbandry, Muş province, Nomadic life, Sheep husbandry Transhumance.*

Introduction

Sheep and goat production is an industrial sector that they transform the natural vegetation cover pasture and the pasture not used in the agriculture into the products such as meat, milk, and wool. Eastern Anatolia Region of Turkey has a different character than other regions in terms of climate conditions. In the winter months, when there are severe storms in this region, extreme cold occurs. Muş is one of the most prominent cities of this area in which its public sustain themselves by animal production. The socio-economic and cultural structure, climate, and topographic features of the region have played a role in gaining importance of sheep breeding. Sheep breeding has a special place and importance in animal production in Muş province. According to the investigations in the region, sheep breeding pasture-based are dominant (Aygün et al., 2019; İnan and Aygün, 2019). For this reason, it is very important to define the condition, potential, and problems of breeding sector especially with respect to the small ruminant husbandry in this city.

It can be said that the fact that sheep breeding is carried out in herd rather than management level at the enterprise level has an important effect on the spread of plateau and nomadic sheep farming with the effect of structural difference. This situation is more evident in the Eastern and Southeastern Anatolia Region in Turkey. In this sense, since sheep farming is mostly done by nomadic families or tribes, it is important to compile information about this section and to determine the general characteristics of the nomadic families (Aşkan and Aygün, 2020).

Animal production is one of the most important economic sectors of Turkey. Sheep production systems in Turkey depend on factors such as the natural and socio-economic conditions of the regions, the availability of feed resources, the connection to plant production and, the consumption habits of the population. These are systems of the stock breeding, the highland sheep husbandry, and the nomadic livestock breeding (Kaymakçı, 2010).

Livestock in Eastern Anatolia province are mostly carried out with traditional methods. Therefore, it will provide contribution to knowledge of the current problems of the industry in the province the current situation of the livestock sector and needs to be determined and the current situation to the steps taken to improve (Şeker and Köseman, 2015).

This review concludes that the nomadic activities and the production habits of breeders in sheep and goat have been discussed. This information has been prepared based on the personal observations and the experiences directly in local area.

Demographic Structure of Muş Province

Muş province is a province in eastern Turkey. It is 8,196 km^2 in area and has a population of 406,886 according to a 2010 estimate, down from 453,654 in 2000. The provincial capital is the city of Muş. It is surrounded by cities such as Erzurum from north, Bingöl from west, Siirt and Diyarbakır from south and Van from east (Anonymous, 2021). Economy of Muş province is an economy mainly based on agriculture and animal production. Livestock sector in Muş province is developing day by day and gaining importance.

The educational status of breeders and families of Muş province is low. This will have a negative impact on the care and feeding of animals and the productivity of the products to be obtained. For this purpose, meetings where business owners can get technical information can be organized and small units can be created and information can be transferred from village to village. Thus, it will be contributed both to the conscious raising of animal production and the economy of the country.

The Importance of Small Ruminant Production in Muş Province of Eastern Anatolia Region in Turkey

Sheep production is an industrial sector that they transforms the natural vegetation cover pasture and the pasture not used in the agriculture into the products such as meat, milk and, wool. There are breeds such as White Karaman, Red Karaman, Awassi, Dağlıç, Kıvırcık, and Karayaka among local sheep breeds of Turkey (İnan and Aygün, 2019). Small ruminant production is indispensable and an important source of income for farmers in Muş province. Muş province is suitable for small ruminant breeding in terms of large pasture areas, water resources, and climate

characteristics. It can be said that the province is rich in terms of underground and surface irrigation sources as well as a suitable land structure for the production of forage crops.
Sheep and goat in this region has been adapted to regional differences, and has been characterized by the prominence of different applications. In the highland sheep production, sheep flocks are removed to the highlands with cool and plenty of grassy plains by pressing hot and dry towards the end of spring.
Sheep and goat production systems in Turkey depend on factors such as the natural and socio-economic conditions of the regions, the availability of feed resources, the connection to plant production and, the consumption habits of the population. These are systems of the stock breeding, the highland sheep husbandry, and the nomadic livestock breeding.
For a period of 3-5 months, sheep remain in control by shepherds in the highland. After the weather cools down, sheep go back to the villages or the farms in the plain. Sheep herds usually consist of 300 to 500 heads. Each sheep is composed of lots of different people with a lot of expenses, depending on the number of animals contributes. Sheep herds were formed by gathering business owners with a different number of animals. Sheep herds are taken to the highlands by grazing or by road transport.

Nomadic Activities in Small Ruminant Production in Muş Province of Eastern Anatolia Region in Turkey

One of the most important examples of livestock farming is highland small ruminant husbandry in Muş province. In order to get more abundant the products such as milk, cheese, wool and so on, the people of the region have to go to the highlands with the arrival of spring animals to find better grazing and water areas. With the arrival of spring to the first zone in the region is exited. With the start of the cold days of autumn again return to the settlements. In this province, it is recommended to keep records in order to obtain a sustainable income source from small ruminant production. Meanwhile, it is directly dependent on the involvement of the breeder to be successful in all studies to improve breeding and environmental factors at the breeder level.
The purpose of sheltering animals is to eliminate the negative effects of the environment on animals within economic limits and to provide comfortable living conditions suitable for their behavior. For this reason, when designing animal shelters, they should be dimensioned so as to provide sufficient space and internal detail for the movement, social, feed and water drinking behaviors of animals, and should be kept within economic and optimal limits in care management and hygienic conditions (Mutaf et al., 2001). The numbers of indigenous sheep and goat are high and there is need for conservation and spread of indigenous pure breeds on other suitable areas. In Muş province of Eastern Anatolia in Turkey, the indigenous sheep and goat were found more in numbers. But the milk productivity of the indigenous sheep and goat breeds is very low. Therefore, improvement in productive and reproductive performance of sheep and goat is the key for increase the milk production. There is need to increase the milk production in relatively low performing dairy sates to achieve future milk demand and make dairy farming sustainable for farmers. The population of sheep and goat in its native tract is decreasing steadily and there is no information on its present status in its home tract. Pure animals are still found in and around Muş province. The sheep-goat breeders in this region are forced to migrate from the home tract to the cities along without their flocks and herds, due to economic and social problems of the region. Migration realised during the 20 years. In this process, they sold their

animals. During the course of migration, the number of sheep and goat in the region decreased steadily. In the current time they are returning back to their dwellings systematically.

The Importance of Berivans and Shepherds in Small Ruminant Production

Berivan and shepherd workers are inseparable parts of each other. They are the most important workers of highland and nomadic animal production. Their ages may range from 10 to 70. Berivan is called as women milking the ewe and the nannie. Milking in migrant small ruminant breeding systems is done by berivans. Berivans are not the only ones who are responsible for sheep milking. They are laboring at all stages of the processing of the obtained plumbing. Berivans and shepherds have many challenges for in nomadic small ruminant husbandry (Aygün, 2017). Berivans and shepherds are one of the most underserved and understudied populations in the Turkey. One characteristic of the traditional nomadic lifestyle group is that berivans and shepherds themselves are certain fixed tents that they find themselves under dangerous conditions and for long hours.

Overview of the General Problems of Small Ruminant Breeders in Highland

The most of sheep production in Turkey are carried out in extensive or semi-intensive systems. The most of sheep breeds reared in Turkey are characterized as rough-mixed wool genotypes and their wools are usually used to carpet, blanket, quilt and weaving socks. Turkey has an important place in the production of fleece with carpet type in the world. However, the wool industry and production in Turkey have not developed and fluctuations of the wool prices negatively affected the wool of production. Recently, there has been an increase for sheep production in Turkey and for use of rough-mixed wool in the world (Öztürk and Odabaşı, 2011).

One of the most important issues to be taken into account for sustainable small ruminant breeding in the region is no doubt nomadic living culture of tribes that they presented this culture and breeding system to nowadays. Some researchers have emphasized that culture of communities consisted of some narrow range cultures, and that national culture also consisted of many local, regional, or sub-cultural backgrounds.

Unfortunately, in most of the farms studied in the region, there are no suitable environments and management conditions for small ruminant husbandry. The environmental conditions must be arranged so as to be suitable for animal husbandry. In accordance with the regulation of environmental conditions, breeders must be equipped as technical information. As a result, the profits of breeders will increase with the livestock breeding in the region and will contribute to the country's economy.

In this region, there are serious problems in the use of litter that provides dryness and softness in the sleeping and resting places of small ruminant farms. In large-scale researches conducted in last years it is observed that the bodies of animal in milking and shearing processing are unacceptably dirty, thus causing frequent foot, breast and reproductive health, shearing, and milking hygiene problems (TOB, 2021).

It is extremely important that the breeders and the organizations engaged in animal production have knowledge of occupational health and safety. The nature of livestock husbandry requires organization that is its own appropriate in accordance with local conditions for the occupational health and safety. These organizations should be units that are tried to be prevented by

determining at the source of the danger. For this aim, the risks at work should firstly be determined. Then, solution suggestions should be presented to remove or minimize these risks.
Zoonotic diseases are one of the most important problems of workers in livestock sector. Workers and animals must be vaccinated against various zoonotic diseases. The rules of order and hygiene must be taken into accounted during the milking and the shearing of the animals. Improved water supply should be combined with improved sanitation, special needs of workers, and a separate toilet in each household to facilitate personal hygiene. Taking precautions for occupational health and safety are very difficult, costly and time consuming. Also, not all agricultural activities carry the same risk, and, as noted above, there are many special populations that must be considered.
Sevinç (1972) reported in her study in this region that collected the solutions of the problems of nomadic ovine livestock in 5 items in general and said that it is necessary;
-To protect the pasture and meadow vegetation in the winter lands with the highland and highland slopes and to take continuous measures to ensure their development,
-To identify and secure migration routes in the most convenient way,
-To provide a continuous and secure market order for migratory sheep breeders,
-To improve and increase the efficiency of the nomadic ovine animals with effective measures compatible with the lives of migratory ovine livestock families,
-To bring order to a structure that will modernize ovine livestock within a certain period of time for migratory sheep breeders. Unfortunately, it can be said that these problems are still not resolved today.
One of the most important problems of the immigrants in the region is undoubtedly related to the education of our children, especially girls, which is emphasized in every platform that is important in the future of the country. Children can always start their education life one step behind. Girls do not even have such a chance, in this way of life.

Conclusion

In this paper, the nomadic activities and the production habits of breeders in sheep and goat production have been discussed in Muş province of Turkey. This information has been prepared based on the personal observations and the experiences directly in local area. Muş province has ecological conditions suitable for sheep and goat presence and animal production. If the current potential especially in Muş province is evaluated, it can become very important in Eastern Anatolia Region of Turkey. It is hoped that it has now been understood by the state that migratory breeders, which have been neglected in many ways for many years, are people engaged in animal production in the Eastern Anatolia Region of Turkey. The results indicate that solving the problems of nomadic and semi-nomadic families is very important to sustain stockbreeding of sheep and goats, and to benefit Muş province economically.

Abstract

One of the most important food-related pathogens worldwide is Campylobacter. The aim of this study was to compare eggs obtained from different egg production systems in terms of *Campylobacter*. In the study, four different egg production systems were used: Conventional cage system, enriched cage system, barn system and free-range system. In the conventional system, the stocking density is set to 600 cm^2/hen. The enriched cages contain that the hens must have at least 750 cm^2 of floor space per hen, a nest, perches, and litter. In the free-range system, seven animals per square meter were housed in the indoor area. In outdoor, an area of 4 m^2 is set for each animal. In the free system, there are walking areas where animals can stay in the open area for at least 8 hours. Housing hens in non-cage alternative systems, such as free-range, floor systems, and aviary systems, allow them to express their natural behaviors with more freedom of movement. The hens were fed with 18% HP and 2800 kcal ME/kg during the experiment. In the study, there were four experimental groups, and each experimental group were formed from four replications. Twenty chickens in each replication and eighty chickens in each group were used. ATAK-S, one of our domestic hybrids, was used as animal material. *Campylobacter spp*. enumeration were made in 5 randomly taken eggs from each group for a total of 2 times, at the 34^{th} and 36^{th} weeks of the laying period. *Campylobacter* was not detected in any of the eggs obtained from all egg production systems in both periods. As a result, it is clear that there will be no problems for humans in different egg production systems in terms of *Campylobacter*.

Keywords: *Conventional cage, enriched cage, barn systems, free-range system, Campylobacter.*

Introduction

In many countries of the world, the cage rearing system is dominant in the rearing of layer hens and this situation will probably continue for a long time. The reason for this is that raising chickens in cages is the most economical mode of production, the price of eggs is low and the product reaches all segments of the society (Rakonjac *et al*., 2017). Conventional cage egg production has been banned in European Union countries since 2012 and egg production has been suggested to be done in alternative systems (EU, 1999). One of these production systems is the free-range system.

Campylobacteriosis is the most frequent zoonotic disease in humans worldwide (Ghareeb *et al*., 2013). The case of human campylobacteriosis, which is characterized by watery and bloody diarrhea in humans, occurs in approximately 2-5 million cases in humans in the United States (Friedman *et al*., 2000).

Cases of campliobacteriosis in humans can generally occur with consumption of raw poultry meat, contact with pets, consumption of raw milk and meat, and water (Friedman *et al*. 2000; Jacobs-Reitsma 2000; Corry and Atabay 2001; Park 2002). While Jones and Musgrove (2007) found thermotolerant Campylobacter infection in 1.1% of eggshells, Sato and Sashihara (2010) reported that 27.9-36% of pasteurized liquid eggs were positive for Campylobacter.
The aim of this study is to compare eggs obtained from different egg production systems in terms of *Campylobacter strains*.

Material and Methods

This study was carried out at Selcuk University, Agriculture Faculty, Department of Animal Science. In the study, four different egg production systems were used: Conventional cage system, enriched cage system, barn system and free-range system. In the study, there were four experimental groups, and each experimental group were formed from four replications. *Campylobacter* spp. was counted in 5 eggs randomly taken from each group 2 times, in the 34^{th} and 36^{th} weeks of the egg production period. A total of 40 eggs were used in microbiological analyses.All egg samples kept for pre-enrichment in Buffered Peptone Water (Merck KGaA, Darmstadt, Germany) for 8 hours at 35 °C was diluted serially in pre-sterilized 9 ml ringer solutions. 0.1 mL of inoculum of each dilution was spread onto the petri dishes containing Campylobacter Selective Agar LAB112 supplemented with X112 (LABM, UK) and Horse Blood Lysed (Liofilmchem, Italy). Petri dishes were incubated at 37 °C for 48 hours using the microaerophilic media provided by Anaerocult C (Merck KGaA, Darmstadt, Germany). The biochemical verification tests were applied to white and beige colonies at the end of the incubation and the results were given.
Analysis of variance was considered if parametric test assumptions were met in terms of *Campylobacter spp*. numbers detected in the experimental groups.

Result and Discussion

Campylobacter spp. load of eggs produced in different egg production systems is given in Table 1. Campylobacter spp. was not detected in any of the eggs obtained from the production systems. Normally, it is stated that the microbial load of the shell of eggs produced in the free-range system, which is one of the alternative egg production systems, is higher than in other systems. But according to the results of our study, it is important that Campylobacter, a pathogenic microorganism for humans, is not detected in the eggshell. Sahin et al. (2003) did not detect Campylobacter in any of the broiler breeder egg samples produced at different ages. But they found Campylobacter spp. in the feces of animals of the same age. Park (2002) stated that Campylobacter has a high sensitivity to dry environment and oxygen and that it is quite difficult for it to stay alive in an oxygenated environment. The absence of campylobacter in our study may probably be due to the ovulation of eggs into the follicles and the environment is high in oxygen.

Table 1. *Campylobacter spp* burden of eggs produced in different egg production systems.

Groups	Period 1	Period 2
G	TE	TE
Z	TE	TE
K	TE	TE
S	TE	TE
SE	-	-
P-Value	-	-

G: Conventional cage system, Z: enriched cage system, K: barn system, S: free-range system

Baker *et al.* (1987) reported that no *Campylobacter* spp. was found from eggs obtained from 23 farms. Similarly, it is consistent with studies indicating that no *Campylobacter* was detected in the shell of eggs obtained from farms (Acuff *et al*., 1986; Izat and Gardner, 1988). On the other hand, Doyle (1984) found *Campylobacter* in only 2 eggs of 226 eggs. He also stated that he did not detect *Campylobacter* in feed and drinking water, and that feed and water could not be the source of *Campylobacter* spp.

Conclusion

According to the results of our study, no *Campylobacter* was detected in eggs produced in the free filling system. In this case, there is no transmission in terms of campylobacter, which can be a problem for humans in the eggs produced in this system.

Abstract

Egg weight shows great variation in poultry, and it is known that there is a positive and strong relationship between egg weight and live weight. In this study, it was aimed to compare the hatching egg weight groups in terms of weekly body weights and Gompertz growth curve parameters in Japanese quails. A total of four egg weight groups were formed in the study. Accordingly, the eggs obtained from the breeding flock were classified according to their weight as being less than 8 g (TRT1), 8-10 g (TRT2), 10-12 g (TRT3) and heavier than 12 g (TRT4). In the study, it was determined that the weight of Japanese quails increased throughout the week, including hatching, in parallel with the increase in hatching egg weight, and the differences between the group averages in terms of egg weight were significant. Similar to weekly body weight values, differences were observed between the groups in terms of asymptotic body weight parameter of the Gompertz growth curve model and weight averages of the curve inflection point ($P<0.05$ for both traits). In terms of β_1 and β_2 parameters, the difference was found to be insignificant. As a result, it is possible to obtain faster growing and heavier birds from high weight hatching eggs.

Introduction

Meat and eggs obtained from poultry are the cheapest products that meet the basic nutritional needs of people. These products are consumed intensively because they have enough ingredients needed for public health and contain essential nutrients in a good way. With this supply, poultry production has increased significantly throughout the world in the last 30 years. This has led to an increase in the production not only of chicken species, but also of species such as goose, duck, partridge, ostrich, and quail. The Japanese quail (*Coturnix coturnix japonica*), which is among these species, is used as a model animal in both commercial production and scientific studies. Japanese quails are disease resistant birds that can be easily raised in small areas, are inexpensive to house and feed. Japanese quails reach sexual maturity in about 6 weeks and are usually used for full egg production at 50 days of age. The growth rate in Japanese quails is also quite high (Haqani et al., 2021; Yavuz et al., 2019; Üçkardeş and Narinç 2014; Karaman et al., 2013; Karadavut et al., 2017). With proper breeding, 250 eggs can be obtained from female quails in a year. If quails have not been subjected to any selection to change their body weight, adult male quails weigh about 100-140 g, while females weigh 120-160 g. With domestication, cage adaptation and intensive production, these weight values are higher today. Japanese quails raised for commercial meat production are usually slaughtered at the age of 5-6 weeks and their carcass yield is between 65-70% (Narinç et al., 2014). As in many countries, quails raised for meat purposes in Turkey are priced as pieces in the market. As a natural consequence of this marketing system, producers want to slaughter at an earlier age to increase profitability, while consumers prefer larger carcasses. Extending the fattening period to obtain heavier carcasses from low body weight genotypes leads to undesirable results such as an increase in inedible parts and excessive fattening due to the development of genital organs (Minvielle, 2009). This situation means economic loss for the producer and poor-quality product for the consumer (Narinç and Aksoy, 2012). It is known that chick hatching weight increases due to the increase in hatching egg weight in poultry of different species (Yannakopoulos and Tserveni-Gousi, 1987; Pinchasov, 1991). In various studies with quails, positive and strong relationships were found between hatching egg weight and hatching weight (Skewes et al. 1988; Uddin et al. 1994; Yıldırım and Yetişir, 1998). In this case, if the production starts with chicks obtained from high-weight eggs, high slaughter weight can be obtained in a short fattening period. In this study, it was aimed to compare the hatching egg weight groups in terms of weekly body weights and Gompertz growth curve parameters in Japanese quails.

Material and Methods

The experiment was carried out in quail coops located in the Animal Husbandry Facilities of Akdeniz University, Faculty of Agriculture, Department of Animal Science (Antalya, Turkey). The animal material of the study consisted of 475 randomly mated quail chicks obtained from a total of 600 eggs collected simultaneously from a previously unselected parent flock. A total of four egg weight groups were formed in the study. Accordingly, the eggs obtained from the breeding flock were classified according to their weight as being less than 8 g (TRT1), 8-10 g (TRT2), 10-12 g (TRT3) and heavier than 12 g (TRT4). Each treatment group was divided according to egg weights, and one-day-old chicks were assigned a wing number, and all yield records were followed individually until the end of the experiment. Individual live weights of quails were weighed weekly. One-day-old chicks were housed in brooder cages in the chick rearing room with a placement frequency of 75 cm^2/quail from hatching to sex determination at the third week. The chicks were housed at 32 °C for the first three days and lowered by 1 °C every three days to provide the in-house temperature of 27 °C at the end of the second week. The quails were fed ad libitum powder compound feed containing 24% HP and 2900 kcal/kg ME throughout the experiment. After the third week, the quails were transferred to 5-storey colony cages with five compartments on each floor, and they were housed in these cages with a placement frequency of 220 cm^2/quail until the end of the experiment.

The Gompertz growth model was used in the nonlinear analysis of the growth pattern of quails (Akbaş and Oğuz, 1998; Alkan et al., 2009). The Gompertz growth curve model is $y=\beta_0\exp(-\beta_1\exp(-\beta_2 t))$. In the model, "t" represents time and "y" represents live weight. Among the model parameters, β_0, adult (asymptotic) weight; β_1 is the integration constant; β_2 represents the instantaneous growth rate (Narinç et al. 2010). The inflection point weight ($BNA=\beta_0/e$) and the inflection point age ($BNY=\ln(\beta_1)/\beta_2$) of the model were calculated. The estimation of the model parameters was carried out by the Levenberg-Marquardt iteration method using the NLIN procedure of the SAS 9.3 program (Ricklefs, 1985; SAS Ins, 2011).

Results and Discussion

In the study, weekly live weight averages and statistical analysis results of quails in the experimental groups are presented in Table 1. According to this, it was determined that egg weight categories and weekly live weights increased in parallel throughout all weeks starting from hatching weight. These results are in agreement with the results of Tserveni-Gousi and Yannakopoulos (1990), Tufft and Jensen (1991), Yannakopoulos and Tserveni-Gousi (1987) in broiler chickens; Tserveni-Gousi (1987), Uddin et al. (1994); Yannakopoulos and Tserveni-Gousi (1987), Skewes et al. (1988) in quail. These results contradict with the reports of Laskey and Edens (1985), Pinchasov (1991), Yıldırım and Yetisir (1998) that the heavy chicks at hatching could not maintain these advantages.

TRT: Treatment, β: Gompertz model parameter, SE: Standard error; IPW: Weight of inflection point, IPT: Time of inflection point

The average values of parameters and inflection points of Gompertz growth curve model and results of statistical analyses are shown in Table 1. The growth curves drawn according to the experimental groups are also presented in Figure 1. When the results were examined, differences were observed between the groups in terms of the weight averages of the asymptotic body weight parameter (β_0) of the Gompertz growth curve model and weight averages of the inflection point of the curve, like the weekly body weight values ($P<0.05$ for both characteristics). In terms of β_1 and β_2 parameters, the difference was found to be insignificant. There is no study in the literature in which the growth of quails obtained from different egg weight classes are modeled.

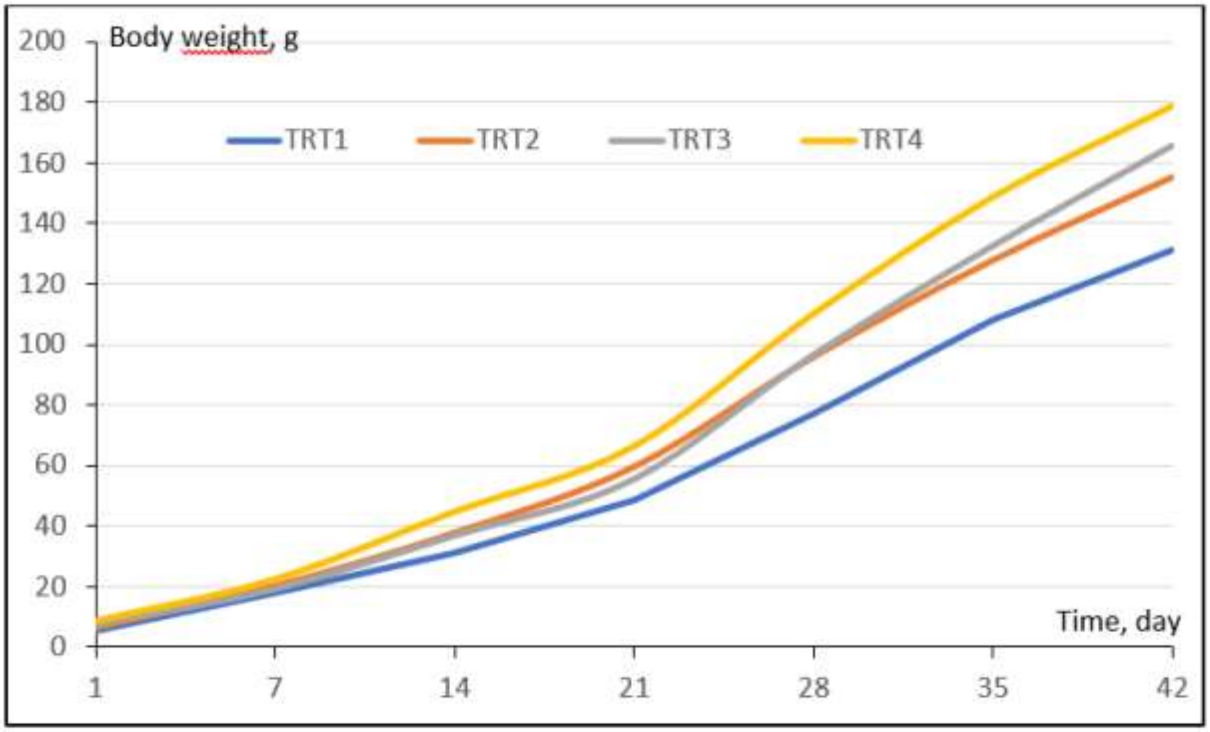

Figure 1. The growth curves of Japanese quails divided into different egg weight categories

Conclusion

As a result of this study, it was determined that hatching egg weight was effective on growth performance in Japanese quails. Considering the weekly live weights of Japanese quails, it was determined that quails hatched from eggs over 12 g reached higher body weight levels than quails hatched from smaller eggs. As a result, it is thought that it will be better to raise chicks to be obtained from high weight eggs.

Abstract

The aim of this study is to investigate the effect of different plants in the free-range system on eggshell microbiology. In the study, 3 different forage plants [(Trifolium repens+ lolium perenne (A), Lotus Corniculatus+ lolium perenne (G) and Medicago sativa + lolium perenne (Y)] were planted in the out-door area. In the study, a total of 12 pens (1.5 * 2m) were made and 20 chickens were randomly placed in each pen. ATAK-S layer hybrid was used as animal material. Total aerobic mesophilic bacteria (TAMB), total coliform, *E. coli* and *Salmonella* loads were determined. A total of 24 eggs (8 egg / group) were used in the study. TAMB values were found as 5.38 log cfu / g eggs, 5.18 log cfu / g eggs and 5.35 log cfu / g eggs in the A, G, and Y groups, respectively (P>0.05). Total coliform values were found as 3.47 log cfu / g eggs, 1.48 log cfu / g eggs and 4.16 log cfu / g eggs in the A, G, and Y groups, respectively (P>0.05). *E. coli* values were found 2.47 log cfu / g eggs, 1.41 log cfu / g eggs and 2.89 log cfu / g eggs in the A, G, and Y groups, respectively (P>0.05). According to the results obtained from our study, it was seen that different plant vegetation in the out-door area did not have a significant effect on the eggshell microbial load.

Keywords: *Coliform, E. Coli, Free-range, Out-door area, Plant vegetation, TAMB.*

Introduction

In many countries of the world, the cage rearing system is dominant in the rearing of layer hens and this situation will probably continue for a long time. The reason for this is that raising chickens in cages is the most economical mode of production, the price of eggs is low and the product reaches all segments of the society (Rakonjac et al., 2017). Conventional cage egg production has been banned in European Union countries since 2012 and egg production has been suggested to be done in alternative systems. One of these production systems is the free-range system. There are studies that show that the eggshell microbial load of eggs produced in the alternative system is greater than that produced in conventional cage systems. (De Reu et al., 2008; Parisi et al., 2015). Parisi et al. (2015) stated that they found an average of 1.0 log CFU/mL more in eggs produced in the Free-range system than caged eggs. Jones et al. (2011) stated that Free-range eggs had the greater levels of shell emulsion coliforms, as well as yeast and mold, compared with Conventional cage eggs. Similarly, Galvao et al. (2018) reported that the average enterobacteria count (log $CFUmL^{-1}$) was 0.09 for conventional and 1.73 for free-range systems. Although there is no requirement for vegetation in the out-door area in the free-range system, it can be advantageous for animals to perform their natural behavior. In the free-range system, animals need to have green plants in the out-door area in order to continue their well-being and healthy lives. In this study, it was aimed to compare different plant varieties in the out-door area in terms of eggshell microbial load.

Material and Methods

The research carried out at the Faculty of Agriculture, Selcuk University. In the study, 3 different forage plants [(*Trifolium repens+ lolium perenne* (A), *Lotus Corniculatus+ lolium perenne* (G) and *Medicago sativa + lolium perenne* (Y)] were planted in the out-door area. Each group is formed from 4 subgroups. Egg samples were taken when the animals were thirty-two weeks old. Total aerobic mesophilic bacteria, coliform, coli and salmonella were analyzed in 8 eggs taken from each. Egg samples were transferred aseptically to sterile sampling bags (LP Italiana SPA, Milano, Italy) then this contents that will be subjected to microbial analysis were kept about 30 min. with 50 mL of sterile phosphate buffer saline (PBS) (Merck KGaA, Darmstadt, Germany). Ten-fold serial dilutions of the samples were prepared using sterile PW (pH 7.0 ± 0.2, Merck KGaA, Darmstadt, Germany). Total mesophilic aerobic bacteria were enumerated by using Compact Dry TC (Nissui Pharmaceutical Co., Ltd, Tokyo, Japan) and petri dishes were incubated at 30°C for 24-48 hours. Total coliform bacteria and *Escherichia coli* number were counted by using Compact Dry EC (Nissui Pharmaceutical Co., Ltd, Tokyo, Japan) and petri dishes were anaerobically incubated at 37°C for 24-48 hours by means of Anaerocult A (Merck KGaA, Darmstadt, Germany). The results were calculated as the means of log colony forming units per g sample (log CFU/g sample) of the eggshells. For *Salmonella* spp. detection, Buffered Peptone Water (BPW) (Merck KGaA, Darmstadt, Germany) was used as pre-enrichment broth and appropriate dilutions from this media were pippetted on Compact Dry SL (Nissui Pharmaceutical Co., Ltd, Tokyo, Japan), then these petri dishes were incubated at 37ºC for 24-48 h. Parametric test assumptions were met to compare the numbers of different microorganisms detected in the eggs obtained from the A, G and Y experimental groups, and then variance analyzes were performed.

Result and Discussion

The effect of different forage plant in the out-door area on the TAMB, coliform, *E. coli* and *Salmonella* spp. load of the eggshell is given in Table 1. In terms of TAMB counts, the differences between groups were not statistically significant. TAMB counts were determined as 5.38 log cfu/g eggs in A group, 5.18 log cfu/g eggs in G group and 5.35 log cfu/g eggs in Y group. TAMB numbers were 5.38 log kob/g eggs in group A, 5.18 log kob/g eggs in group G and 5.35 log kob/g eggs in Y group. Samiullah et al. (2014) determined the TMAB in eggs produced in the free-range system between 2.50 and 4.39 log cfu/egg.

Table 1. The effect of different forage plant in the out-door area on the eggshell microbial activity (Log Cfu/g egg; $\bar{X}$)

Group	TMAB	Coliform	E. coli	Salmonella
A	5.38	3.47	2.37	-
G	5.18	1.48	1.41	-
Y	5.35	4.16	2.89	1/8
SEM	0.242	0.882	0.851	-
P-value	0.833	0.138	0.485	-

A: *Trifolium repens+ lolium perenne*, G: *Lotus Corniculatus+ lolium perenne*, Y: *Medicago sativa + lolium perenne*

Total coliform numbers were determined as 3.47 log cfu/g eggs in A group, 1.48 log cfu/g eggs in G group and 4.16 log cfu/g eggs in Y group Y, and the differences between the groups were statistically insignificant. Jones et al. (2011) found that the number of coliforms in eggs produced in a free-range system was 4.31 to 5.36 log cfu/g eggs.

E. coli counts were determined as 2.37 log cfu/g eggs in A group, 1.41 log cfu/g eggs in G group and 2.89 log cfu/g eggs in Y group, and the differences between the groups were statistically insignificant. *E. coli* is one of the main food pathogens and can be transmitted to people due to the cross contamination when food products are insufficient and during the meal preparation (Adeboye et al., 2020). Samiullah et al. (2014) found the total number of *Enterobacteriaceae* in the free-range system between 0.84 and 2.10 log cfu/egg. Tomar et al., (2021) detected coliform in 21% of eggs obtained from chickens raised in the free-range system.

Only *Salmonella* has been identified in one of the eight eggs analyzed in the Y group. In this regard, Tomar et al. (2021) detected *Salmonella* in 20% of eggs produced in the free-circulation system. Samely, Chousalkar et al. (2016) stated that eggs produced in the free-range system were contaminated with *Salmonella* between 5 and 7.5%.

Conclusion

According to the results obtained from our study, it was seen that different plant vegetation in the out-door area did not have a significant effect on the eggshell microbial load.

Abstract

Herpesviruses can infect all animals and poultry. 19.8 billion eggs and 2.2 million tons of poultry meat were produced in Turkey in 2020. Due to high production capacity, avian herpesviruses (AHVs) have a significant economic and ecological impact potential on poultry health in Turkey and around the world. AHVs are group of pathogens that affect most species of domesticated and wild birds and belongs to Alphafaherpesvirinae. Gallid alphaherpesvirus-1 (GaHV-1) causes infectious laryngotracheitis (ILT). It is potentially fatal and widely recognized as one of the most contagious chicken disease. Transmission occurs through respiratory tract. ILT can affect all birds, including poultry, broilers, free-range, commercial laying hens and wild birds. ILT tends to occur more frequently in areas with heavy broiler production. Marek's disease virus (MDV) agent Gallid alphaherpesvirus-2 (GaHV-2) is highly contagious, characterized by tumors, unilateral leg paralysis and visual disturbances in poultry. Despite having a very protective vaccine, it can cause significant economic losses in laying hens. Infection transmit by respiration. Psittacid herpesvirus-1 (PsHV-1) is the agent of Pacheco's disease. It is highly contagious and affecting exotic species, particularly in parrots of high economic value. Due to high mortality rate, it is a concern of health for domestic bird markets and breeders. Most of the herpes virus infections of poultry are persistent in individuals and are ubiquitous in populations, and the viruses can be scattered for long periods after infection. Prevention and control of AHV infections mainly include improved biosecurity measures, healthy and young poultry production, coordinated rapid diagnostics, and vaccination.

Keywords: *Avian herpesviruses, Gallid alphaherpesvirus, Infectious laryngotracheitis, Mareck Disease, Pacheco Disease.*

Introduction

Avian herpesviruses (AHVs) are group of pathogens that affect most species of domesticated, captive and wild birds. The herpesviridae virus family consists of alpha, beta and gammaherpesvirinae subfamilies. A large number of avian herpesviruses from eight orders have been identified to date. Six of these have importance in veterinary medicine; infectious laryngotracheitis virus (ILT), Marek's disease virus (MDV), Pacheco's parrot disease virus (PsHV-1), Columbid herpesvirus-1 or Pigeon herpesvirus (PIHV) and duck plague virus or duck viral enteritis (DEV) causes infections in avian. Herpesvirus of turkeys (HVT) is nonpathogenic in Turkeys and chickens, however, it is known to be effective in the formation of protective immunity against MDV1 and hence it is used in vaccine studies (Biggs, 1982; Kaleta, 1990; Towazewski *et al*., 2001; Witter, 1972). The Committee on Taxonomy of Viruses (ICTV) has classified them all taxonomically as members of the Alphaherpesvirinae subfamily. Most herpes viruses from wild, captive and domesticated birds are tentatively classified as betaherpesvirinae and Avian beta- or gamma herpesviruses have not been identified precisely yet (Alfonso *et al.*, 2001; Biggs, 1982; Kaleta, 1990; Towazewski *et al*., 2001; Trapp and Osterreider, 2008). AHVs are DNA viruses and belonging to the herpesvirus family. Herpesviruses share a common structure; they contain a relatively large, monopartite, double-stranded, linear DNA genome encoding 100-200 genes, surrounded by the capsid, which is an icosahedral protein structure, viral mRNAs, and a bilayer lipid envelope (Biggs, 1982; Kaleta, 1990; Murphy *et al.,* 1999; Pirbright, 2021; Towazewski *et al*., 2001; Trapp and Osterreider, 2008). Gallid alphaherpesvirus-1 (GaHV-1) was first described in 1926 and causes infectious laryngotracheitis (ILT) (May and Tittsler 1925).

It is potentially fatal and widely recognized as one of the most contagious diseases of chickens. Marek's disease virus (MDV) agent Gallid alphaherpesvirus-2 (GaHV-2) is highly contagious, characterized by tumors, unilateral leg paralysis and visual disturbances in poultry. Psittacid herpesvirus-1 (PsHV-1) is the agent of Pacheco's disease. It is highly contagious and affecting exotic species, particularly in parrots of high economic value. Columbid herpesvirus-1 or Pigeon herpesvirus (PIHV), cause infections in pigeons (Tomaszewski *et al.,* 2001). Herpesviruses known to cause inclusion body hepatitis and splenitis in wild birds such as falcons and owls were reported to be identical to Columbid herpesvirus-1. Owls, like other raptors, are abnormal hosts for this alphaherpesvirus, and the infection is usually courses in a subclinical form. It is known that wild birds fed with infected pigeons are getting the disease in this way (Beaufrère and Laniesse, 2016; WHA, 2012). Duck enteritis virus (DEV) causes duck viral enteritis (DVE) or duck plague and DVE is one of the main contagious and deadly diseases of ducks, geese and swans (Dhama et al., 2017). Herpesvirus of turkeys (HVT) is a non-pathogenic virus of domestic turkeys and can be found in all poultry environments. It is antigenically and genetically classified as the third serotype within the Marek's disease virus (MDV) group of avian herpes viruses (Alfonso *et al.,* 2001; Callnek and Writer, 1991; Witter, 1972).

Poultry meat production amongst the world became the most produced in 2015. Poultry meat and egg production reaches to 132 and 90 million tons respectively at 2019 and represented 39% percent of global meat production. According to the forecasts of FAO, while the total meat amount will reach 358.9 million tons in 2025, the amount of poultry meat will maintain its position as the most produced meat with a share of 37.8 percent with 135.8 million tons (FAO, 2021; TUIK, 2021; Türktarım, 2021; ZMO, 2021). It was reported that 19.8 billion eggs and 2.2 million tons of poultry meat were produced in Turkey in 2020 and ranked 8th in production worldwide. Due to high production capacity, avian herpesviruses (AHVs) have a significant economic and ecological impact potential on poultry health in Turkey and around the world (TUIK, 2021; Türktarım, 2021; ZMO, 2021). This review focuses on avian herpes viruses, especially the infectious laryngotracheitis virus and Marek's disease virus, which are significantly important for poultry health and poultry production.

Infectious Laryngotracheitis (ILT)

Infectious laryngotracheitis (ILT) is a highly contagious avian herpes virus infection caused by Gallid alpha herpesvirus type 1 (GaHV-1), commonly known as infectious laryngotracheitis virus (ILTV) and is economically important for poultry health and poultry production worldwide. In studies conducted after it was first discovered in 1925, it has been reported that the disease is occasionally seen in some poultry enterprises in Turkey (Bagust *et al.,* 2000; MSD, 2021; Kahn, 2005; Kaleta, 1990; May and Tittsler 1925; Murphy *et al.,* 1999; Trapp and Osterreider, 2008). Infectious laryngotracheitis agent, ILT belongs to Alphaherpesvirinae subfamily and representing all the morphological characteristics of alphaherpesviruses. The disease is mostly observed in adult animals and laying hens of any age can be infected, commonly progressing in acute, subacute and chronic forms, characterized by respiratory system inflammation, cough, respiratory distress and conjunctivitis. Roosters and heavy breeds are known as more susceptible to the disease. The mortality rate varying between 10-30%. Morphologically electron microscopy of chicken embryo cell cultures infected with ILT virus represented that the virus resembled the Herpes simplex virus structure. The virus structure is cuboidal and the viral particles are in icosahedral formation. Virions are in hexagonal structure and about 80-100 mm in diameter. The whole virus particle has an irregular envelope membrane surrounding the nucleocapsid and is 95-250 mm in diameter (Bagust *et al.,* 2000; Callnek and Writer, 1991; Murphy *et al.,* 1999; Trapp and Osterreider, 2008; Yumuşak, 1988). Infection begins when the virus is adsorbed on the cell surface. Viral entry occurs with pinocytosis in the cell. Adsorption varies with the cells and the amount of inoculum. ILT virus particles are sensitive to lipolytic agents, heat and some disinfectants. It can survive for a longer period in lyophilization at -20 and -60°C and destroyed in 10-15 minutes at 55 °C (Yumuşak, 1988). The virus is mostly transmitted by respiratory tract; sick animals spread the virus around with nasal discharge and coughing, especially in the air as droplets. Transmission through the conjunctiva is possible. The crowded, neglected and unhygienic conditions of the henhouses, the intensity of stress factors and the winter months are effective in the emergence and spread of the infection in the henhouses. In such cases, mortality varies between 10-30%, and may increase up to 50% with the accompanying of secondary infections. Virus can be isolated from trachea up to 2 months after patients recover. There is no vertical transmission were reported of the virus to the egg (Bagust *et al.,* 2000; Biggs, 1982; Kahn, 2005, Kaleta, 1990; MSD, 2021; Yumuşak, 1988).

There are commonly variable non-specific clinical signs are observed mostly including respiratory distress, ocular lesions, enteritis and liver involvement. Clinical signs and respiratory symptoms are not pathognomonic for the disease. Infected birds are inactive and no appetite. The precursor symptoms are ocular discharges. If the disease progresses, the ocular discharge increases, conjunctivitis may associated and the eyelids swell and stick together, the nasal discharge increases and the animal's face starts to swell, they extend their heads upwards to breathe, wheezing sounds are made during breathing, the virus is spread around with coughing and sneezing at around 5-12 days after exposure. Occlusion of the trachea and especially the larynx with mucoid secretion or plugging fibrin tissue causes an increase in deaths from asphyxia. In cases where secondary infections complications and stress factors are high, deaths can reach up to 50%. Animals exposed to the virus do not always become clinically ill and may appear healthy. The incidence of the disease may vary depending on the pathogenicity of the virus strain, host health condition and stress factors. Low virulence virus strains cause few or no mortality, with mild respiratory infection and can lead to a slight decrease in egg production. Latent infections are possible after recovery of the diseased birds which of those remain an infection source as a lifelong carrier of the infection. The role of latent infected animals is quite high in the continuation of the virus shedding, its spread and the emergence of the disease. In addition, it is known that if a preventive vaccination is made in poultry houses with such animals that do not show any clear clinical signs, the disease may become active in animals with latent infection and animals can easily get sick and die. Disease symptoms in infected animals begin to subside after 2 weeks, and recovery is usually observed within 4-8 weeks, but some animals are

known to show signs of illness for a longer period and low productivity in laying animals can reach 50%. There is no effective etiological medication and treatment of the disease. Secondary bacterial infections in severe cases may control with choices of antibiotics. Lowering the dust level and keeping the birds in quiet hen houses with maintaining a clean water system may avoid transmission between flock members. Transmission can be possible with infected birds and fomites. Birds that die from the disease should be destroyed immediately. Transportation of infected birds, and spread of contaminated litter facilitates wit lack off biosecurity spread of the ILT virus (Bagust *et al.,* 2000; Biggs, 1982; MSD, 2021; Kahn, 2005; Kaleta, 1990; Murphy *et al.,* 1999; Pirbright, 2021; Trapp and Osterreider, 2008, Yumuşak; 1988).
Diagnosis is based on virus isolation, serological tests, and laboratory animal tests, PCR based molecular diagnosis and histopathology of trachea and conjunctiva of the suspected animals. The key principles of disease control include rapid diagnosis, improved biosecurity, and coordinated efforts for vaccination. Biosecurity measures are a leading barrier of protection in ILT, as in other viral diseases. Preventive vaccinations success depends on a good determination of the vaccine administration strategy. Live attenuated vaccines and viral vector vaccines are in choices for the development of adequate immunity (Bagust *et al.,* 2000; Biggs, 1982; Kahn, 2005, Kaleta, 1990; MSD, 2021; Yumuşak, 1988).

Marek's Disease

It is a viral, infectious, neural, tumorous, lethal and lymphoproliferative disease. Marek's disease virus (MDV) etiological agent Gallid alphaherpesvirus-2 (GaHV-2) is highly contagious, characterized by tumors, unilateral leg paralysis and visual disturbances in poultry. MDV represented all the characteristic morphological features of the alphaherpesviruses. There are three serotypes of MDV; Serotype-I is virulent and oncogenic, while serotype-II in chicken and serotype-III in turkey are non-oncogenic (Witter, 1972). Chickens are the main species affected by Marek's disease (MD or fowl paralysis). MD can be seen commonly worldwide and affects both commercial and backyard poultry and can cause death or severe productivity loss and is rarely seen in some other bird species. There are two forms of MD of those are nervous and visceral forms. Nervous form occurs typically with a progressive paralysis, visceral form occurs as tumors in internal organs, and most diseased birds usually die (Alfonso, 2001; Biggs, 1982; Calnek abd Witter, 1991; Biosecurity Tasmania, 2021; Kahn, 2005, Kaleta, 1990; Murphy *et al.*, 1999; Pirbright, 2021; Trapp and Osterreider, 2008). The disease develops as a result of accumulation and reproduction of mononuclear lymphocytes in the liver, kidney, spleen, gonads, pancreas, iris, lung, muscle and skin, and causes tumors and pathological changes in most of the nerves and internal organs. In the neural form of the disease, the affected peripheral nerves cause paralysis, while the locomotor nerves cause incoordination, shaky gait and unable to stand. Ballerina posture (characterized by extending one leg forward and the other leg back) is very characteristic for Marek's disease. When the wing and neck nerves are affected, the wings drop and the head falls down. As the vagus is affected, the crop enlarges, droops, and breathing difficulties are observed. In some cases, ocular forms may be seen with blindness. In the visceral form, tumors in internal organs accompanied with depression, loss of appetite and weight, greenish diarrhea, dehydration, pallor, and exhaustion (Biggs, 1982; Biosecurity Tasmania, 2021; Kahn, 2005, Kaleta, 1990; MSD, 2021; Trapp and Osterreider, 2008).
The diagnosis of Marek's disease can be made with a detailed veterinary examination. Evaluation of the clinical findings together with the post-mortem examination will not only help in the

correct diagnosis, but will also enable other possible diseases to be ruled out. Browning and thickening of the sciatic nerves and plexus brachialis, which is one of the characteristic findings of Marek's disease observed in the postmortem examination, and the presence of gray color and depigmentation in the eyes are among the findings confirming the diagnosis of the disease. In addition, lymphoid tumors of various sizes are encountered in the internal organs, depending on the severity and course of the infection. Tumors are localized in ovary, spleen, liver, kidney, testis, intestines, glandular stomach, muscles, skin, bursa fabricius and heart. Marek's disease virus is highly contagious, the main route of transmission is respiratory and can be widely found wherever chickens are raised. When the virus introduced newly to a flock, it spreads rapidly among unvaccinated birds, and most chickens in an unvaccinated flock become infected. Infected chickens carry the virus for life and shed it for long periods, whether they are infected or not (Biggs, 1982; Biosecurity Tasmania, 2021; Kahn, 2005, Kaleta, 1990; Murphy *et al.,* 1999; MSD, 2021; Trapp and Osterreider, 2008). The virus sheds from feather roots and spreads easily in feathers and dust, the susceptible bird ingesting the virus when inhaling infected dust particles. The virus can also easily transmit to other farms and susceptible flocks through people with access to poultry facilities, vectors (rodents, birds, insects, etc.) and contaminated equipment. The virus is quite resistant to the environment and room temperature and can survive for several months. It is known that there is no hen-to-chicken transmission through eggs. There is no effective etiological medication and treatment of the Marek's disease and symptomatic birds usually dies. Diseased birds should be immediately removed from the flock and humanely euthanized. Other birds in the flock are also likely to be infected at this stage, so close monitoring of all birds is important. Virus isolation, PCR-based molecular, serological, histopathological and cytotoxic tests are performed for the laboratory diagnosis of the disease. ELISA, fluorescent antibody assay, agar gel precipitation and neutralization tests are widely used in serological tests. A high level of biosecurity measures are the first measure in disease prevention. A biosafety checklist should be established across the farm and for bird keepers and its compliance monitored. A detailed deep disinfection and cleaning process should be experienced before the introduction of new birds in the flocks of an enterprise with Marek's disease in the previous period. Chicks should be reared separately to be free of infected feathers and dust from older birds. Standard hygiene measures are also important, including thorough cleaning and disinfection of kennels and equipment between groups of chicks with a disinfectant effective against viruses. Good nutrition and protection from other diseases and parasites are also very important. These practices will help maintain flock health and ensure that birds have optimum resistance to Marek's disease infection (Biggs, 1982; Biosecurity Tasmania, 2021; Kahn, 2005, Kaleta, 1990; Murphy *et al.,* 1999; MSD, 2021; Trapp and Osterreider, 2008). The second important issue is vaccination. Although vaccines are widely used in commercial poultry farming, it is often not possible to purchase a small number of doses for use in small family businesses and backyard chickens, as they are commercially available in volumes of 1000 doses and above. For these free-range birds, the best protection against Marek's disease can be obtained by purchasing correctly vaccinated birds from a trusted breeder. Vaccination alone will not prevent Marek's disease. Especially for commercial flocks, it is important to have good biosecurity to allow vaccinated chicks to develop immunity before being exposed to a serious virus threat. Currently, the generally accepted vaccination protocol is the use of a combination of frozen live vaccines containing chicken herpesvirus (CVI-Rispens strain, Serotype 1) and turkey herpesvirus (HVT - serotype-3). It is applied to day-old chicks and it is aimed to ensure the development of immunoglobulins before entering the hen with the immunity effect of the chicks.

However, the more effective method recommended is to vaccinate the chicks before hatching (in-ovo). This allows the chicks to gain a period of three to four days for the development of immunity. In addition, the HVT strain is used as vector virus in vector vaccine combinations to protect against some other viruses (Alfonso *et al.*, 2001; Biggs, 1982; Biosecurity Tasmania, 2021; Kahn, 2005, Kaleta, 1990; Murphy *et al.*, 1999; MSD, 2021; Trapp and Osterreider, 2008).

Conclusions

Poultry meat production, which has been increasing worldwide, became the most produced meat in 2015. FAO reported that poultry is raised by approximately 80% of rural households in developing countries. There are approximately 12 thousand poultry enterprises throughout Turkey and the sector grows by an average of 8% every year. In the poultry industry, the control of diseases that adversely affect animal health and productivity, especially avian herpesvirus infections, is of great importance for healthy food consumption.

Abstract

Cow milk is widely consumed by human children and adults due to its nutritional value. Besides nutrients, milk contains naturally occurring hormones, including insulin like growth factor-1 (IGF-1), that may alter their blood levels in the consumers. At the same time, the impact of IGF-1 on human health is still unclear and controversial. The aim of the study was to determine IGF-1 concentrations in cow colostrum and milk and to discuss them from the aspect of human health. Twenty Holstein cows were enrolled in the study and subjected to colostrum, milk and venous blood sampling in order to determine the IGF-1 concentration by the radioimmunoassay (RIA). Colostrum was sampled at 2, 14 and 26 hours (1^{st}, 2^{nd} and 3^{rd} colostrum) after calving, while milk and venous blood were taken 10 days after calving. The concentration of IGF-1 was the highest in the 1^{st} colostrum and decreased significantly with each subsequent sampling, so the lowest concentrations were detected in milk sampled 10 days after calving. High concentrations of IGF-1 observed in colostrum, especially in the 1^{st} colostrum, reflect its potential for eventually use in the treatment of various intestinal diseases. However, further research should determine the conditions and limitations of its application. On the other hand, additional research is needed to determine whether IGF-1 in milk has harmful effects on human health and whether it is necessary to limit the permitted presence of this hormone in cow milk.

Keywords: *cow milk, insulin like growth factor-1 (IGF-1), human health.*

Introduction

Cow milk is considered as nutritionally valuable food in the human diet, which is consumed from birth to old age (Marangoni et al. 2019). It contains proteins of high biological value, fats, carbohydrates, minerals and vitamins, that provide beneficial effects on the overall growth of children and qualify the use of milk in the prevention and treatment of them malnutrition (Agostoni and Turck 2011; Turck 2013). In addition to nutrients, cow's milk also contains biologically active substances, including immunoglobulins, lactoferrin, enzymes, cytokines, growth factors and naturally occurring hormones. The presence of biologically active substances in cow milk is essential for the newborn (Kirovski 2015). They support the growth of the newborn calves and the development and activity of their gastrointestinal and immune functions (Kirovski et al. 2002; Georgiev 2008; Park and Nam 2015). However, when consumers ingest biologically active substances, they may also cause a wide range of biological effects in the body. For instance, milk hormones could affect hormones levels in the blood and may affect physiological and pathological processes in the organism of consumers (Malekinejad and Rezabakhsh 2015). Therefore, it has been proven that milk estrogens have harmful effects on human health (Snoj and Majdič 2018), while the impact of insulin-like growth factor-1 (IGF-1) from cow's milk has not been elucidated and attracts attention from researchers and consumers also.

Bovine IGF-1 is a polypeptide composed of 70 amino acids predominantly synthesized in the liver but can also be synthesized in other tissues and exhibit endocrine, paracrine, and autocrine effects (Fruchtman et al. 2002). This hormone is known as a strong mitogen factor, promoting cell growth and proliferation and inhibiting apoptosis (Clatici et al. 2018). In all biological fluids, IGF-1 is almost entirely (95-99%) bound to one of six structurally similar IGF binding proteins (IGFBP-1 to -6) (Forbes et al. 2012). Consequently, less than 1 % of IGF-1 circulates freely – unbound to IGFBPs (Clemmons 1993; Kirovski et al. 2008; Melnik 2009). The concentration of IGF-1 in cow milk varies widely, from approximately 1 ng/mL to 150 ng/mL, depending on the stage of lactation, milk composition, and other environmental factors (Malekinejad and Rezabakhsh 2015). Thus, the highest concentrations of IGF-1 occur immediately after parturition in colostrum and then gradually decrease until it falls to the level of 1 to 5 ng/mL (Šamanc et al. 2009; Castigliego et al. 2011).

There are several reasons why the presence of IGF-1 in cow milk is a source of human health issues. IGF-1 has a highly conserved sequence across species because bovine IGF-1 can bind with identical affinity to IGF receptors on human tissues, thus achieving physiological effects (Renaville et al. 2002; Melnik 2009). Furthermore, there are data on both beneficial and harmful effects of IGF-1 on human health in scientific literature. Ungvari and Csiszar (2012) report that low levels of circulating IGF-1 increase the risk of cardiovascular and cerebrovascular diseases in humans. At the same time, a low concentration of IGF-1 in the early phase of acute myocardial infarction predicts a worse prognosis (Conti et al. 2001). The protective effect of IGF-1 on Alzheimer's disease (O'Neill et al. 2012) and all forms of dementia, including Parkinson's disease dementia (Westwood et al. 2014), has also been documented. Typically, there are numerous estimates that IGF-1 has a positive effect on bone health; therefore, it is considered that clinical determination of IGF-1 may be useful in assessing the risk of bone fractures (Lombardi et al. 2005; Locatelli and Bianchi 2014).

On the other hand, numerous epidemiological studies have linked high levels of circulating IGF-1 to an increased risk of several cancers in humans. In this context, breast, prostate, lung and colon-rectal cancers are most commonly reported in the literature (Sutariya et al. 2018). This is important because the digestion of IGF-1 ingested through cow's milk is prevented by milk proteins, which potentially enables its intestinal absorption. Thus, higher milk consumption leads to an increase in circulating IGF-1 levels by 20-30% in children and 10-20% in adults (Melnik 2009). At the same time, homogenization and pasteurization do not significantly decrease the content and activity of IGF-1 in cow milk (Collier et al. 1991). Therefore, Tate and coworkers (2011) suggest that patients with prostate or breast cancer should be informed about the possible promotional effects of dairy products.

The study aimed to determine the concentrations of IGF-1 in cow colostrum and milk, and analyze them in the context of human health.

Materials and Methods

Animals and Housing

The experiment was conducted at the commercial dairy farm in Belgrade, Serbia. Twenty Holstein cows were assigned for the study. Cows received diets as total mixed ration (TMR) to allow ad libitum feed intake throughout the study. After calving, cows were assigned to the lactation diet (crude protein = 161 g/kg DM; crude fat = 21 g/kg DM; NEL = 7.3 MJ/kg DM; ADF = 221 g/kg DM; NDF = 358 g/kg DM). Diet was formulated to either meet or exceed the NRC (2001) requirements. The feed was offered in two equal portions at 0700 and 1600 h, and cows had free access to water. Cows were maintained under a loose housing system.

Colostrum and Blood Sampling Procedures

The primary (1^{st}), secondary (2^{nd}) and tertiary (3^{rd}) colostrum were sampled from each cow 2, 14, and 26 h after calving, respectively. The milk sample was taken 10 days after calving. The samples were collected in sterile cups and were stored at – 20 °C for the further analyses. Blood was sampled by *v. jugularis* puncture at day 10 day after calving at 1000 h. The samples were collected into serum clot activator tubes.

Sample Preparation and IGF-1 Measurement

Colostrum and Milk Samples. Thawed colostrum and milk were centrifuged (2000×*g*, 20 min) and the fatty layer was carefully removed through vacuum aspiration. Casein was precipitated by adding 175 µL of rennet to 10 mL of centrifuged colostrum supernatant. After 30 min of incubation at 37 °C, samples were centrifuged for 15 min at 3000×g, and whey (supernatant) was aliquoted and stored at − 20 °C until analysis. IGF-1 concentration in colostral and milk whey was determined using radioimmunoassay (RIA-IGF-I, INEP, Belgrade, Serbia) (Nikolić et al. 1996).

Blood Samples. On the day of sampling, blood in the serum clot activator tubes was kept at room temperature and was allowed to clot. Serum was decanted, centrifuged within 30 min at 3000×g, portioned into aliquots of 1.5 ml, and stored in polypropylene microtubes at − 20 °C until analyses. Concentrations of IGF-1 in blood were measured by radioimmunoassay (RIA-IGF-I, INEP, Belgrade, Serbia) (Nikolić et al. 1996).

Statistical analysis

The statistical analysis was performed by determination of the mean value and standard error of the mean (SEM) for each sample. The statistically significant difference between the samples was evaluated by the Student's t-test and *p* values less than 0.05 were considered to be statistically significant. The analyses were performed using Excel 2019 software (Microsoft, Redmond, WA, USA) (Vega et al. 1991).

Results and Discussion

Preliminary results of our study demonstrate that the highest concentrations of IGF-1 are present in the 1st colostrum (59.23±3.32 nmol/L) (Figure 1). At the same time, these values were statistically significantly higher compared to the 2nd colostrum (37.91±2.49 nmol/L; $p<0.001$), 3rd colostrum (22.03±1.44 nmol/L; $p<0.001$) and milk (19.16±0.77 nmol/L; $p<0.001$). Moreover, Figure 1 reveals that the concentration of IGF-1 at each subsequent colostrum sampling period, including milk sampling on the 10 days after calving, was significantly lower ($p<0.05$, respectively) than in the previous one. Consequently, the lowest concentrations of IGF-

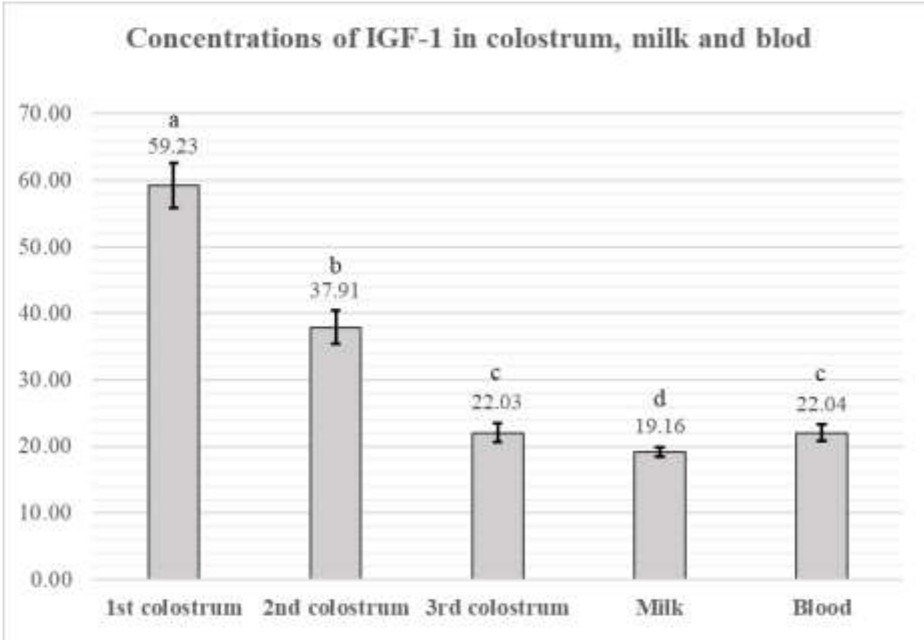

Figure 10. Mean IGF-1 concentrations (± SEM) in cow colostrum, milk and blood. 1st colostrum – sampled 2 hours after calving; 2nd colostrum – sampled 14 hours after calving; 3rd colostrum – sampled 26 hours after calving; Milk and Blood – sampled 10 days after calving. Different lowercase letters above the bars indicate a statistically significant difference ($p < 0.05$).

1 were found in milk sampled 10 days after calving, which were also significantly lower ($p<0.001$) than those determined in the blood serum (22.04±1.27 nmol/L) on the same day.

The obtained results suggest that the concentration of IGF-1 in colostrum decreases rapidly within the first day after calving, but a similar trend remains until the tenth day after calving. Analogous findings were obtained by Elfstrand and colleagues (2002), who reported that the highest concentrations of IGF-1 were present in colostrum in the first six hours after calving. Mentioned researchers also documented a rapid decrease in the concentration of IGF-1 in colostrum by 44% after 11-20 hours. This is relatively consistent with our results reflecting a 30% and 63% reduction in IGF-1 colostrum concentration after 14 and 26 hours after calving. Additionally, the further decline in IGF-1 concentration in cow's milk found in our study confirms the previously published results of Daxenberger et al. (1998), who described that IGF-1 concentrations in milk decrease gradually until 7 weeks after calving and remain low until 33 weeks of lactation. Finally, the biological importance of high IGF-1 levels in colostrum can be explained by its beneficial effect on the morphological and functional development of newborn calves (Blum and Hammon 2000; Kirovski et al. 2009).

Since colostrum is not a standard part of the human diet, the high level of IGF-1 in this mammary secretion cannot be considered a health risk for consumers. Moreover, previous literature data indicate that cow colostrum can be viewed as a functional food with health benefits for consumers. This is based on the fact that cow colostrum is a consummate source of biologically active proteins that can modulate the immunological function and improve intestinal peristalsis of consumers. Accordingly, a whole range of bovine colostrum-based products, such as various dietary supplements, drinks, and chewing gums, can be found in the markets of certain countries (Dzik et al. 2017; Mir et al. 2021). In addition, there is a growing scientific interest in the field of beneficial effects of bovine colostrum related to the physiological effects of IGF-1.

Mir and coworkers (2021) report that IGF-1 from bovine colostrum repairs intestinal morphology and function, stimulating the proliferation of intestinal crypt cells. IGF-1 also exhibits anti-inflammatory effects by several described mechanisms (Zatorski et al. 2016). Consequently, there are recommendations for using bovine colostrum or purified IGF-1 to treat inflammatory bowel diseases (IBD), including Crohn's disease and ulcerative colitis as the most common forms (Yadav et al. 2016; Zatorski et al. 2016). This perspective in the use of colostrum is very important because the number of diagnosed cases of IBD has increased dramatically worldwide in the last 50 years. Noteworthy, the number of new cases is growing in the population of children (Molodecky et al. 2012; Gasparetto and Guariso 2013). Furthermore, Crohn's disease and ulcerative colitis are accompanied by decreased intestinal production and circulating levels of IGF-1, which leads to other health complications. Indeed, patients with Crohn's disease or ulcerative colitis are at increased risk of developing osteopenia, osteoporosis, and osteoporotic bone fractures (Koutroubakis et al. 2011). In this context, the large amounts of IGF-1 in cow colostrum, shown by results of our previous (Kirovski et al. 2012) and presented study, only support the recommendations for the use of colostrum in the treatment of various intestinal diseases. However, subsequent research should examine the limitations of its use, because IGF-1 may have a promotional effect in patients with premalignancy conditions (Zatorski et al. 2016).

In contrast to colostrum, cow's milk and dairy products are widely used in human nutrition in our cultural sphere; therefore, consumer's interest in cow's milk safety is far greater compared to colostrum. Although it has been confirmed in various animal models (mice and rats) and cell cultures that IGF-1 promotes the growth of cancer, especially prostate (Tate et al. 2011; Cao et al. 2015) and breast cancer (Mawson et al. 2005), it is not entirely clear whether milk-borne IGF-1 can achieve a similar effect in humans. Namely, the proven increase in circulating IGF-1 in humans after milk consumption (Melnik 2009; Ventura et al. 2020) may not be the only consequence of intestinal resorption of IGF-1. There is a theory that dairy proteins are responsible for increasing IGF-1 levels after milk consumption (Giovannucci et al. 2003) because they are a source of essential amino acids that up-regulate hepatic IGF-1 gene expression (Thissen et al. 1994). If this theory is confirmed by future research, milk will be incriminated as a food independent of IGF-1 concentrations.

On the other hand, there is a theory that milk proteins, such as casein, protect IGF-1 from digestion, therefore the IGF-1 remains active in the serum after milk consumption (Melnik 2009). Accordingly, Philipps et al. (2000) suggested that radiolabeled IGF-1 could be found in the portal circulation at low concentrations. However, it is difficult to extrapolate these results to humans. Therefore, it is necessary to determine the essence of the increase in circulating IGF-1 in humans after milk consumption, as well as the critical levels of IGF-1 in cow's milk.

Conclusions

In the presented investigation, we found that IGF-1 concentrations are highest immediately after calving (first two hours) and decrease rapidly during the following 24 hours. After that, IGF-1 concentration gradually decreases, which is indicated by the measured values of IGF-1 in milk sampled on the tenth day after calving. Future research should examine the potential benefits of high concentrations of IGF-1 in colostrum, or the possible adverse effects of cow milk IGF-1 on human health.

Abstract

Eggs of class "L" produced of Isa Brown genotype were used for the research needs. The research aimed to determine the external (length, width, shape index and mass of eggs), internal (proportion of main parts of eggs, albumen height, Haugh units and yolk color) and eggshell quality parameters (purity, thickness and strength). The eggshell strength was determined by applying the direct method of puncture, using a specially constructed measuring and acquisition device. The results of the research showed that the average egg length was 58.33 mm, width 45.17 mm, and shape index 77.44. Of the average egg mass (65.79 g), the albumen proportion was 59.87%, yolk 27.33% and eggshell 12.90%. Albumen height ranged from a minimum of 4.42 mm to a maximum of 6.76 mm, with a coefficient of variation of 16.90%. Accordingly, values of the Haugh units ranged from 60.2 to 80.2 and the coefficient of variation of 10.96%. The average yolk color was 13 Roche. The purity of the eggshell was rated 4.44. The eggshell quality of the tested eggs was quite uniform because the average puncture force of the eggshell was 25.88 N, with a coefficient of variation of 4.20% and an average thickness of 0.40 mm. Knowledge of the values of external, internal and properties of eggshell quality can be used in a selection of laying hens hybrids with increased eggshell strength, as well as for cage construction, design of egg collection equipment and design of egg packaging.

Keywords: *hen eggs, egg quality, eggshell puncture force.*

Introduction

The cage rearing system is the dominant way of rearing of laying hens all over the world, and this situation probably will continue for a long time. The reason for this is because the rearing of hens in the cage is the most economical way of production, and it provides that the price of eggs is low and that product be accessible to all segments of the population (Rakonjac et al., 2017). In Serbia, more than 90% of eggs for consumption are produced in this - industrial way, in closed facilities with automatic feeding and watering systems, with control of all ambient conditions and the use of artificial lighting and ventilation.

In recent years, great attention has been paid to the quality and health safety of eggs, as one of the most important foodstuffs. In addition to the chemical composition of eggs and their external and internal quality properties, a special attention is paid to the quality of the eggshell, which can be crucial for success in hen eggs production. Thus Coucke et al. (1999) state that 6-8% of produced eggs break up before it comes to use, which makes financial losses of millions of dollars. A large percentage of this damage is caused by the inadequate quality of the shell because eggs cracks during manipulation.

The research aimed to determine the external (length, width, shape index and mass of eggs), internal (proportion of main parts of eggs, albumen height, Haugh units and yolk color) and eggshell quality parameters (purity, thickness and strength). In addition, the research aims to test a device that was constructed for the experiment, for determining the stress of the eggshell by direct puncture method.

Material and Methods

A total of 30 "L" class eggs (produced of 63 weeks old Isa Brown hens on the "Grbović" farm in the vicinity of Čačak) were used in this research. These eggs (one day old) were evaluated for external (length, width, shape index and egg mass), internal (proportion of main parts of eggs, albumen height, Haugh units and yolk color) and eggshell quality properties (purity, thickness and strength).
The shape index was calculated by formula according to the research of Panda (1996):

$$\textit{Shape index (\%)} = \textit{egg width} / \textit{egg length} * 100$$

Haugh units were calculated according to the following formula (Haugh, 1937):

$$HU = 100 * \log (h - 1.7w^{0.37} + 7.6)$$

where h = albumen height, mm, w = egg weight, g.

The yolk color was determined by comparison with the color on the "Roche-Yolk Color Fan 1969" range, classified by the intensity of color shades on a scale from 1 to 15. The length and width of eggs and eggshell thickness were measured by Fowler Pro-max electronic caliper with an accuracy of 0.01 mm. The mass of whole eggs and main parts of eggs were measured using an analytical balance Kern EMS 3000-2 with an accuracy of 0.01 g. The purity of the eggshell was visually assessed from 1 (very dirty) to 5 (completely clean).
A special measuring and acquisition device was constructed to determine the eggshell strength using the direct puncture method. The device for measuring the eggshell stress by determining the puncture force of eggshell was constructed in the Laboratory for Mechatronics of the Faculty of Technical Sciences and the Faculty of Agronomy in Čačak. A detailed description of the measuring acquisition device for measuring the mechanical properties of the puncture force of cracking and breaking of rapeseed fruits was given by Božić et al. (2014) and Koprivica et al. (2021). The procedure for determining stress of the eggshell is performed in such a way that the egg is placed on a support plate in a horizontal position (along the length) perpendicular to the direction of the force. With a 2 mm diameter probe, the eggshell puncture is performed on the equatorial part of the egg. At the moment of eggshell puncture, the minimum puncture force expressed in N is registered and represents the maximum of the eggshell strength. The device registers and displays data on measured values of the eggshell puncture force in Excel table and graphic. The tabular report provides data on eggshell puncture forces, as well as basic statistical data (minimum, maximum, mean, coefficient of variation, standard deviation).

Results and Discussion

Egg quality was determined based on obtained values of 4 external, 3 internal and 3 properties of eggshell quality. The properties of the external quality of eggs are shown in Table 1.

Table 1. External quality of eggs

Egg properties	Mean	St. Dev.	CV in %	Min.	Max.
Length (mm)	58.33	1.05	1.79	56.65	59.72
Width (mm)	45.17	1.06	2.34	43.96	46.94
Shape index (%)	77.44	3.91	5.01	74.63	81.04
Mass (g)	65.79	3.01	4.57	62.89	70.79

The average length of eggs was 58.33 mm and width 45.17 mm, so the shape index was 77.44%. Based on the shape index and mass index, the eggs are graded and packaging is designed. The shape index is important from an economic point of view because, with an irregular shape, the cracking of eggs during collection, packaging and transport is much higher. The results for shape index is in agreement with the results published by Kralik et al. (2013), Ahammed et al. (2014), Dikmen et al. (2017), Rakonjac et al. (2018) and Turker and Alkan (2019), and greatest than the value it states by Nedomova et al. (2009). The mass is the main indicator of egg quality and it ranged from 62.89 g to 70.79 g, with an average of 65.78 g, so the eggs were classified in the "L" class (large eggs). These values are following the technological norm for Isa Brown laying hens in the later stages of the production cycle (Isa Brown Management Guide, 2018), and the results determined by Đukić-Stojčić et al. (2009) and Rakonjac et al. (2017).

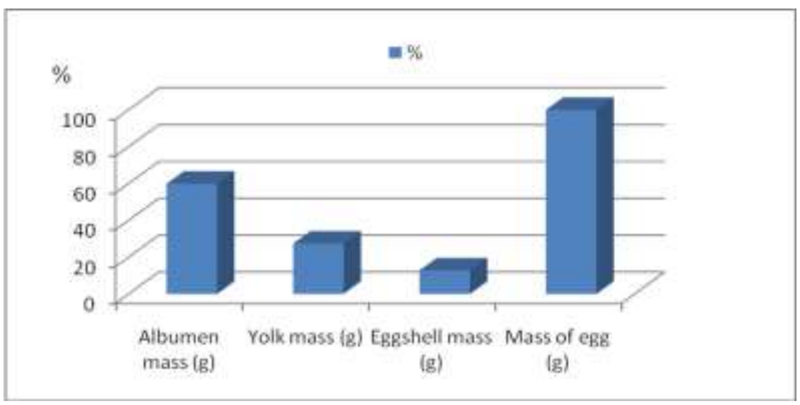

Figure 1. The average share of basic parts of egg

The proportion of the main parts of eggs is shown in Figure 1. The obtained values are in accordance with the results given by Rakita et al. (2016), Rakonjac et al. (2017) and Keta and Tumova (2018). Internal egg quality parameters are presented in Table 2.

Table 2. The internal quality of eggs

Egg properties	Mean	St. Dev.	CV in %	Min.	Max.
Albumen height (mm)	5.57	0.94	16.90	4.42	6.76
The Haugh units	70.77	7.76	10.96	60.2	80.2
Yolk color (Roche)	13.00	0.87	6.66	12	14

The values of albumen height ranged from a minimum of 4.42 mm to a maximum of 6.76 mm, with a coefficient of variation of 16.90%. Accordingly, the values of the Haugh units varied from 60.2 to 80.2 and with a coefficient of variation of 10.96%. Similar results for the same hybrid and approximately the same age of the hens were also determined by Minelli et al. (2007) and Rakonjac et al. (2018), who state that the hen's age is one of the main factors that affecting the value of these parameters.
The yolk color depends on a large number of factors, primarily on genotype (Kucukyilmaz et al., 2012), age of the laying hens (Škrbić et al., 2011) and nutrition (Mugnai et al., 2009). The average value of the yolk color in this study was 13 Roche, which is similar to the results published by Perić et al. (2016), and significantly higher than the results reported by Kralik et al. (2013) and Rakonjac et al. (2018). Eggshell quality parameters are presented in Table 3.

Table 3. The quality of eggshell

Properties of eggshell	Mean	St. Dev.	CV in %	Min.	Max.
Purity eggshell (points)	4.44	0.73	16.35	3.0	5.0
Eggshell thickness (mm)	0.40	0.02	6.16	0.37	0.45
Puncture force (N)	25.88	1.09	4.20	23.41	26.46

For eggs to be sold, the eggshell must be clean, without visible cracks. On average, the purity of the eggshell was rated 4.44. The quality of the eggshell is determined by the thickness and eggshell strength. The strength of the eggshell is the ability of the eggshell to resist the action of external forces that would break it. The eggshell strength values obtained by the direct puncture method represent the stress force to load the eggshell to the limit when it is punctured or cracked. The quality of the tested eggs was uniform because the average puncture force of the eggshell was 25.88 N, and varied from 23.41 N to 26.46 N. These values of eggshell strength measured by puncture force are in agreement or approximate with the results published by Krawczyk (2009), Ahammed et al. (2014) and Turker and Alkan (2019), and less than measured values by Hunt et al. (1977), Voisey et al. (1979), Hamilton and Thompson (1986) and Rakonjac et al. (2019). Inconsistency of the obtained results for values of eggshell puncture force presented in the research with the results of other authors can be explained by using different genotypes, different rearing and feeding conditions, different ages of laying hen, but also by using different methods to determine values of this parameter.
The average eggshell thickness with membranes on the equatorial part of the egg was 0.40 mm with a coefficient of variation of 6.16%. These values are in agreement with the values presented by Ahammed et al. (2014), Dikmen et al. (2017) and Keta and Tumova (2018).

Conclusion

The most important parameters for determining the quality of egg are external, internal and eggshell quality properties. Knowing the value of these parameters is of great importance for both egg producers and consumers, as well as for science and practice. Only by knowing the mentioned properties, it is possible to create new or improve existing hybrids of laying hens by the selection, which are characterized by a better external and internal quality of eggs and

eggshell strength increased. The obtained values of some parameters are important for cage construction, design of collection equipment and design of egg packaging.
The research shows that the device for measuring egg strength by eggshell puncture method is simple, light construction, easy to use, non-invasive, efficient, reliable in work, and the obtained results of puncture force are precise, concrete and comparable with the results of other authors. The constructed device for measuring the strength of eggs and the method of puncture eggshell have application not only in laboratories of scientific institutions but also in practice on farms.

Abstract

The aim of this study was to evaluate the spoilage patterns of pasteurized milk microbiota. Additionally, the microbiological quality of raw and pasteurized milk regarding total aerobic and psychrotrophic counts was assessed. Samples were collected from two dairies at the milk reception point and different sites along pasteurized milk production line. Total aerobic and psychrotrophic counts in raw milk samples from Dairy 1 and 2 were at similar levels (approximately 6-7 log CFU/ml). The pasteurization step significantly reduced the total mesophilic bacteria counts. Samples from both dairies did not contain a detectable level of culturable psychrotrophic bacteria before the filling. However, psychrotrophic count in milk packages from Dairy 1 increased from 0.66±0.26 log CFU/ml to 3.76±0.19 at the end of the shelf-life. Forty-eight isolates with the different colony morphology selected from plate-count agar plates were screened for spoilage potential under laboratory conditions. The most prominent enzymatic trait (64.58% isolates) was proteolytic activity. Out of 17 enzymatically active isolates, 10 isolates were successfully identified as following: *Bacillus pumilus* (n=3), *Bacillus licheniformis* (n=2), *Leifsonia aquatica* (n=2), *Pseudomonas oryzihabitans* (n=2) and *Bacillus megaterium* (n=1). More stringent hygiene is required at each step of the dairy production chain to achieve a high microbiological quality of raw and pasteurized milk and to control spoilage microbiota.

Key words: *pasteurized milk, microbiota, spoilage potential.*

Introduction

The shelf life of pasteurized milk is largely dependent on the number of post process contaminants and storage temperature. Since pasteurized milk must be stored under refrigeration, psychrotrophic bacteria are favored and due to their ability to produce extracellular heat stable enzymes contribute to spoilage of heat-treated milk even when the microorganisms that produce enzymes are destroyed (Marchand et al., 2009). Proteolytic enzymes can lead to the development of bitter flavour, and physico-chemical instability (increased viscosity and milk gelation) (Datta and Deeth, 2003), while lipolytic enzymes cause rancid, butyric, or soapy flavors and also may lead to a reduction in milk foaming properties (Deeth and Fitzgerald, 2006).
Spoilage-associated microbiota may enter the pasteurized milk either as part of raw milk microbiota or as recontaminants during the dairy plant operations. In the first case, spoilage of pasteurized milk may occur as a consequence of contamination at the farm level, when psychrotolerant spore-forming bacteria, mainly *Bacillus* spp. and *Paenibacillus* spp., enter the fluid milk continuum, survive pasteurization, and subsequently germinate and outgrow to spoilage levels during refrigerated storage. Although transmission of spores into to end product

does occur, the psychrotolerant sporeformers may established themselves as in-house microbiota leading to the different recontamination sites throughout the pasteurization production line. Recontamination of milk after pasteurization, mainly with gram-negative bacteria such as *Pseudomonas* spp. may also lead to product's spoilage (Martin et al., 2021). Despite the fact that adherance to good manufacturing practices, sanitation and cleaning protocols have always been a cornerstone of dairy everyday practice, postpasteurization contamination is still very much an issue in the dairy industry. According to Martin and co-workers (2018), almost 50% of the fluid milk supply shows evidence of postpasteurization contamination with heat-labile gram-negative bacteria that originate from the dairy processing environment.
In Serbia fluid milk (pasteurized and sterilized milk) accounts for approx. 45% of the total production (Djekic et al., 2013). Pasteurized milk is one of the most preferred dairy product due to its flavor and „fresh" image with average consumption of 1075 ml a week (153.6 ml/day) (Djekic et al., 2020). The research activities that capture diversity and spoilage potential of pasteurized-associated microbiota are on the rise. Therefore, in order to contribute to this body of knowledge, the aim of the present study was to evaluate the spoilage patterns of pasteurized milk microbiota. Additionally, the microbiological quality of raw and pasteurized milk was assessed.

Materials and methods

Milk sample collection

The study was conducted in two dairies in the Republic of Serbia. Milk samples were obtained to represent the processing continuum from the raw milk reception point to packaged product. Raw and pasteurized milk samples were taken out at different sites along the production line (raw milk storage tank, just after the pasteurization step, sealed milk packages). Packaged pasteurized milk was also analyzed at the end of the shelf life.

Microbiological testing of milk samples

Milk samples were diluted with 0.1% sterile buffered peptone water (Oxoid, Basingstoke, UK) and aliquots of 1ml of the appropriate decimal dilutions were plated in duplicates on the plate count agar (PCA, Oxoid, Basingstoke, UK). Plates were incubated aerobically at 30°C for 48h and 7°C for 10 days for the enumeration of mesophilic and psychrotrophic bacteria, respectively. After viable counts, total of 48 colonies with different morphology were randomly isolated from countable plates and purified on PCA plates. The purified isolates are preliminary characterized by microscopic observation, Gram staining, catalase and oxidase reaction.

Proteolytic and lipolytic activity

Ability of selected isolates to produce extracellular enzymes was determined by agar diffusion assays. The following experimental setup was used: bacterial colonies were picked from nutrient agar (Oxoid, Basingstoke, UK) and suspended in the sterile saline solution to achieve cell density corresponding to McFarland 1. Aliquots of 10 µl of bacterial suspensions were then spotted on the surface of solid media. Skim milk agar (2x nutrient agar + 10% (w/v) skim milk powder) was used for screening of protease activity; Tributyrin Agar (Oxoid, Basingstoke, UK) was used for screening of lipolytic activity, and 2x PCA (Oxoid, Basingstoke, UK) with addition of 10% yolk emulsion was used for screening of lecithinase. Plates were incubated at 30°C for 5 days. At the end of the incubation period the Petri dishes were checked for enzymatic activity indicated by a clear halo.

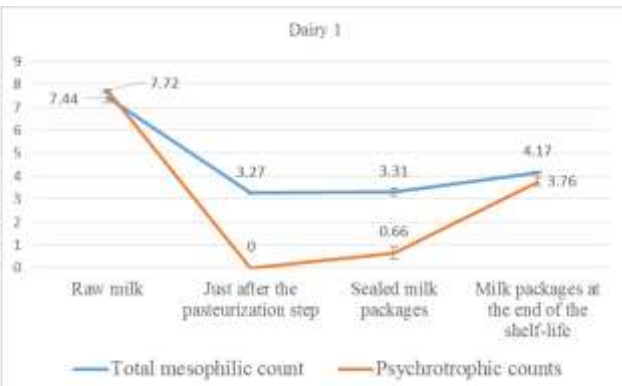
Identification of isolates

Based on their enzymatic activity, a total of 17 isolates were selected for the identification. Isolates were identified using commercial assays according to manufacturer's instruction. The Gram positive cultures (n=11) were identified using the Gram-Positive (GP) Identification (ID) kit (Beckton Dickinson, Sparks, USA), while the Gram negatives cultures were identified using the BD BBL CRYSTAL™ Enteric/Nonfermenter (E/NF) Identification (ID) kit (Beckton Dickinson, Sparks, USA). Identification was performed using BD BBL ™ Crystal ™ MIND identification software by entering the ten-digit code obtained from the results of performed tests.

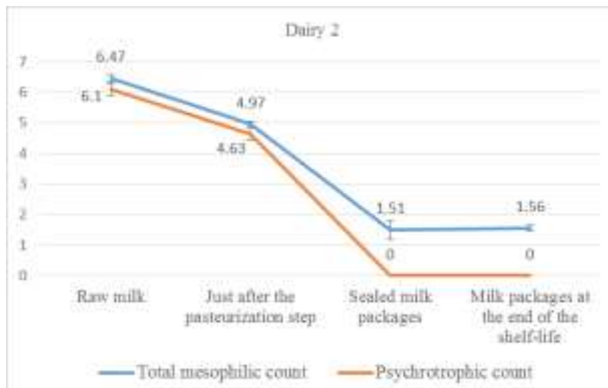
Results and discussion

The microbiological quality of pasteurized milk is traditionally estimated by the counts of both total mesophilic and psychrotrophic microbial load.

The total mesophilic and psychrotrophic counts determined in milk samples collected during the pasteurization production line in two dairies were presented in Graphs 1 and 2.



Graph 1 – Total mesophilic and psychrotrophic counts in milk samples collected from Dairy 1



Graph 2 - Total mesophilic and psychrotrophic counts in milk samples collected from Dairy

High total mesophilic count in samples taken from raw milk storage tank in both dairies indicate poor microbiological quality of raw milk. According to Serbian legislation (The Official Gazette of the Republic of Serbia no. 25/11 and 27/2014; The Official Gazette of the Republic of Serbia no. 106/17), raw milk from both dairies did not meet required quality criteria. Psychrotrophic counts were high in both dairies – 7.72±0.08 log CFU/ml in Dairy 1 and 6.1 log CFU/ml in Dairy 2. Contrary to our results, studies by other authors (Hantsis-Zacharov et al., 2007; Ercolini et al., 2009; Vithanage et al., 2014) showed the psychrotrophic microbial load of raw milk up to 10% of the total number of microorganisms. However, when milk is produced in poor hygiene conditions and/or contains increased numbers of somatic cells, the number of psychrotrophic microorganisms can make up 75% of the total raw milk microbiota (Hantnis-Zacharov and Halpren, 2007; Malacarne et al., 2013), or for more than 90% of the total microbial population in cooled raw milk (Catanio et al., 2012). Pasteurization step significantly decreased total mesophilic and psychrotrophic counts in both dairies. It is worth mentioning that both dairies have internal pasteurization procedures that differ from the HTST pasteurization process that is conventionally applied. In Dairy 1, pasteurization is performed at temperatures over 80°C for few minutes, while in Dairy 2, pasteurization at temperature higher than 80°C is performed twice before the filling step. Although psychrotrophic bacteria in milk samples from Dairy 1 were not detectable right after pasteurization, they were present at 0.66±0.26 log CFU/ml after milk packaging, and increased to 3.76±0,19 at the end of the shelf-life. According to Eneroth et al. (2000) increase in the number of microorganisms in milk packages, can occur as a result of contamination by microorganisms originating from the air in the filling machines, water used for washing, or aerosols generated during cleaning. Moreover, milk pasteurization can cause psychrotrophic bacteria to switch to the viable but non-culturable state, so the application of culture-independent methods is recommended in order to get reliable information about reducing effect of pasteurization on psychrotrophic microbiota (Oliviera et al., 2015). Culturable psychrotrophic bacteria were not detectable in samples from Dairy 2 after the packaging and during the product's shelf-life. In none of the samples microbial load reached the number of 6 log CFU/ml, which represents the limit above which pasteurized milk spoilage can occur (Doll et al., 2017). A total of 48 colonies showing different macromorphology on PCA agar were tested for their ability to produce extracellular enzymes at 30°C (Table 1). Extracellular enzymatic activity was visualized by agar diffusion assays. The most prominent enzymatic trait was proteolytic activity, which was present in 31 isolates (64.58%). Lipolytic activity showed 28 isolates (58.3%), and lecithinase activity 12 isolates (25.0%). Proteolytic activity, as the most common enzymatic trait in milk associated microbiota, was reported by other authors (Vithanage et al., 2014; von Neubeck et al., 2015). Moreover, proteolytic and lipolytic activity, and the less pronounced lecithinase activity, were characteristic of bacteria from the genus *Bacillus* (Hantnis-Zacharov and Halpern, 2007), which are the most frequently identified isolates covered by this study.Isolates obtained from different points in pasteurized milk production process were selected for the identification, based on their enzymatic activity. Out of 17 selected isolates, 10 were successfully identified at the species level (Table 1).

Table 1. Identified isolates and their enzymatic traits

Origin of isolate	**Species**	**ID accuracy (%)**	**Protease**	**Lipase**	**Lecithinase**
Raw milk	*Pseudomonas oryzihabitans*	84.70	+	+	-
Just after the pasteurization step	*Bacillus pumilus*	99.10	+	+	+
Just after the pasteurization step	*Pseudomonas oryzihabitans*	84.70	+	+	-
Just after the pasteurization step	*Bacillus megaterium*	99.90	+	+	-
Just after the pasteurization step	*Leifsonia aquatica*	99.99	+	+	-
Just after the pasteurization step	*Bacillus licheniformis*	98.70	+	+	+
Sealed milk packages	*Leifsonia aquatica*	99.99	+	+	-
Sealed milk packages	*Bacillus pumilus*	99.90	+	+	+
Sealed milk packages	*Bacillus pumilus*	99.10	+	+	+
Sealed milk packages	*Bacillus licheniformis*	96.70	+	+	-

The largest proportion of successfully identified gram-positive isolates were members of the genus *Bacillus*, ie *Bacillus pumilus*, *Bacillus licheniformis* and *Bacillus megaterium*. All *Bacillus* isolates originated from heat-treated milk, which is in accordance with the results from other studies where members of *Bacillus* spp. are identified as one of the main causes of pasteurized milk spoilage, in cases where recontamination with gram-negative bacteria is ruled out (Coorevits et al., 2008; Ivy et al., 2012; Masiello et al., 2014). *Bacillus* spp. have numerous routes of contamination of milk, such as through water, air, soil, feces, udders and milking equipment (De Jonghe, 2010). As thermoduric microorganisms, they have the ability to survive the pasteurization process, but there is also the possibility of recontamination during the pasteurized milk production process (Kumari and Sarkar, 2016). As mentioned before, in both dairies, the pasteurization process is carried out at higher temperatures than conventional pasteurization. According to the study of Ranieri et al. (2009), higher pasteurization temperatures favor spore germination and stimulate the growth of *Bacillus* spp, especially *Bacillus pumilus* and *Bacillus licheniformis*. Also, *Bacillus pumilus* and *Bacillus licheniformis*, in addition to being thermoduric, are also psychrotolerant (Ranieri et al., 2009).
Pseudomonas spp. is most common psychrotrophic microorganisms isolated from raw milk stored in the cold chain (Eneroth et al., 2000; Hantsis-Zacharov et al., 2007; Ercolini et al., 2009; von Neubeck et al., 2015. Yuan et al., 2017). However, since the pasteurization process removes all gram-negative bacteria (Ranieri et al., 2009), isolation of *Pseudomonas oryzihabitans* from pasteurized milk indicates post process recontamination.

Conclusion

The majority of enzymatically active isolates are identified as *Bacillus* spp. As sporeformers primarily enter into the milk chain on farms, control strategies must start at the farm level and continue throughout processing. Thus, the key strategy in ensuring the desired shelf life of pasteurized milk is to meet increased raw milk quality standards. This would be very hard and challenging task as high initial mesophilic and psychrotrophic plate counts of raw milk samples related to unhygienic practice during the production, storage and handling of milk is observed in this study.

Abstract

Poultry is one of the major animal protein sources for human nutrition. In recent years, the interest of consumers and the pressure against the use of the antibiotics in animal production have been increasing for safety and healthy foods. Due to ban of the antibiotics as growth promoters, the alternative feed additives have been suggested to improve growth rate and feed efficiency, stimulates intestinal health, and inhibit the pathogenic diseases. One of these alternatives is probiotic which is defined as live microbial that produce beneficial effects in the host animal by improving microbial balance of the intestines. Probiotics consist of living bacteria's, fungi's, yeast, and enzymes which support the gastrointestinal flora and health of digestive system. Commercial probiotic products include *Lactobacillus* spp. and *Bifidobacterium* spp. and other microorganisms (*Streptococcus thermophilus*, *Escherichia coli*, *Bacillus cereus*) and yeast (*Saccharomyces boulardii*, *Saccharomyces cerevisiae*) in poultry nutrition. There is an emerging preference for Bacillus-based probiotics in the poultry industry because this genus has characteristics that overcome the challenges associated with conventional probiotics. Their endospore forming ability enables them to be stable and viable during feed manufacturing, storage, and gut transit. The expected target of the usage of the probiotics in poultry nutrition is to maximize profitability with the lowest economical losses in production chain. The supplementation of probiotic could have potential to decrease mortality due to some infectious diseases, because it stimulates the immunity, intestinal health, and digestibility. The objective of this paper is to evaluate the beneficial effects of probiotic additives on performance parameters, nutrient digestibility, intestinal histomorphology and immunity, and the feeding cost in broiler and layer hens.

Key words: *Poultry industry, Bacillus-based probiotics, performance parameters, nutrient digestibility, Intestinal health.*

The identification and characteristics of probiotics

A probiotic is defined as a viable microbial dietary supplement that beneficially affects the host through its effects in the intestinal tract. They have a special role among functional foods and form a major part of the functional foods market, especially in the last decades. Probiotics contain lactic acid bacteria (LAB) or *Bifidobacterium* spp. The functional probiotics in dairy products must be more than 108 (cfu/ml) (Homayouni, 2014). Probiotic-containing products include dairy products such as yogurt, cheese, ice cream, acidophilus bifidus milk, ayran, kefir, kumiss, probiotic-containing doogh and milk drinks (both fermented and unfermented).

Probiotics could been classified as *Bifidobacterium, Lactococcus, Lactobacillus, Bacillus, Streptococcus and Candida yeasts*. Besides bacterias, fungis or yeasts are among the probiotics that enhance the gastrointestinal flora and the maintenance of a healthy digestive system. *Lactobacilli* and *Enterococci* have been widely used of microbial species as probiotics (Elam *et al.,* 2003; Patterson and Burkholder, 2003; Russell and Grimes, 2009). These species have recently gained more interest for use as probiotics. Their endospore forming ability enables them to be stable and viable during feed manufacturing, storage, and gut transit. It have been influenced the intestinal composition and metabolism (Huyghebaert *et al.,* 2011; Das *et al.,* 2012). It has been found that the addition of live microorganisms to the ration in animal nutrition increases immunity by strengthening the immune system. (Koenen *et al.*, 2004; Placha *et al.*, 2010).

The reason of probiotics usage in poultry nutrition

Probiotic microorganisms, even once ingested with living microbial cells, can regulate the basal and intestinal balance and activities of the gastrointestinal microbiota (Chaucheyras-Durand and Durand, 2010).

The impacts of probiotics appear in different ways after consumption by animals;

1) Maintenance of normal intestinal microflora with competitive exclusion and antagonist effect (Nurmi and Rantala., 1973; Jin *et al*., 1998).

2) Increasing digestive enzymes activity, regulating metabolism by decreasing ammonia production and bacterial enzyme activity (Jin *et al.,* 2000),

3) Improving feed consumption and digestion, and stimulating the immune system (Jin *et al*., 1998).

Probiotic microorganisms may regulate the in intestine microflora benefically.

Microflora activity may provide several benefits;

• Increased weight gain and feed effiency
• Increased the intestinal health and immunity of the poultry
• Suppressing pathogens such as Campylobacter and Salmonella species (Vilà *et al.,* 2009).

The ability of probiotics to utilize feed efficiency includes positive change in intestinal flora, enhanced growth of non-pathogenic facultative anaerobic and gram-positive bacteria, lactic acid formation, suppression of growth of intestinal pathogens, and enhanced digestion and utilization of nutrients. In addition to probiotics contribute positively impact to the development of the immune system (Coconnier *et al.,* 1993; Yeo and Kim, 1997).

Table 1. Description of the reasons using probiotics in poultry nutrition (Bahadıroğlu,1997; Kumprechtova *et al.,* 2000).

Usage of a potential alternative to antibiotics.
Contribute to the improvement of digestion and effective utilization of nutrients.
Intestinal flora in poultry have been improved by the increased feed conversion efficiency.
Prevention of intestinal pathogens growth rate.
Survival rate of poultry have been increased by using probiotics.
Benefical effecs in lowering the pH of the intestine.
Producing some symbiotic enzymes such as cellulase, xylanase, lipase, protease, β-glucanase and amylase.
Prevent the accumulation of toxic substances in the intestine.
Promotes the growth of non-pathogenic facultative anaerobic and gram-positive bacteria that form lactic acid and hydrogen peroxide.

By producing enzymes such as cellulase, xylanase, lipase, protease, β-glucanase and amylase, which works symbiotically with the enzymes produced by the digestive system cells of the poultry, that enhances the digestion of nutrients especially in chicks digestive system. Besides, these various microorganisms have been used to contribute to digestion system by synthesizing B group vitamins (Niacin, Biotin, Pyridoxine, Folic Acid, Pantothenic Acid) (Hooper, 1990; Vanbelle *et al*.,1990). Probiotics reduce the pH of the intestine (pH below 4-4.5) with organic acids such as lactic acid and acetic acid that prevents the growth of pathogenic microorganisms living at neutral or basic pH (Jernigan *et al.,* 1985).
In addition to these advantages; the significant impact of adding probiotics in poultry nutrition which is enables animals to gain resistance against pathogens (Mountzouris, 2014; Mountzouris *et al.,* 2015). To protect the intestines from pathogenic microorganisms, strengthen intestinal function and contribute to the development of the immune system could be possible by using probiotics in poultry (Ng *et al.,* 2009). Probiotics strengthen the intestinal barrier function and preserve against pathogens by improving the intestinal environment, enhancing the beneficial intestinal microflora (Ganguly (2013).
In poultry nutrition, probiotics should be include tolerance to gastrointestinal conditions, ability to protect the gastrointestinal mucosa from pathogens. As a result of various studies, the impacts of probiotic use in reducing pathogenic microorganisms in poultry, probiotic supplementation in poultry rations revealed that *Salmonella enteritidis, S. typhimurium, Escherichia coli, Clostridium perfringens, Listeria monocytogenes, Campylobacter jejuni, Staphylococcus aureus, Eimeria sp.* and Actinomyces have been reported to have antibacterial effects on many pathogens (Gadde *et al.,* 2017). After probiotic supplementation, non-pathogenic bacteria from probiotics inhibit the harmful bacteria in the intestines and secrete digestive enzymes (galactosidase, amylase, etc.) (Jadhav *et al.,* 2015).

Egg production and quality

The inclusion of probiotics in laying hens increases daily feed intake, nitrogen and calcium retention, and egg production by reducing intestinal length (Jha *et al.,* 2020). The dietary supplementation with probiotics is not only capable of increasing egg production, but also increasing feed conversion ratio and productivity, chicken performance and eggshell quality (Mikulski *et al.,* 2012). The addition of *Lactobacillus acidophilus* (0.1%) and *Bacillus subtilis* (0.05%) to the ration of laying hens resulted an improvement in performance, in antibody production, and a decrease in the amount of blood triglycerides and cholesterol (Forte *et al.*, 2016). It has been determined that probiotics (L. acidophilus) in laying hen rations reduces the plasma cholesterol level (Mohan *et al.,* 1995).
Zhang *et al.,* (2013) found that higher density lipoprotein (HDL) cholesterol in laying hens fed diets containing probiotics compared to chickens fed diets not supplemented with probiotics. As a result, 0.01% probiotic dietary supplementation to the ration improved egg production and egg quality and reduced fecal ammonia emission in this research. Besides it has been stated that *Lactobacillus salivarius* and *Bacillus subtilis* to the diets of layer hens, could be caused increases in egg production, daily egg yield, Haugh unit, damaged egg ratio (Zhang *et al.,* 2012). Mátéová *et al.,* (2009) found that Hyssex layer hybrids treated with probiotics did not cause significant changes in egg yolk cholesterol.

Feed intake, feed efficiency and growth rate

Probiotics could improve feed conversion, reduce morbidity or mortality, and improve product quality. It has been reported that probiotic consumption causes suppression of pathogenic microorganisms in the intestine, exclusionary competition and a growth in some digestive enzymes. The increase in feed efficiency is due to the use of nutrients lost by pathogenic microorganisms for growth and efficiency and the development in some digestive enzymes increases the dry matter digestibility (Tortuero and Fernandez, 1995; Yeşilbağ and Çolpan, 2006).
Usage of probiotics in improvements for growth performance and feed efficiency have been reported in broiler chickens (Kabir *et al.,* 2004; Mountzouris *et al.,* 2007; Samli *et al.*, 2007). Kurtoğlu *et al.,* (2004) found that feed conversion ratio were positively affected by supplementation of 250 and 500 mg kg (-1) probiotic compared with controls in their study. On the contrary to this research, Pruszynska- Oszmalek *et al.*, (2015) found in their research, the use of probiotics in roosters increased body weight but the feed conversion ratio was not changed. In Awad *et al.*, (2006) study indicates that probiotics supplemantation was found uneffective for feed efficieny in broilers.

Carcass yield and quality in broiler

Many studies have been conducted to investigate that the use of various probiotics to enhance performance characteristics in broilers (Patterson and Burkholder, 2003; Amerah *et al.*, 2013; Fuentes *et al.*, 2013; Zhang and Kim, 2014). *Lactobacillus*, *Bifidobacterium*, *Bacillus*, *Streptococcus*, *Pediococcus*, *Enterococcus*, and yeast such as *Saccharomyces cerevisiae* probiotics has been effected on the different performance parameters in chickens including feed efficiency in broilers (Endo and Nakano, 1999). Similarly, the use of *C. butyricum* and *S. boulardii* in poultry nutrition could improve growth performance in broilers. The addition of probiotics (*Bacillus, Lactobacillus, Streptococcus, Clostridium, Saccharomyces and Candida spp*.) to broiler rations increased the carcass and meat quality of broiler chickens (Zhao *et al.*,2013; Rajput *et al.*, 2013).
In another study, the inclusion of *Lactobacillus acidophilus* and *Streptococcus faecium* probiotics in broiler ration increased protein, ash, water holding capacity, emulsion capacity and stability in meat in broiler nutrition (Mahajan *et al.,* 2000).
Supplementation of probiotics to the diet in broilers has been associated with increased body weight gain and feed intake (Mountzouris *et al.*, 2007). Al-Zenki *et al.*, (2009) examined the effect on performance in broiler chickens by using commercial probiotics *Saccharomyces cerevisiae* and *Pediococcus acidilactici*. In the results of this research probiotic treatments was found be uneffective on the production parameters of broiler chickens.
Yang *et al.*, (2010) researched that *Clostridium butyricum* supplementation reduced the ratio of n-6:n-3 fatty acids in breast muscles and enhanced eicosapentaenoic acid (EPA(and total n-3 fatty acids. For another study, it was reported that adding bacteria (Rhodobacter capsulatus) to the broiler diet could improve the fatty acid content of broiler chicken meat (Salma *et al.*, 2007).
In the contrary to this researches that the effect of probiotic dietary supplementation probiotic was found no significant on carcass yield, breast meat and lymphoid organs weight (Karaoğlu and Durdağ, 2005; Cengiz *et al.*, 2015). Due to differences of animal material and variety and

amount of probiotics could be differences in the results of the studies (Kumprechtova *et al*, 2000).
Furthermore, *Bacillus subtilis*, on musculoskeletal health and related meat quality in broilers. In relation to meat quality and musculoskeletal development in broilers, the *Bacillus subtilis* probiotic has been widely used in other animals, including broilers. (Mohammed *et al*., 2021). It is also stated that growth in poultry is accelerated by increasing probiotic doses (from 0.5 g to 1.5 g per 10 kg feed) (Zulkifli *et al.*, 2000).

Nutrient digestibility and intestinal histomorphology

Probiotic microorganisms have been found to maintain on intestinal microflora in poultry nutrition. Regulation the digestion of intestinal enzymes and nutrients and impromevent pH and flora could be possible by probiotics. In addition to that the intestinal amylase activity have been increased with the enzyme secretion of lactobacilli colonization in the intestine with the addition of probiotics (Duke, 1977; Dierck, 1989). The addition of probiotics to the ration in poultry has beneficial effects on digestion and absorption in the intestines. Probiotics have a growth-promoting effect due to their benefits on the growth of intestinal microbiota and their contribution to intestinal functions (Jin *et al.*, 1998; Fioramonti *et al.*, 2003; Guillot., 2003).
The growth of lactic acid bacteria occurs in the gastrointestinal organs after probiotic consumption of the animals including poultry. These microorganisms change the intestinal environment and produce enzymes and other beneficial substances in the intestine Also, lactic acid could been produced by some bacterias such as *Lactobacillus, Leuconostoc, Pediococcus, Streptococcus* (Marteau *et al*., 1993).
Probiotics regulate the intestinal pH by producing organic acids such as lactic acid and formic acid, thus preventing the growth of gram (-) pathogenic microorganisms that live in a neutral and basic environment and are harmful. *Staphylococcus* species used as feed additives cause competition between gram (-) bacteria and vibrio species living in the intestines and lactic acid producing microorganisms, thereby reducing the effect of microorganisms that are pathogenic for animals such as *E. coli, Salmonella, Proteus, Pseudomonas, Klebsiella* (Ülger *et al.*, 2016).
Due to antibacterial effects, *bacteriocins* have been obtained by the probiotic with the competitive effect of bacteria in the intestine (Patterson and Burkholder, 2003). Some studies in laying hens and broilers have indicated that probiotics may be beneficial for improving intestinal health (Deng *et al.*, 2012; Bai *et al.*, 2013).
The inclusion of *C. butyricum* in the ration contributes to the performance of laying hens and the development of normal intestinal morphology. Besides in the laying hens, *Butyricum* and *S. boulardii* and *P. acidilactici* combination was found effective in enhancing of the intestine (Xiang *et al.*, 2019). In addition to other studies results, probiotic supplementation in the diet increases villus height and villus height/crypt depth ratio in ileum and cecum. As the result better epithelial growth after probiotic supplementation could been found (Kim *et al.*, 2011; Sen *et al.*, 2012).

The economical impacts and targets of the probiotics

The major component of feed cost in poultry production could be reach until %70. Recently probiotic supplementation has proven to be more profitable and economical in order to gain maximum profit from poultry production. The use of probiotics as feed additives could be caused to reduce production costs by increasing feed efficiency (Rufino *et al.,* 2015).

Probiotic to the ration as a nutritional supplement also in broilers is among the significant impacts leading to a decrease in production costs. It has been determined by Anjum *et al.*, (2005) study, the experimental group fed with the broiler diet supplemented with probiotics could be obtained at a lower cost than the control group. As the result of this study the using of probiotics was found more economical and productive for broiler production. Besides in many studies have found that probiotic supplementation in broiler production enhances growth performance (Fuentes *et al.*, 2013; Zhang and Kim, 2014).

Ray *et al.,* (2019) found in the research that probiotics to the ration increases economic profitability and the useage of probiotics containing *Bacillus subulans* and *Bacillus soagulans (PB-2)* positively affects the cost. Similarly, Patel *et al.,* (2015) found that various probiotic supplements to the ration could contribute to more economical production. Besides, adding probiotics in egg layers feeding, many economic benefits have been provided to increase eggshell breaking strength and egg quality (Sakai *et al.,* 2006).

There is an emerging preference for Bacillus-based probiotics in the poultry industry because this genus has characteristics that overcome the challenges associated with conventional probiotics (Ramlucken *et al.,* 2020).

Conclusion

In conclusion, there are many points that need to be explained regarding the full understanding of the mechanism of action in probiotics. Both consumer preferences and the limitation of using antibiotic will make the probiotics and prebiotics inevitable for today and the future. Usage various types of microorganisms that can be used as probiotics in the future will lead to profitability in yield and economic gain.

Abstract

The purpose of given research was to study the quality of grass fodder (hay, silage, haylage), harvested in the farms of Perm Region in 2017-2020 and to determine the relationships between cattle metabolism and quality of feed ration. According to the results of the studies, corn silage from 56% of the samples did not comply with national standards for dry matter (DM) - the content was below 20%. Thirteen batches have high content of acetic and butyric acid. Herbaceous fodders with higher quality were obtained from leguminous plants. Haylage in plastic packaging is the highest quality forage among the fodders harvested in the farms of the region – 92% of total volume batches of tested feed received the high quality degree. This type of fodder is characterized by high energy concentration – up to 13.33 MJ/kg per kg DM, as well as an increased content of crude protein in DM – up to 23.29%, especially batches from goat's-rue (*Galega orientalis*), alfalfa and mixture of clover and alfalfa. Unbalanced diet and low nutrient digestibility led to metabolic processes violation in cows organism, which was expressed in the form of ketosis and alkalosis noted for 90-95 % animals of the dairy herd. The scientific novelty of the work enclose detailed study of biochemical composition of fodder prepared in Perm Region and their influence on the metabolic processes in the body of animals.

Key words: *herbaceous fodders, legume hay, corn silage, haylage, exchange energy, protein.*

Introduction

The cows breeding stock with genetic potential of milk productivity from 10 000 to 14 000 kg per lactation, with elevated milk fat and protein was created in Perm Region as a result of breeding work to improve the black-and-white breed using Holstein producers. However, in 2020, the average milk yield for all farms in region was 6633 kg from one cow (Volgin et al.,2016). Realizing the genetic potential of that breed depends largely on the biological usefulness of the herbaceous fodders used in feeding. Home grown fodder obtained in most farms in Perm Region have significant deviations from the requirements of national standards (GOSTs) in regard of basic nutrient content.

It is impossible to provide balanced feeding for highly productive livestock without having high-quality herbaceous fodders in accordance with the detailed diets, since it depends by 50% on providing the animals with metabolic energy, 25% - by protein and 25% - by minerals and vitamins (Volgin et al.,2016, 2018). So, it is necessary to have certain set of forage crops characterized by different content of animal nutrition elements for every soil and climatic zone of Russia. Technological approaches to the fodder preparation and storage also have different specifics. A lot of analyses of different fodder types from farms of Perm Region are carried out annually in the analytical laboratory of Perm Federal Research Center Russian Academy of

Sciences. From 1949 samples of grass forage tested in the last 4 years (2017-2020), 4% of silage batches, 3% of haylage and 17% of hay batches were classified as low quality ones.
The purpose of the work is to study the quality of bulky herbaceous fodders harvested in the farms of Perm Region, to reveal the reasons for obtaining low-quality herbaceous forage and give recommendations for the fodder preparation with a high content of exchange energy and digestible protein.

Materials and methods

The analyses were carried out in certified analytical laboratory of Perm Agricultural Research Institute - division of Perm Federal Research Center using national standards, (GOSTs), conventional techniques and modern laboratory equipment: the infrared feed analyzer SpectroStar 2600 XT-1, the Unico spectrophotometer, Fibretherm-12 (device for automatic fiber analysis) , etc. The laboratory fulfilled analytical studies to determine the chemical composition of raw materials and prepared fodders on the basis of the conclusion No. 07-10/18-18 on the state of measurements in the laboratory dated May 31, 2018, issued by the Perm CSM FBU.
The study of biochemical parameters of animal blood and metabolic processes was fulfilled on the dairy farms in Perm Region: «Rus» ltd; «Hohlovka» ltd; «Lipovaya Gora» ltd with control and experimental groups of dairy cows. The analyses of the biochemical composition of the cows blood were carried out in Veterinary Center «Permskiy».

Results and discussion

The detailed analysis summarized the studying a large number of samples of hay, silage and haylage, prepared in 67 farms during 2017-2020, for the main parameters of feed quality was fulfilled. Information about the forage quality is given in terms of absolutely dry matter, as it accepted by the relevant standards; the data for the content of exchange energy, crude protein, feed units and other parameters of feed quality is provided.
The main volumes of herbaceous fodders are prepared in Perm Region from perennial legume-cereal grass mixtures, legumes (red clover *Trifolium pretense*, L. alfalfa *Medicago varia* goat's-rue, *Galega orientalis*, L.), , perennial poaceous grasses and corn.
Hay is prepared from red clover and its mixtures with timothy grass (*Phleum pretense*, L.), poaceous-legumes grasstands and poaceous perennial grasses. The significance share of hay is prepared from natural meadow grasses. In general, 26 sources of raw materials were used for hay making during the analyzed period. Hay has the lowest nutritional value among all kinds of forage prepared in Perm Region: 66.47% of the tested batch of feed belonged only to third duality class and even out of quality classes (Table 1).
The tested hay samples have a low concentration of exchange energy (EEC). Only 8% of hay legume samples have EEC more than 10 MJ/kg of dry matter. There were no samples among samples from poaceous-legumes mixtures and poaceous grasstands with such EEC. Crude protein (CP) deficit was noted for all hay samples. CP content of more than 15% in dry matter of legume hay was noted only for 42.4% of samples, in poaceous-legumes batches - for 4.0%, in poaceous batches -1.40%. Crude fiber content in hay varied within 24.97% - 44.78 % for absolutely dry matter (optimal value 27-29%). The main reason of the hay low quality is the late harvesting time and the deterioration of the botanical composition of old age grass stands.

Table 1. Chemical composition of hay prepared in Perm Region, 2017-2020

Type of hay	Tested samples amount	Dry matter content, %	Content in dry matter, %				Feed class	
			crude fiber,	Crude protein,	EEC , MJ/kg	feed. units/kg	I+II, %	III+ non%
Legume	23	72,30-88,20*	25,03-36,45	7,12-21,20	8,08-10,72	0,56 – 0,66	75	25
GOST		83,00	27,00	15,00				
Poaceous-legume	127	67,60-90,15	24,97-44,78	6,48-21,31	6,94-9,46	0,54 – 0,64	55	45
GOST		83,00	28,00	14,00				
Poaceous	82	70,88-88,95	27,88-38,81	5,93-15,01	7,76-9,25	0,52 – 0,63	55	45
GOST		83,00	29,00	13,00				

Note: * - here and further –the range of values for forage batches.

In order to reach balanced diet for cows the hay should have 9.0-9.5 MJ and 14-15% digestible protein in one kg of hay DM (Morozkov et al., 2015).

Analyzing the data of the chemical composition of hay, it is necessary to pay attention to the fact that the carotene content in hay dry matter was 12.73 mg/kg in average with deviations from 6.40 to 26.65 mg/kg (optimum level 25.00 mg/kg). The most important condition for obtaining high-quality forage is mowing time. Now it is well-known fact. The optimal time means not only date or phase of plant development, but also times of day. The best time for mowing is considered to be in the morning, starting from dawn until 11 o'clock a.m. Grasses have the highest possible carotene content during this period and dry out faster. Hay making using the method of forced ventilation provides obtaining high-quality fodder. Due to the rapid drying and elimination of losses method permits to increase the hay yield by 15-20%, the yield of feed units and digestible protein - by 20-25%, and carotene – by 2-3 times compared to conventional drying in the field. Feeding the hay prepared by the method of forced ventilation allows to raise the cows productivity by 10-12% (Guryanov et al., 2007; Faritov, 2010).

The largest share of silage making is prepared from clover-timothy mixtures, perennial legume-poaceous mixtures, red clover and corn. High quality of silage (I-II classes) was noted for 85.50% of the tested batches (Table 2). Low quality silage occupy 14.50% in total amount. It should be noted that butyric acid was present in 572 samples (48.97%), including 16 samples (1.37%), that they are not allowed to be fed according sanitary rules. The most valuable silage was obtained from legumes, 68 % of the tested feed contains 10 or more MJ/kg of exchange energy and over 15 % of crude protein in dry matter.].

Table 2. Chemical composition of silage prepared in Perm Region, 2017-2020

Type of silage	Tested samples amount	Dry matter content, %	Content in dry matter, %				Feed class	
			Crude fiber,	Crude protein, %	EEC, MJ/kg	feed. units/kg	I+II, %	III+ non, %
Legume	322	15,31-37,92*	23,04-34,86	9,35-23,80	7,96-13,33	0,79 – 0,85	85	15
GOST		27,00	28,00	15,00				
Poaceous-legume	712	15,81-39,89	23,74-41,24	7,92-23,55	7,38-12,67	0,78 – 0,86	83	17
GOST		25,00	28,00	13,00				
Poaceous	46	16,50-35,41	24,13-35,39	9,61-19,06	8,30-12,60	0,73 – 0,84	82	18

GOST		20,00	28,00	12,00				
Corn	88	16,60-28,01	24,94-33,79	9,45-14,90	9,22-11,25	0,74 – 0,86	92	8
GOST		26,00	28,00	8,00				

The phenological phase during mowing has a major impact on the quality of prepared silage (Nagibin, 2018).In 47 tested corn silage samples from total amount 88 samples of corn silage dry matter content was less than 20 %, while the feed mixture should contain 50-55% dry matter for lactating cows. The average EEC for all samples was 10.22 MJ/kg in dry matter. Silage, prepared in Perm region, is traditionally characterized by an acute shortage of crude protein, only nine samples had more than 14 % in dry matter.
High milk productivity is possible with a concentration of exchange energy in a corn silage at least 10.5 MJ/kg (Zezin, 2017). That level of EEC may be achieved in corn silage when the ear content in the silage mass is at least 40-50% and provided their ripeness milk-wax and wax (Zscheischler, 1984). The technological minimum of dry matter content according in the green mass of corn before ensiling should be at least 25% (Zezin N., 2017).
The predominant amount of haylage is harvested from perennial legumes and legume-poaceous grass mixtures. 474 batches (92%) from total amount 549 were assigned to I and II quality classes (Table 3).

Table 3. Chemical composition of haylage, prepared in Perm Region, 2017-2020.

Type of haylage	Tested samples amount	Dry matter content, %	Concentration in dry matter				Feed class	
			Crude fiber, %	Crude protein, %	EEC, MJ/kg	feed. units/kg	I+II, %	III+ non %
Legume	247	25,41-69,82*	20,85-34,67	9,61-23,79	7,80-13,37	0,77 – 0,83	98	2
GOST		45,00-55,00	27,00	16,00				
Poaceous legume	240	19,79-71,18	23,26-36,36	7,58-21,06	7,81-12,38	0,72 – 0,84	96	4
GOST		45,00-55,00	29,00	15,00				
Poaceous	62	22,18-76,54	24,56-37,71	6,88-16,17	7,81-11,09	0,61 – 0,66	54	46
GOST		45,00-55,00	30,00	14,00				

Haylage making in trenches deserves special attention. The share of haylage in trenches was about 16% of the tested haylage samples. The predominant amount of haylage in trenches is prepared from perennial poaceous-legume mixtures, red clover, clover-timothy mixtures, goat's-rue, and alfalfa. Compared with silage, the tested batches contain 2.5 times less batches with the presence of butyric acid and only 2% of the batches do not comply with GOST R 55452-2013 for this parameter. Haylage from legumes is the most valuable forage in this type in terms of the of exchange energy and crude protein in dry matter.
Haylage in plastic packaging (rolls) has the highest feed quality among the grasses fodders harvested in the farms of the region – 92% of the batches of the total volume were classified as belonging to I-II quality classes. This forage type is characterized by high energy concentration – up to 13.33 MJ/kg in dry matter, as well as an increased content of crude protein – up to 23.29% dry matter, especially batches from goat's-rue, alfalfa and clover- alfalfa mixture. The safety of carotene in the haylage in plastic rolls was 12-15 times higher compared with the hay in usual

rolls, which testifies that the safety of all biologically active substances of haylage in plastic packaging was also higher. Therefore, it is necessary to give preference to that kind of fodder. However, haylage in plastic accounts only 2,60% of herbaceous forage total volume prepared in Perm Region. According to research data (Bondarev, 2008; Kosolapov et al, 2008,2009), in order to have 10 MJ of exchange energy in dry matter, grass should be harvested in time when fiber content does not exceed 26%. These parameters correspond to the phase of the beginning of earing of poaceous grasses, the beginning of budding of legumes (clover, alfalfa). Harvesting grasses in more late phases leads to a decrease in energy nutrition by 1% daily. At the same time, the average protein loss per day is 0.25%, and the fiber content increases by absolute 0.33% per dry matter. According to data of Korelina (2019), the enlargement of forage crops assortment the replacement of low-yielding varieties with more productive and nutritionally valuable ones is a significant reserve for increasing feed production and improving their quality.

The results of research in Perm Agricultural Research Institute (Maysak, Voloshin, 2015) showed that the optimal period for grasses mowing is determined taking into account the intensity of average daily changes in the chemical composition of forage crops green mass and balance between relatively high yield and sufficient feed quality. The optimal mowing period for winter rye was 15 days in average (for the years of research), for goat's-rue and alfalfa -16 days, for early maturing variety of red clover Trio mixed with poaceous grasses -7-17 days, for late maturing variety of red clover Perm local -20 days, perennial legume-poaceous mixtures -14 days in average, annual grasses -11 days from the date when crops reach the yield of 9-10 t / ha of green mass, or the branching of legumes, stem elongation– for poaceous grasses. Harvesting in a later phase leads to reduction of the exchange energy content by 0.1 MJ / kg daily. The losses of digestible protein are 0.36 %, and the fiber content increases by 0.46 % (absolute) per dry matter. The experiments fulfilled by scientists of Perm Agricultural Research Institute in the farms of Perm Region over the last 10 years revealed that unbalanced diet and low nutrient digestibility of applied fodders led to metabolic processes violation in cows organism, which was expressed in the form of ketosis and alkalosis, reported in some cases for 90%-95 animals of the dairy herd (Morozkov et al., 2015). In later studies the content of beta-carotene in the blood serum of cows in the first phase of lactation was lower than the physiological rate for the entire studied livestock and varied in the range of 4.39-7.40 mmol/l (optimum 7.50-18.6 mmol/l.) Carotene content in blood of cows confirmed the actual carotene deficiency in their diet (Morozkov, Sukhanova, 2020).

Conclusion

The fodders made in the farms of Perm Region does not provide the needs of highly productive cattle for basic nutrients, especially silage. Disturbance in technological requirements for harvesting grass fodders leads to metabolic processes violation in cows organism, decrease in productivity and, as a result, to essential economic damage for the farms in the region.That is why, the main objective of feed production is provision of forage with a high level of exchange energy concentration and digestible protein, since energy-saturated, high-protein fodders are the main condition for high dairy productivity. The reality of this objective is confirmed by the results of testing the forage harvested in the region – among the silage batches from legume perennial grasses and haylage from legumes, there were samples with a EEC 12-13 MJ/kg and with crude protein content of more than 15 % in dry matter. Haylage in rolls with plastic packaging obtained from legumes is the most valuable forage in this type. Urgent task in feed production is to expand the set of forage crops, to increase the share of most productive species and cultivars with valuable biochemical content, comply with the recommended time of perennial grasses use and timely replace old age grass stands with poor-quality botanical composition by highly productive species and mixtures.

Abstract

Qualitative and quantitative parameters of stallion ejaculate are influenced by various factors. The age of stallion is one of them. The aim of this study was to evaluate the effect of stallion age on the ejaculate gel-free volume, concentration, motility and sperm morphology. The total number of 15 stallions of various breeds housed in the Tlumačov Regional Stud Farm were included in this research. The total number of evaluated ejaculates was 103. Stallions were divided into three age categories (3-7 y, 10-14 y, 18-20 y). The highest values of ejaculate gel-free volume were reached by the group aged 10 to 14 years (57.33 ml) and the lowest values were reached by the group of the oldest stallions (34.17 ml) ($p \leq 0.05$). Stallions from the age category 10-14 y also achieved the highest values of sperm concentration (254.21 * 10^6 / ml). The lowest sperm concentration was measured in the age group of the oldest stallions (197.07 * 10^6 / ml). The oldest age group (18-20 y) achieved the highest values of sperm motility (86.57%) while the lowest values were achieved within he youngest age group of stallions (79.27%). Differences in sperm concentration and motility were not statistically significant. The highest values of spermatozoa with normal morphology were reached by the oldest age group (89.64%), while the lowest values were reached by the youngest group from 3 to 7 years (85.22%) ($p \leq 0.05$). The effect of age on ejaculate parameters was demonstrated in both sperm volume and morphology. Therefore, the age of the stallion should be taken into consideration when evaluating stallion ejaculate.

Introduction

Artificial insemination is a widely spread biotechnical method of reproduction in animal breeding (Foote et al., 2020). Its use in the field of horse industry is constantly increasing (Janett et al., 2003a). Fresh and frozen semen have become the most used tools for breeders (Aurich and Aurich, 2006).

Artificial insemination brings many advantages such as reducing the risk of injury and transmission of infectious venereal diseases, the accelerating of genetic progress by making the best stallions available and to eliminate the stress factors caused by animal transportation (Aurich and Aurich, 2006; Aurich, 2012; Daigneault, 2012; Janett et al., 2003a; Parkinson and Morrell, 2019). The rate of fertilization of AI is the same even higher than with natural breeding (Janett et al, 2003a; Janett et al, 2003b; Langlois and Blouin, 2004). These results are significant also with problematic mares (Pickett and Shiner, 1994).

The success of artificial insemination mainly depends on the quality of the ejaculate used (Samper, 2001), which is influenced by many physiological and external factors (Kandiel and El

Khawagah, 2018). One of these factors is the procedure for the preparation of insemination doses (Rečková a Filipčík, 2020), seasonality, (Janett et al, 2003a), stallion individuality, nutrition, breed and the age of the stallion (Dowsett and Knott, 1996). Factors such as nutrition, age of the stallion when we start using him for reproduction and the process of preparing insemination doses can be easily influenced. On the other hand, the influence of the season, individuality and changes in the quality of ejaculate caused by the age can be only partially influenced. Therefore, it is important to know how age influences the quality of an ejaculate. This information is important to take into consideration when choosing the right stallion and the subsequent success rate of insemination.

The aim of this work was to evaluate the effect of age on the quantitative and qualitative parameters of ejaculate, such as gel-free volume, concentration, motility and morphological changes of sperm.

Materials and Methods

For this study we used 15 stallions of various breeds in the age from 3 to 20 years, housed in the Tlumačov Regional Stud Farm (Czech Republic). Stallions were routinely used for the production of short-term stored insemination doses and were included in the offer for an artificial insemination in the year 2019. The stallions were divided into age categories from 3 to 7 years old, from 10 to 14 years old and from 18 to 20 years old. The total number of evaluated ejaculates was 103. Ejaculates were collected during breeding season (April-August 2019).

Each ejaculate was macroscopically and microscopically evaluated in the Reproduction Center of Tlumačov Stud Farm. Immediately after the collection, gel fraction was removed from the native ejaculate by filtrating it through the sterile gaze. Ejaculate gel-free volume, sperm concentration and motility were determined, and smears for morphological evaluation of ejaculate were prepared. Morphological evaluation of sperm was executed in the laboratory of Mendel University in Brno, Department of Animal Breeding.

The gel-free volume of ejaculate was determined by weighing and it is given in millilitres. Sperm concentration was determined by an objective method CASA (Computer Assisted Sperm Analyzer), a minimum of 500 sperm were evaluated in a minimum of 5 fields of view. Total and progressive sperm motility was assessed using CASA (Computer Assisted Sperm Analyzer), minimum of 500 sperm were evaluated in a minimum of 5 fields of view. Smears of native ejaculates were fixed and dyed according to the Farelly method. At least 200 sperm were evaluated and the percentage of sperm of normal morphology to the percentage of pathological sperms were determined. Sperm without visual deformations or other pathological changes were classified as those with a normal morphology.

Pathologically formed sperm included immature sperm (containing protoplasmic drop), sperm with developmental anomalies (double tails, double head, deformity), spermatozoa with head defects (non-standard head shape, acrosome defects) and tail defects (crooked and curled tails, mid-piece defects, neck defects).

Program STATISTICA CZ 12 was used for the statistical evaluation through variational analysis. The HSD test was used to determine statistical signification within each factor.

Results and discussion

Table 1. Qualitative and quantitative parameters (means ± SEM) of stallion ejaculate for different age groups

Age categories	*n* - number of collection	Gel-free volume [ml]	Sperm concentration [10^6 / ml]	Sperm motility [%]	Sperm of normal morphology [%]
3-7 years	37	37.86 ± 0.48	214.68 ± 20.24	79.27 ± 4.63	85.22 ± 1.85 a
10-14 years	24	57.33 ± 2.54 a	254.21 ± 31.60	85.63 ± 3.45	89.04 ± 1.02
18-20 years	42	34.17 ± 0.39 b	197.07 ± 16.96	86.57 ± 1.57	89.64 ± 0.73 b

a, b Differences are significant for $p < 0.05$

In the oldest age category (18-20 y), the gel-free volume of ejaculate was 34.17 ± 0.39 ml, statistically demonstrably lower ($p \leq 0.05$) than in stallions in the age range from 10 to 14 years (57.33 ± 2.54 ml). The youngest age category of stallions (3- 7 y) had gel-free volume of 37.86 ± 0.48 ml.

The oldest age category of stallions had the lowest average sperm concentration (197.07 ± 16.96 x 10^6 / ml). In the contrast, the age category from 10 to 14 years had the highest average sperm concentration (254.21 ± 31.60 x 10^6 / ml). The youngest stallions reached the average sperm concentration 214.68 ± 20.24 x 10^6 / ml. Differences in sperm concentration among age categories were not statistically significant.

In the youngest category of horses was determinate the lowest average sperm motility 79.27 ± 4.63 %. Stallions of the age range from 10 to 14 years had the average motility of 85.63 ± 3.45 %. %. In the oldest stallions, the average value of motility reached 86.57 ± 1.57 %. Differences in sperm motility among age categories were not statistically significant.

In the youngest age category, the proportion of sperm of normal morphology (85.22 ± 1.85 %), was statistically demonstrably lower ($p \leq 0.05$), than in the oldest age category (89.64 ± 0.73 %). The age category of stallions from 10 to 14 years had a proportion of sperm of normal morphology 89.04 ± 1.02 %.

The parameters of ejaculate such as volume and sperm concentration can directly affect the total number of sperm and thus the number of insemination doses that can be produced (Samper, 2008). Sperm motility and morphology are common methods for assessing the quality of stallion ejaculate (Samper, 2008; Varner, 2008).

Ejaculate parameters are influenced by many factors (Kandiel and El Khawagah, 2018). One of them is the age of the stallion (Dowsett and Knott, 1996; Gottschalk et al., 2016; El Sisy et al., 2016; Kandiel and El Khawagah, 2018).

Based on the results, a lower ejaculate volume and sperm concentration and a higher average motility and the proportion of sperm with normal morphology were observed in the oldest age category of stallions. The highest average sperm volume and concentration were recorded in the category of stallions from 10 to 14 years, while the average values of motility and the proportion of sperm with normal morphology were slightly lower than in the oldest group of stallions. The average values of motility and the proportion of sperm with normal morphology were the lowest in the youngest group of stallions.

There were statistically significant differences in the volume of ejaculate, which was higher in the middle age category than in the oldest age category, and in the proportion of sperm with normal morphology which was higher in the oldest group than in the youngest group of stallions. Despite the differences in the monitored parameters, all stallions met the requirements for native ejaculates.

Dowsett and Knott (1996) proved that a higher proportion of immotile and abnormal sperm may be observed in younger stallions. The effect of age on ejaculate parameters is associated with less effective spermiogenesis of colts and testicular degeneration due to stallion aging (Brito, 2007). Despite the decrease in volume and concentration in oldest category of stallions, a higher proportion of sperm with normal morphology were observed than in the age category from 3 to 7 years. This agrees with statement of Gottschalk et al. (2016), who state that stallions can be used to high age while constantly monitoring ejaculate quality.

Conclusion

Age affects the parameters of ejaculate, especially the volume and the portion of sperm with normal morphology. Although all stallions met the established requirements for further ejaculate processing, the age factor must be taken into consideration when evaluating stallion reproduction characteristics.

Abstract

The aim of this study is to examine the influence of the age of laying hen hybrid on the basic characteristics of the egg structure (the yields and the share of shell, egg white and yolk). Additionaly, the aim of this paper is to examine what happens to certain egg structure characteristics after the established 72nd week of laying hen age, until the end of 79th week of age of the Lohmann Brown hybrid hens. The examination of the egg structure characteristics was performed on light-line hybrid Lohmann Brown, on the farm"Agrovet" Foca, at four periods of laying hen age (27th, 46th, 72nd and 79th week) with 60 individually measured eggs in each period. The basic parameters of egg structure included the egg mass (g), the share of the shell (g, %), the share of the yolk (g, %) and the share of egg white (g,%). The influence of the egg mass on the basic characteristics of the egg structure was also determined by calculating the correlation coefficients between those parameters. Based on the results of examination, it was concluded that the average absolute mass of the shell, yolk and egg white also increased along with the age of laying hen. The relative values of the shell very around 13% through all periods, while the share of the yolk gradually increased through the periods, and ranged from 24.76% to 25.77%, with minor exception at the last period. The mass of egg white was determined by calculating the difference between the total mass of egg on one side and the mass of yolk and shell on the other side. The share of egg white in total egg mass was the highest in the first period (61.83%) and the lowest at the end of the production cycle (61.05%). It can be concluded that the egg mass of analyzed commercial flock of light-line Lohmann Brown hybrid, had influenced basic characteristics of the egg structure, in all examined periods.

Key words: *Lohmann Brown, Egg structure, Egg mass, Correlation.*

Introduction

The characteristics of egg structure, i.e. the percentage of egg components in the total egg mass, is determined by genetic and paragenetic factors.

The egg is made of the shell, egg white and yolk. The purpose of the shell is to protect the sensitive parts of egg from external influences, and it enables the the gas exchange and heat transfer. The shell is built from calcium carbonate, which makes it solid and porous. The inside of the shell is covered by three-layer membrane, and by separating the inner membrane from the outer membrane on the top of the egg, the air chamber is created, which grows bigger as the egg grows older, due to evaporating of water from the egg content.

The eggs are an excellent source of nutrients. The basic structure of eggs consists of shell, egg whites and yolk. The average egg weight of 64.5 g contains 57.18% of egg white, 29.25% of yolk and 13.57% of shell (Kralik et al., 2013).
In the research performed on the Lohmann Brown hybrid in the period from 20^{th} to 72^{nd} week of age, Pandurevic (2011) obtained results that shows the average values of shell mass increased through examination periods (WA_{20} – 6.12 g, WA_{28} – 8.03 g, WA_{72} – 8.11 g), except around the middle of production cycle (WA_{48} – 7.93 g). The percentage share of the shell in egg weight through the examination periods was: WA_{20} – 13.27%, WA_{28} – 13.41%, WA_{48} – 11.85% and WA_{72} – 11.78%. Along with the age, the average absolute values of egg whites mass increased (WA_{20} – 29.16 g, WA_{28} – 36.40 g, WA_{48} – 42.79 g, WA_{72} – 44.28 g) as well as the yolk mass (WA_{20} – 10.88 g, WA_{28} – 15.47 g, WA_{48} – 16.40 g, WA_{72} – 16.72 g). The average relative values of the egg whites mass in the same periods were: 63.13%; 60.69%; 63.66% and 63.97%, while the yolk share in total egg mass by periods were: 23.60%; 25.90%; 24.49% and 24.25%. Heavier eggs from older hens had significantly higher absolute mass of egg whites and yolks ($P<0.01$ and $P<0.001$) than lighter eggs from younger hens, while the differences in shell were statistically significant ($P<0.001$), except for the difference between the second and third, ie second and forth sampling, when the significance was not confirmed ($P>0.05$).
Examining the eggs of Lohmann Brown hybrid hens at the age of 25 weeks, Pavicic (2014) found the average shell mass was 7.84 g, yolk mass 12.83 g and egg white mass 34.63 g, while at the age of 69 weeks old hens, the shell mass was 8.79 g, yolk mass 17.23 g and egg white mass 35.51 g. Based on the obtained results, it can be concluded that the age of hen has statistically significant influence ($P<0.001$) on the weight of the shell, yolk and egg white.
According to Zaheer (2015), the shell makes 9-12% of total egg mass, the egg white around 60% and the yolk from 30% to 32% of total egg mass.
Examining the egg production of Hisex Brown hybrid, Gjorgovska et al. (2016) found the average egg mass of 67.53 g, of which the average mass of egg white was 40.11 g, the average yolk mass 19.28 g and the average shell mass 8.14 g. Expressed in percentages, the average egg was consisted of 59.33% of egg white, 28.31% of yolk and 12.06% of shell.
The average egg mass of Lohmann Brown hybrid, kept in conventional cage from 20^{th} to 60^{th} week of age, obtained in research by Dikmen et al. (2017), amounted 58.35 g. The average mass of shell was 5.68 g (9.78%), while the average yolk mass was 14.07 g (23.94%) and egg white mass 38.60 g (66.29%).
The aim of this study is to examine the influence of the age of laying hen hybrid on the basic characteristics of the egg structure (the yields and the share of shell, egg white and yolk). Additionaly, the aim of this paper is to examine what happens to certain egg structure characteristics after the established 72^{nd} week of laying hen age, until the end of 79^{th} week of age of the Lohmann Brown hybrid hens.
Based on the obtained results, the phenotypic correlation between the egg mass and egg structure characteristics was determined.

Material and Methods

In order to examine the influence of the age of laying hens on the basic characteristics of the egg structure, an appropriate research was performed by organizing proper experiment and statistical processing of the obtained data. As the initial material for the research, we have used hens of

light-line hybrids Lohmann Brown, housed on the farm "Agrovet" Foca, Bosnia and Herzegovina. The production period lasted for 61 weeks, i.e. 427 days.
In the course of raising (exploitation) of the commercial flocks, a technology proposed by the selector of laying hens hybrid was used (http://www.ltz.de). All technological phases (feeding, power, temperature, lighting, ventilation, drainage system and collecting the eggs) are automatically regulated.
The eggs research, that included examination of basic characteristics of the egg structure, was performed in the appropriate, acredited, laboratory of Faculty of Agriculture in East Sarajevo. There were four control measurements during the production cycle, with 60 individually measured eggs in each period, with total of 240 eggs. The eggs were selected by random sample method (3 eggs from each row x 5 floors x 4 rows).
The examination of the egg structure characteristics was performed at the following age of laying hens: 27 weeks (WA_{27}), 46 weeks (WA_{46}), 72 weeks (WA_{72}) and 79 weeks (WA_{79}).
The following parameters of egg structure were defined:

- Egg mass (g)
- The share of shell in egg mass (g, %)
- The share of egg white in egg mass (g, %)
- The share of yolk in egg mass (g, %).

The egg mass was determined by measuring each egg on special technical weighing scale of the brand "$KERN_{PFB}$", which is accurate to 0.01 g.
The mass of the raw shell was measured on the same scale, after the egg was broken, the egg content removed, and the shell measured together with egg membranes. The obtained values are expressed both in grams (absolute values) and as percentages (relative values).
The mass of yolk was measured on the same technical scale, after the yolk was previously separated from the egg whites by a separator.
The mass of egg white was determined by calculating the difference between the total mass of egg on one side and the mass of yolk and shell on the other side.
Percentages of raw shell, yolk and egg white in total mass of egg were obtained by calculation.
Based on the obtained data, the appropriate databases were formed. The software package SPSS - Statistical Package for Social Sciences was used for statistical analysis. Statistical processing of the obtained data included the calculation of common variational-statistical data and the assessment of the significance of the obtained differences with the implementation of appropriate mathematical-statistical methods (Hadzivukovic, 1991).
Based on the experimental data and the defined frequency distributions of the examined occurrences, the following parameters were calculated for the most of the monitored egg structure characteristics:
Mean ($\bar{X}$),
Standard deviation (S)
Based on the obtained results, a phenotypic correlation was determined between the mass of egg and egg structure characteristics.
The coefficient of phenotypic correlation is calculated according to pattern (Latinovic, 1996):

$$r_{xy}=\frac{\sum xy-\frac{\left(\sum x\right)\left(\sum y\right)}{n}}{\sqrt{\left[\sum x^{2}-\frac{\left(\sum x\right)^{2}}{n}\right]\left[\sum y^{2}-\frac{\left(\sum y\right)^{2}}{n}\right]}}$$

The strength of phenotypic correlation coherence is discussed on the basis of the Roemer-Orphal classification (Latinovic, 1996). The testing of significance of differences between various ages of laying hens, in terms of monitored characteristics, was performed using an appropriate t-test model with the same number of repetitions according to the following pattern:

$$t=\frac{\bar{x}_1-\bar{x}_2}{Sp\sqrt{1/n_1+1/n_2}}$$

$$S_p=\sqrt{\frac{(n_1-1)S_1^2+(n_2-1)S_2^2}{n_1+n_2-2}}$$

Results and Discussion

The average values and variabilities of egg structure in different ages of laying hens are shown in table 1.

Table 1. The average values and variabilities of egg structure in certain phases of the production cycle

Indicators	Week of age (WA)	$(\bar{x})$	S
The shell mass (g)	WA_{27}	8.14	0.86
	WA_{46}	8.50	0.91
	WA_{72}	8.61	0.88
	WA_{79}	8.98	1.17
The share of the shell (%)	WA_{27}	13.41	1.27
	WA_{46}	13.42	1.15
	WA_{72}	12.92	1.27
	WA_{79}	13.29	1.59
The yolk mass (g)	WA_{27}	14.96	1.16
	WA_{46}	16.06	1.36
	WA_{72}	17.18	1.53
	WA_{79}	17.33	1.48
The share of the yolk (%)	WA_{27}	24.76	1.88
	WA_{46}	25.36	1.66
	WA_{72}	25.77	1.86
	WA_{79}	25.66	2.17
The egg white	WA_{27}	37.70	4.12

mass (g)	WA_{46}	38.78	3.53
	WA_{72}	40.87	3.89
	WA_{79}	41.24	4.75
The share of the egg white (%)	WA_{27}	61.83	2.39
	WA_{46}	61.22	1.97
	WA_{72}	61.31	2.29
	WA_{79}	61.05	3.01

As it can be seen from the table 1, the average shell mass increased over the periods of examination (WA_{27} – 8.14 g, WA_{46} – 8.50 g, WA_{72} – 8.61 g, WA_{79} – 8.98 g). The share of the shell in total egg mass waried through the control periods. During WA_{27} it averages at 13.41%, in WA_{46} it was 13.42%, WA_{72} 12.72%, while the average share of the raw shell in total egg mass in WA_{79} was 12.92%. A slightly lower values in terms of the shell mass (4.92-6.64 g) and the share of the shell in total egg mass (11.36-12.69%) were found by Zita et al. (2009). We can find lower values in other authors research: Pandurevic (2011) 6.12-18.11 g and 11.78-13.41%, Dikmen et al. (2017) 5.68 g and 9.78%, and Gjorgovska et al. (2016) 8.14 g and 12.06%. Lower values for the shell mass were found by Taha (2012) 6.27 g, and Kralik and Ljuboja (2017) 6.68 g, while the similar results were obtained in research by Rajicic et al. (2008) 8.20 g, and Pavicic (2014) 7.84-8.79 g. A slightly lower values in the share of the shell in total egg mass were found by Ren et al. (2010) 10.50%, Djogatovic and Maric (2014) 9.67-12.23% and Zaheer (2015), while the slightly higher value was found by Kralik et al. (2013) 13.57%.

Along with the age, the average absolute values of the yolk mass and egg white mass also increased. When it comes to the share of the yolk in total egg mass, it increased over the first three periods (24.76%, 25.36%, 25.77%) while it slightly decreased in the last period than the previous measurement (25.66%). The highest share of the egg white in total egg mass was in the first period (WA_{27} – 61.83%) and the lowest at the eng of the production cycle (WA_{79} – 61.05%). In the second and third period, the egg white had the share of 61.22% in WA_{46}, and 61.31% in WA_{72}. Similar values in terms of the yolk mass and share can be found in research by Zita et al. (2009) 11.94-19.64 g and 23.12-30.13%. A slightly lower values were recorded by Pandurevic (2011) 10.88-16.72 g and 23.60-25.90%, Pavicic (2014) 12.83-17.23 g, Dikmen et al. (2017) 14.07 g and 23.94%, while the higher values of the yolk were found by Taha (2012) 19.13 g, Kralik and Ljuboja (2017) 17.51 g, and Gjorgovska et al. (2016) 19.28 g and 28.61%.

When it comes to the mass and the share of the egg white, the similar results were obtained by Pandurevic (2011) 29.16-44.28 g and 60.69-63.97%, Djoganovic and Maric (2014) 59.53-61.53%, Gjorgovska et al. (2016) 40.11 g and 59.33%, Dikmen et al. (2017) 38.60 g and 66.29%. A slightly lower values are found by Zita et al. (2009) 32.78-38.49 g and 58.50-64.57%, Ren et al. (2010) 58.50%, Taha (2012) 35.60 g, Kralik et al. (2013) 57.18%, Pavicic (2014) 34.63-35.51 g, Kralik and Ljuboja (2017) 31.59 g.

The results of testing the significance of differences for the examined characteristics of the egg structure is given in table 2.

Table 2. Significance of differences of the egg structure in certain phases of the production cycle

The results in table 2 show that the age of laying hen has a statistically very significant influence ($p<0.001$) on the shell mass in all examined periods except between 46th and 72nd week of age, while the absolute values of the shell mass increased along with the age of laying hen. When it comes to the share of the shell, the age of laying hen has statistically significant ($p<0.05$) impact on this structural characteristic of the egg in two periods: between 27th and 72nd, and between

46th and 72nd week of age. In other comparisons, no statistically significant difference was found ($p>0.05$).

The absolute values of the yolk mass increased along with the age of laying hen. The yolk mass has changed statistically very highly significant ($p<0.001$) in examined periods between 27th week of age in relation to 72nd and 79th week, as well as between 46th week of age in relation to 72nd and 79th week. The difference was highly significant ($p<0.01$) between 27th and 46th week of age, while no statistically significant difference was found ($p>0.05$) between 72nd and 79th week of age. The age of laying hen had statistically significant influence ($p<0.05$) on the share of the yolk in examined period between 46th and 72nd week of age, and statistically very high significance ($p<0.001$) between 27th week of age and all other periods. No statistically significant difference was found ($p>0.05$) between 46th and 79th week of age, and between 72nd and 79th week of age.

When it comes to the egg white mass, the absolute values increased along with the age of laying hen. The age had no statistically significant influence ($p>0.05$) on this structural characteristic of egg only between 72nd and 79th week of age. Statistically highly significant difference ($p<0.01$) was noted between 27th and 46th week of age, while statistically very highly significant difference ($p<0.001$) was noted between all other periods. The mean values the egg white share was highly significant ($p<0.01$) between 27th and 46th week of age, significant ($p<0.05$) between 27th and 72nd week of age, while the difference was very highly significant ($p<0.001$) between 27th and 79th week of age. No statistically significant difference was found ($p>0.05$) between 46th and 72nd, between 46th and 79th, and between 72nd and 79th week of age.

The results in table 3 show coefficients of phenotypic correlation between the egg mass of four age groups of laying hens (WA_{27}, $WA_{46,}$ $WA_{72,}$ WA_{79}) and examined characteristics of egg structure.

Table 3. Phenotypic coefficients of correlation between the egg mass and the shares of the shell, yolk and egg whites

***p<0.001; **p<0.01; *p<0.05; ^{ns}p>0.05

Older laying hens have show better correlation than young hens. The coefficient of correlation between the egg mass and the share of shell in older hens amounted r_p= 0.416, and it was statistically highly significant (p<0.01). In young hens, the coefficient of correlation was r_p= 0.062, and was not statistically significant. Although all correlation coefficients between egg mass and shell mass (g) were positive, the coefficients between the egg mass and the share of shell (%) were all negative and statistically significant (p<0.05), while in older hens the coefficients were statistically highly significant (p<0.01).
Positive cofficients of correlation were determined between the egg mass and mass of both the yolk and egg whites, and they were all statistically highly significant (p<0.01) or very highly significant (p<0.001). Almost all coefficients showed medium strong to very strong correlations. Both old and young hens had statistically significant (p<0.05; p<0.01) coefficients of correlation calculated between the egg mass and the shares of both yolk and egg white. With the age of laying hens, the coefficients were significant at level p<0.001, and between the egg mass and egg white share (%) they were positive, while the coefficients were negative between the egg mass and yolk share (%) as shown in table 3.

Conclusion

Based on the examination of basic characteristics of egg structure of light-line hybrid Lohmann Brown, during experiment that lasted for 61 production week, the following conclusions can be drawn: Along with the age of laying hen, the average absolute mass of the shell, yolk and egg white also increased. Statistical significance was not found in the shell mass between 46th and 72nd week of age, as well as for the mass of the yolk and egg whites between 72nd and 79th week of age. When it comes to the relative values (percentage share) of the egg shell, it varied through the examined periods, but was pretty much steady around 13%. The share of the yolk gradually increased through the periods, and ranged from 24.76% to 25.77%, except in the last period when it was slightly lower than the previous.
The share of egg white in total egg mass was calculated, and it was the highest in the first period (WA_{27} - 61.83%) and the lowest at the end of the production cycle (WA_{79} - 61.05%). Statistically significant differences were found between WA_{27} and all other periods.
The coefficient of correlation between the egg mass and the share of shell was statistically significant (p<0.01) in older hens, while no statistical significance was found in younger hens. The coefficient of correlation between the egg mass and shell mass (g) were positive, while the coefficients of correlation between the egg mass and the share of shell (%) were negative and statistically significant (p<0.05; p<0.01). Positive cofficients of correlation were also determined between the egg mass and both yolk and egg whites. Almost all coefficients showed medium

strong to very strong correlations. Both old and young hens had statistically significant ($p<0.05$; $p<0.01$) coefficients of correlation calculated between the egg mass and the shares of both yolk and egg white. With the age of laying hens, the coefficients were significant at level $p<0.001$, and between the egg mass and egg white share (%) they were positive, while the coefficients were negative between the egg mass and yolk share (%).

It can be concluded that the egg mass of analyzed commercial flock of light-line Lohmann Brown hybrid, had influenced basic characteristics of the egg structure, in all examined periods, as shown by correlation between egg mass and examined characteristics of the egg structure.

Abstract

The objective of this paper was to describe a methodological procedure for defining the economic value of primiparous sows production and reproductive traits of which some were used for assessment of sow`s breeeding value. This is a novel methodological procedure whose purpose is to reduce the influence that constant changes both in production cost and price of fatenners may have on selection work and to enable planning of long-term selection strategy in pig breeding. The obtained economic value is presented as a relative relationship between the changes in costs per unit of the trait and a primary trait, when the traits achieve the values defined by selection goal wherein the expenses are unknown value regarded for one feeding day. In this way the obtained economic value defines selection pressure and gives the trait the significance wished for by a selectionist without regarding it through the profit realized in the production expressed in money, which is still of a variable character in developing countries, thus allowing for its use as an indicator in calculating the genetic parameteres.

Key words: *trait economic value, selection index, pigs, methodological procedure to obtain economic value, genetic potential.*

Introduction

The proces of defining the economic value of the traits included in the models for assessment of animal breeding value is a real problem even in the countries with developed pig breeding with stable parity between the price of fatenners and the prices of inputs included into pig breeding industry, while this branch of livestock production in developing countries is characterized by continual variable relation between the production costs and the price of product *(Vukelić et al.,2004)*, what additionally complicates the determination of the economic value of the traits included in the method for assessment of animal breeding value. The value of some traits which cannot be expressed as a real market value presents an additional problem. For example, the traits such as liveborn piglet or backfat thickness have no fixed market value, because they cannot as such be found in the market, therefore the value of these traits cannot be properly expressed in monetary units. On the other hand, even if there are stable relationships between the input costs included into production and the value of the products obtained, the market value of the trait expressed in monetary units determines a selection goal *(Dube et al., 2013)*, in which some traits that have higher monetary value can be favoured, while at the same time, the traits

which are also very significant, but of lower market value difficult to determine (backfat thickness, percent of intramuscular fat and similar) may be neglected in selection.
Regarding the equation of selection index as the method for assessment the breeding value of pigs and other animals, the animal breeding value is obtained by multiplying partial regression coefficients and phenotypic difference of the traits of each individual. These partial regression coefficients express relative importance of the features included in the index, and are obtained by solving the system of matrices which includes phenotypic and genetic variances and covariances and the economic value of each of the traits *(Vidović, 2009)*. Respecting the fact that the values of genetic and phenotypic parameteres cannot be influenced in the moment of construction of selection index, but that they represent factual state displayed through mathematical solution, the only way to realize a desirable selection pressure on each of the traits in accordance with set selection goal is by way of defining the trait economic value and on that base to assess the animal breeding value. All this shows that the trait economic value represents not only a market value of some trait expressed in money but that it is mostly the sublimation of monetary value of the traits, their mutual relative relationship, desired selection goal or profit to be realized in the production *(Quinton et al., 2006)*.
Literature data indicate various possibilities of expressing traits economic value on the basis of which breeding value of farm animals is being assessed. Thus *Quinton et al. (2006)* express the economic value of sows` reproductive traits as the profit expressed in dollars which is being realized when the trait value has been improved by one genetic standard deviation, regarding the profit through kg of live weight of fatenners sold at the market. *Houška et al. (2010)* determine the economic value of swine production and reproductive traits by means of bio-economic model based on the relationship between the profit realized per unit of product and the profit which would be realized supposing the value of the trait changed for a defined size of that trait where we obtain marginal economic value which multiplied by genetic standard deviation can provide the economic value of the trait expressed in euros per trait unit. *Suzuki et al. (2005)* define the economic value of production traits by assessing the breeding value of performance tested boars and gilts of Durok breed as a relative relationship of profit of studied traits when defined value of the trait is being for desired selection goal.
On the other hand, *Radojković (2000)* and *Vukelić et al. (2004)* obtain the economic value of the traits in the conditions of a continual disparity of the cost of input and output in pig breeding production as a relative relationship of changes in the expenses per trait unit and the changes of expenses per unit of primary trait when the value of the traits is changed for one unit. The methodology described by previously mentioned two authors was used as a basis for methodological procedure displayed in this paper.
The objective of this paper was to describe a methodological procedure for defining the economic value of primiparous sows production and reproductive traits of which some were used for assessment of sow`s breeeding value.

Material and method

Data set on whose basis we determined the economic value of production and reproductive traits of the sows called fertile meaty breeds (Swedish Landrace and Great Yorkshire) and their cross-breds is formed on the basis of realized production results of 3912 sows raised on one of the pig farms in Serbia. The economic value is calculated for following production traits measured at the end of performace test: backfat thickness (SL1), sidefat thickness (SL2), depth of *m. longissimus* *dorsi* (MLD), carcass meat percentage (%MES), liveweight gain (DP), and for the reproductive traits defined after the first farrowing such as: number of total born piglets (BUP), number of liveborn piglets (BZP) and number of raised piglets (BOP). The traits mean values and duration of the period expressed in feeding days in which the traits were accomplished, and which served for calculating the economic value of traits are shown in Table 1.

Table 1. Traits mean values ($\bar{X}$) and duration of the period expressed in feeding days* in which the traits were realized

Trait	SL1 mm	SL2 mm	MLD mm	%MES %	DP g	BUP Piglet	BZP Piglet	BOP Piglet
Mean value($\bar{X}$)	12.27	10.16	48.11	59.36	541.13	9.88	9.22	8.48
No. of feed. days*	200.98	200.98	200.98	200.98	200.98	151.01	151.01	180.74

This is a research methodology paper where in the section "Results and discussion" there is a detailed methodological procedure of how to obtain the economic value of the traits of primiparous sows, on the basis of which the breeding value of animals can be defined.

Results and discussion

In this paper we tried to express the economic value of production and reproductive traits of primiparous sows in which some traits might be included into the methods for the assessment of their breeding value through relative relationship between the changes of the expenses realized (regarded through one feeding day) per product unit when the values of the traits reach the level defined by selection goal.

A primary presumption which served as a starting point of this methodological procedure is that the costs of one feeding day as an economic value are the same during a whole examined period what is not the case in practice, but smaller costs in the initial phase of breeding compensate for greater costs in later phases. These costs are unknown value T and they include the costs of care, nutrition, housing, health care, replacement and similar, for the entire life period in which the traits have been determined lasting from sow`s birth up to the weaning of her first litter of pigs (381.72 days). Out of this came the result that the cost of one feeding day is T/381.72.

Further on we determined the costs of each of the phase of the analysed life span in which we established the value of the traits, this period being divided into the period 1, from birth to the end of performance test, period 2, from the end of test until the first farrowing and period 3, from the end of test up to the first weaning, taking the view that periods 2 and 3 should also include, besides the costs of pregnancy and lactation, the costs related to the period from the end of test up to the successful conception, because the gilts practically started their reproduction in that period (the occurrence of the first puberty oestrus and so on). On the basis of the analysed records it was found that period 1 lasted on average 200.98 days, period 2 lasted 151.01 days and period 3 lasted 180.74 days. On the basis of these records the calculated costs were as follows:

for period 1: 200.98 / 381.72T = 0.5265T
for period 2: 151.01 / 381.72T = 0.3956T
for period 3: 180.74 / 381.72T = 0.4735T

The obtained values of the costs for the periods 1, 2 and 3, respecting the biological characteristics of the traits established in these periods, served to calculate the costs per unit of products, obtained by means of following pattern:

$$T_i \ / \ \overline{X} = T_j$$

Where: T_i – are the costs of the period in which the value of the trait was measured, $\overline{X}$ - mean value of the trait, T_j – costs per products unit.
On the basis of previous pattern the costs (T_{jx}) per unit of products were calculated and shown in Table 2.

Table 2. Costs per unit of products in realized production

Trait	SL1 mm	SL2 mm	MLD mm	%MES %	DP g	BUP Piglet	BZP Piglet	BOP Piglet
T_{jx}	0.04291	0.05182	0.01094	0.00887	0.00097	0.04004	0.04291	0.05584

The next step was to establish the costs T_{jy} per unit of trait when it has reached the value set as selection goal. Table 3 shows relative change of the traits according to set goal, the value of the trait defined by selection goal and the costs per unit of traits when they reach the values defined by selection goal.

Table 3. Selection goal, value of the traits defined by selection goal and the costs per unit of traits when they reach the values defined by selection goal

Trait	SL1 mm	SL2 mm	MLD mm	%MES %	DP g	BUP Piglet	BZP Piglet	BOP Piglet
Selection goal %	-6.00	-5.00	6.00	5.00	15.00	12.00	14.00	16.00
Value of trait defined by selection goal	11.53	9.65	51.00	62.36	622.30	11.07	10.51	9.84
T_{jy}	0.04565	0.05455	0.01032	0.00845	0.00085	0.03575	0.03764	0.04814

Then we determined the difference between the costs T_{jx} per unit of the traits realized in production and the costs T_{jy} per traits unit when they have reached the values defined by selection goal. Difference (T_{jx}-T_{jy}) between these costs is shown in Table 4.

Table 4. Difference (T_{jx}-T_{jy}) between the costs per unit of the traits realized in production and the costs T_{jy} per unit of the traits when they have reached the values defined by selection goal

Trait	SL1 mm	SL2 mm	MLD mm	%MES %	DP g	BUP Piglet	BZP Piglet	BOP Piglet
T_{jx}-T_{jy}	-0.00274	-0.00273	0.00062	0.00042	0.00012	0.00429	0.00527	0.00770

The obtained differences displayed in Table 4 were used in calculating the economic value of the traits, the primary trait being determined first. Knowing the biological characteristics of pig production where fatenner is the final product, the number of raised piglets was determined as the most important one among the traits displayed or as the primary trait because it is the trait that most affects the number of fatenners. It should be pointed out that any of the traits could be chosen as primary one because a relative relationship of economic value remains unchanged. By dividing the difference of costs per unit of trait displayed in previous table with the difference of costs of primary trait, when the traits reach the level defined by selection goal, the economic value of that trait has been obtained. Table 5 shows the traits economic values in which some served for the assessment of the breeding value in primiparous sows.

Table 5. Traits economic values

Trait	SL1	SL2	MLD	%MES	DP	BUP	BZP	BOP
Economic value of the trait	-0.356	-0.355	0.081	0.055	0.016	0.557	0.684	1

Having completed a whole metodological procedure of obtaining the economic value of the traits included in the model for assessment of the breeding value of primiparous sows, the economic value can be defined as a relative relationship between the changes of costs per trait unit and primary trait when the traits have reached the values defined by selection goal. In this way the economic value determines the selection impact on each of the trait, on the basis of which the animal breeding value is being assessed. The costs on whose basis we obtain economic value in this way expressed in money can be very different, but their relative relationship observed through feeding day is always the same, so that the obtained economic value and set selection goal are not dependent upon constant change of the price of production process and market price of fatenners as final product of pig breeding production. Also it should be pointed out that the traits for which we envisage greater relative change, contribute, in a greater extent, to the animal assessed breeding value, affecting such defined economic value to give such contribution of traits in animal overall breeding value which is wanted for by a selectionist, according to the importance of some traits defined by a selectionist.

Comparing the methodological procedure of obtaining economic value displayed in this paper where it is expressed as a relative relationship of reducing the costs per trait unit by means of methodological procedures *(Brkić, 2002; Suzuki et al., 2005; Quinton et al., 2006; Houška et al., 2010; Dube et al., 2013)* in which the economic value of different traits is expressed in money units (dollar, euro, dinar and likewise) of the realized profit, the advantage of such obtained economic value of the traits is that it represents a relative relationship of traits in set selection goal, which is not under the significant impact of constant fluctation of production prices and obtained final product. On the other hand, a negative side of this metodological procedure in relation to the methodology of obtaining economic value shown by some other authors *(Brkić, 2002; Suzuki et al., 2005; Quinton et al., 2006; Houška et al., 2010; Dube et al., 2013)* is that it starts from the presumption that the unknown costs of one feeding day are the same during a whole analysed period what cannot be confirmed knowing the biological and economic characteristics. This shortcoming might be solved by using the function of bio-economic model used by *Houška et al. (2010)* and thus try to define a relative value of each feeding day during production life, expressed through the value of average feeding day and then on that basis try to define the costs made in every period in which the traits were realized.

Methodological procedures suggested by *Radojković (2000)* and *Vukelić et al. (2004)* served as the basis of methodological procedure for obtaining economic value of swine traits described in this paper. However, the advantage of this methodological procedure in relation to the methodology of *Radojković (2000)* and *Vukelić et al. (2004)* is in the fact that in this way by set selection goal the selectionist himself defines selection pressure and contribution of some traits in animal estimated breeding value while the selection pressure and contribution of some traits in animal estimated breeding value in the methodology suggested by previous authors is exclusively defined by a relative value of one unit of the trait out of total value of that same trait because the economic value of the traits is obtained as a difference of costs between realized value of the trait and the value when that trait has been changed for one unit. This actually means that the traits with low relative value of one unit (gramme of liveweight daily gain) participate far less in estimated breeding value of the animal in relation to the traits with high relative value of one unit in total value of the trait (raised pig), and their importance regarding selection is most often almost equal.

Conclusion

On the basis of the facts displayed it can be concluded that this is a simple methodological procedure for obtaining economic value of the traits on the basis of which the animal breeding value is being estimated and which can be widely used in livestock production. It should also be pointed out that in this way the obtained economic value and the very models for assessing the animal breeding value are not under the constant influence of the costs fluctuations in livestock production and final products, which is charateristic of developing countries, as well as the fact that through such defined economic value we can clearly define and realize selection goal which in a considerable degree is not dependent upon constant market fluctuations while the selection can be directed into desired direction and within wanted scope.

Acknowledgments

The presented work is a part of the research done in the project TR31081, granted by the Ministry of Education, Science and Technological Development Republic of Serbia

RURAL DEVELOPMENT AND AGROECONOMY

MONITORING THE CONDITION OF AGRICALTURAL LAND AS A TOOL OF THE PRECISION FARMING SYSTEM

Anna KAZAK

Vitebsk State University named after P.M. Masherov, Vitebsk, Belarus
Corresponding author: anna.kazak711@gmail.com

Abstract

We regard agricultural land monitoring as part of the system of "precision farming", which is positioned as the future of agriculture by all the leading economies of the world. The constituent elements of the system are: technology of parallel driving and autopilot of agricultural machinery based on GPS (Global Positioning System) and GNSS (Global Navigation Satellite System) navigation systems; monitoring and assessment of the biological state of plants (construction of maps of vegetation indices) and correction of agrotechnical measures; assessment of soil condition and construction of maps of fertility, productivity and profitability of agricultural land. The most important element of monitoring territories is the use of UAVs (Unmanned Aerial Vehicle) with multispectral cameras, agricultural drones and neural network data analysis in order to form recommendations for correcting agricultural technology. Currently, OOO "Intelligent Systems of Agriculture" together with the Vitebsk State University named after P.M. Masherov, using the example of a model farm, develops a fundamental methodology for monitoring agricultural land using UAVs (DJI) (Dajiang Innovation Technology). The proposed information and analytical monitoring system includes hardware-software, natural science and legal blocks. The ultimate goal of using the system is to increase labor productivity in crop production in the north of Belarus by 10-35%. The basis of such growth is the saving of chemicals, fuel and the most accurate calculation of the place, time and volume of agrotechnical measures. In addition, the introduction of this system will increase the "environmental friendliness" of agricultural production.

Keywords: *monitoring, precision farming, agriculture, multispectral cameras, UAV*

Introduction

The development of agriculture is the most important factor in guaranteeing the food and economic independence of any country. Precision farming technologies are the leading direction in the development of this industry and monitoring of the state of crops is an integral part of them. The introduction of unmanned aerial vehicles takes the monitoring process to a completely new level, makes it possible to monitor the indicators of the state of vegetation in almost any conditions and observe the changing environmental conditions.

The ultimate goal of this project is to increase labor productivity in agricultural production, reduce costs and create new jobs for highly qualified specialists and, ultimately, increase the profits of agricultural producers. The basis for achieving this goal is the extremely accurate calculation of the time and volume of agrotechnical measures (sowing time, weed control, fertilization, etc.) and the systematic nature of assessment and control measures during monitoring observations.

The main tasks performed during the implementation of the project are: selection of options for monitoring software and hardware that meets the needs and capabilities of agricultural producers in the context of the realities of Belarusian agriculture; providing an information and cartographic base, assessing the regulatory and legal aspects of the use of unmanned aircraft and precision farming technologies in the country's agriculture; development of methodological aspects of the observation and operation of the system (criteria for assessing the state, frequency and objects of observation, development of recommendations and correction of agrotechnical measures based on monitoring data, etc.); preparation of options for commercial solutions for the implementation of the project.

Material and Methods

The project is being developed by a team of students, undergraduates and teachers of Vitebsk State University named after P.M. Masherov for LLC "Intelligent Systems of Farming", focused on the agricultural market of the Republic of Belarus. The work is carried out on the basis of the model farm of Sushchevo Agro LLC (Vitebsk region, Belarus). The object of the study is a pair of fields similar in terms of conditions of winter rapeseed, maize and winter cereals. In each pair, a control field was determined, where the farm agronomist determined the need for activities based on his data obtained in the traditional way, and an experimental one, where the correction of agricultural technology was planned to be carried out based on the data of unmanned and satellite monitoring using multispectral survey data and, ultimately, vegetation indexes such as NDVI (Normalized Difference Vegetation Index). The initial data were farm materials on the history of experimental and control fields, high-precision survey data using UAVs, information on fertilizers and plant protection products used in the farm, a database of plant pests and diseases, materials of the Land Information System of the Republic of Belarus, soil research, meteorological observations.

Results and Discussion

The precision farming system includes three main components: technologies of parallel driving and autopilot system based on GPS and GNSS navigation systems, which provide the necessary accuracy of guidance of aggregates on sowing cereals, planting potatoes, ridge formation, etc.; current assessment of the biological state of plants using UAVs, satellite data (construction of vegetation indices) and, based on the processing of the obtained data, the management of "point" application of plant protection products and correction of agrotechnical measures in general; long-term assessment of soil conditions, construction of maps of fertility, yield, and in the long term, maps of profitability of each specific plot of agricultural land on the basis of data accumulated in the process of monitoring observations.

At the current stage of research, efforts have been focused on the ongoing assessment of the biological state of plants using UAVs, satellite data and the use of these materials in the cultivation of some crops. In the process of analyzing the options for organizing the monitoring software and hardware, we selected a complex that would meet the tasks of the experimental stage of the project. An unmanned system based on a Phantom 4 multispectral quadrocopter equipped with a multispectral camera and software for data analysis was chosen as a tool for monitoring observations on a number of parameters. An important element of the analytical block of the system was the use of technologies for neural network analysis of cartographic data, which made it possible to automatically draw the boundaries of lands and areas with different conditions of crops according to maps of vegetation indices. An example of using a neural network for the automatic creation of high-precision maps is the allocation of characteristic "technological stripes" - parallel lines on the map, formed as a result of the operation of agricultural machinery, row planting of crops and other factors.

Shenzhen Dajiang Baiwang Technology (DJI) software Terra and DJI Assistant 2 For Phantom were selected for data processing. However, in order to integrate monitoring materials into the economic activities of the model farm, experiments were carried out on the use of cloud platforms for organizing agricultural activities "Geomir" and "Interra", which made it possible to synchronize databases for all elements of the farm (equipment, fields, accounting, etc.), visualize any information in a convenient form, carry out an automated calculation of indicators of the state of vegetation and corrective measures.

During the implementation of the project, it is also planned to test Agros agricultural drones for targeted agrotechnical measures, which will allow adjusting the state of crops based on automatically generated flight tasks based on the monitoring drone data. The most important characteristic of the use of unmanned aircraft is also the environmental friendliness of its use in comparison with traditional methods of monitoring and agricultural work. UAVs are used to monitor the state of the territory, accurately apply extremely dangerous chemicals in ultra-small volumes, as well as spot fertilizers and chemicals to correct the situation in certain areas of the fields, which allows: to reduce the consumption of fertilizers and chemical plant protection products to the minimum required volumes, which in turn reduces the pollution of soils and agroecosystems in general; to abandon the use of heavy agricultural machinery, this allows to reduce the risk of erosion and other dangerous geomorphological crops on agricultural land, as well as the operation of drones on batteries minimizes the emission of pollutants into the atmosphere, which occurs during the operation of internal combustion engines.

As part of the project to date: completed scientific research to prepare for the field stage of work; the structure and main components of the projected information and analytical system have been determined; the technical and technological aspects of the project have been developed - the configuration of the software and hardware complex has been selected, the system of information exchange between the blocks of the projected system has been modeled; a concept for the operation of a neural network has been developed, tests have been carried out for the algorithm for differentiating the territory by aerial photographs; high-precision survey of the territory of the model farm and the purchase of equipment are carried out.

Practical advantages of using / implementing the proposed system: saving expensive plant protection products (no overlapping of application zones, precise control of consumption during spraying, selectivity of treatment sites); saving time for processing crops (speed of deployment, mobility); extremely accurate determination of the timing of agrotechnical measures. It is especially important with a large number of small or, conversely, very large fields in area; the possibility of carrying out work in case of waterlogged soil, when the equipment cannot enter the fields; work without mechanical damage to plants and tramlines on tall crops (corn, rapeseed, etc.); reduction of environmental risks (environmental pollution, impact on health, provocation of erosion as a result of the actions of heavy equipment, etc.).

Conclusions

The territory monitoring system makes it possible to facilitate the process of tracking changes in certain areas and to make a clear analysis of the requested criteria necessary for successful farming. The projected system represents a full cycle from information support to the implementation of agricultural solutions. Due to high productivity, accuracy and mobility, it will significantly reduce the cost of work. Accordingly, the costs of the customer will decrease, and a high level of profitability of the enterprise will be ensured. In addition, optimization of the agrotechnical work map will have a positive effect on the environmental aspects of agricultural production countries (reduction of fertilizer and herbicide costs, technological load on soils, etc.).

TRANSITION TOWARDS BLUE ECONOMY IN THE EUROPEAN UNION

Monika SABEVA*

Department Economics of Natural Resources, University of National and World Economy, Sofia, Bulgaria
*Corresponding author: monikasabeva@abv.bg

Abstract

Oceans cover more than two-thirds of the earth's surface and contain 97% of the planet's water. In addition to producing half of the oxygen in the atmosphere and absorbing about 25% of CO_2 emissions, they are home of vast biodiversity and a source of food, water and jobs. In recent decades, pressure on the water ecosystems have intensified as a result of climate change, excessive pollution, increasing exploitation of water resources and the inability to tackle illegal activities. This leads to an aggravation in the quality of water resources and their productivity, to an endangerment of species, to habitat destruction and to overall deterioration in the quantity and quality of all resources extracted from oceans and seas. The interconnectedness of oceans and their specific characteristics and requirements impose that the responsibility for their conservation and restoration should be shared globally. According to The European Union (EU) Blue Economy Report 2020, the directly employed in these sectors are close to 5 million people and they have generated around €750 billion in turnover and €218 billion in Gross Value Added (GVA) in 2018. This determines their great significance for the economic development of the EU. The main objective of the paper is to represent the international efforts aimed at the protection of water resources and to evaluate the measures taken to stimulate the EU transition towards blue economy through a review of available official documents, strategies, reports, plans, communications and information provided by the EU and United Nations (UN).

Keywords: *Blue Economy, Water Resources, European Union, Sustainable Development Goals*

Introduction

Oceans cover more than two-thirds of the earth's surface, contain 97 % of the planet's water and 80 % of all life forms. They are the source of life of the planet and have an extremely important role for humanity, for its existence and development. (EU, 2018 and EU, 2021). However, at global level, measures related to protection of water and aquatic life, to the fight against climate change, water pollution, overexploitation of oceans and seas and illegal activities related to them are still lagging behind. Improper water management leads to deficit of drinking water, droughts, floods, to an aggravation in the quality of water resources and their productivity, to an endangerment of population of a number of species, to habitat destruction and to overall deterioration in the quantity and quality of all resources extracted from oceans and seas.

Ecosystems, including marine ones, provide a wide number of services like climate regulation, food, water and so they have a vital role for human survival and for the world's sustainable development aspirations (UNEP, 2016). Water conservation and sustainable use of water resources is vital to human survival and is an integral part of the overall environmental protection and the achievement of sustainable development. As stated in the first EU Blue Economy Report (BER) 2018, oceans can produce investment, jobs and economic growth – and the heathier they are, the more productive they'll be (EU, 2018).

The interconnectedness of oceans and their specific characteristics and requirements impose that the responsibility for their conservation and restoration should be shared globally. The adverse effects of climate change on the ocean (UN, 2017), including the temperature rise, ocean and coastal acidification, deoxygenation, sea level rise, the decrease in polar ice coverage, coastal erosion and extreme weather events necessitate the need to mitigate the adverse impacts or the crucial ability of the ocean to act as climate regulator, source of marine biodiversity and as key provider of food and nutrition, tourism and ecosystem services and as an engine for sustainable economic development and growth will be lost.

The origins of the blue economy concept can be traced back to the 2012 UN Rio+20 conference and the report on 'Green Economy in a Blue World' (EU, 2020). The term "Blue Economy" includes the economic sectors and related policies that together determine whether the use of oceanic resources is sustainable. The Blue Economy encompasses all sectoral and cross-sectoral economic activities based on or related to oceans, seas and coasts divided into two groups – Marine-based and Marine-related activities (EU, 2021).

The Blue Economy established sectors are Marine living resources, Marine non-living resources, Marine renewable energy, Port activities, Shipbuilding and repair, Maritime transport and Coastal tourism and the Blue Economy emerging and innovative sectors include Marine renewable energy, Blue bioeconomy and biotechnology, Marine minerals, Desalination, Maritime defence, security and surveillance, Research and Education and Infrastructure and maritime works (submarine cables, robotics). The emerging sectors offer significant potential for economic growth, sustainability transition, as well as employment creation. (EU, 2021).

The main objective of this paper is to represent the international efforts aimed at the protection of water resources and to evaluate the measures taken to stimulate the EU transition towards blue economy.

Materials and methods

This paper is based on a thorough review of available reports, analysis of official documents as action plans, declarations, communications, programs and provided by the EU and UN data related to Blue Economy, its sectors and the policies aimed at supporting the transition towards Blue Economy at EU level in the context of global efforts for achieving sustainable development.

For the period 1949 – 2021, UN and EU put considerable efforts towards nature conservation and sustainable development, including water resources management, water conservation and development of water-related sectors and activities. The current state of development of the Blue Economy is a result of many international summits, conferences, programs and significant work at international level to adopt common goals and policies to ensure the sustainability of natural resources and the world's oceans in particular and to prevent habitat destruction, species extinction, increasing emissions and the overall deterioration of natural conditions worldwide.

In some of the reviewed documents, the information related to water protection and development of ocean-related activities and sectors is represented in the context of the overall progress towards sustainable development. However, for the purpose of the analysis, only data related to Blue Economy sectors and water conservation is taken into account.

Results and discussion

During the first session of the International Law Commission in 1949, the regimes of both territorial waters and waters of high seas were put as topics for codification (UN, 1949). In 1956, the Commission adopted its final report on the territorial sea (UN, 1956) and scheduled the United Nations Conference on the Law of the Sea in 1958. In 1960 the second United Nations Conference on the Law of the Sea was held during which the topics which had not been agreed upon at the previous Conference were considered and the third conference was held from 1973 to 1982, resulting in the adoption of the United Nations Convention on the Law of the Sea, which came into force in 1994 (UN, 1982). The Convention (UN, 2012) outlines the responsibilities and the rights related to the use of world's oceans, their management and preservation of countries which ratified it. Each of the XVII Parts is focused on a different aspect of ocean and marine resources use. The first considerable steps towards sustainable development and nature conservation were taken during the United Nations Conference on the Human Environment, which was held in 1972. It led to the creation of government environment agencies and the UN Environment Program and to the adoption of the first Environment Action Program by EU later that year. The Declaration of the United Nations Conference on the Human Environment (Stockholm Declaration) was adopted in 1972 and it is known to be the first international document in which the right to a healthy environment is brought to the fore. It states 26 principles which form the framework of responsibilities and point out the main issues the world is facing and Principle 7 is directly focused on protecting the world's oceans and aquatic organisms and it points out that „States shall take all possible steps to prevent pollution of the seas by substances that are liable to create hazards to human health, to harm living resources and marine life, to damage amenities or to interfere with other legitimate uses of the sea." (UN, 1972). The UN Environment Programme (UNEP) states that prevention is preferable to follow-up actions to eliminate the consequences for nature and brings to the fore the 'polluter pays' principle and assists governments to quantify and understand the value of ecosystems and how to best use that information in their national decision-making processes (UNEP, 2016). Since 1972, UNEP has been setting the global environmental agenda, promoting the coherent implementation of the environmental dimension of sustainable development within the United Nations system (UNEP, 2019). In 1992, 2002 and 2012 were held the second, the third and the fourth UN Conferences on Sustainable Development, the main outcomes of which are the adoption of Agenda 21, the United Nations Framework Convention on Climate Change (1992), the Kyoto Protocol (1997) and the UN Action Plan for Sustainable Development (UN, 2002). A milestone for sustainable development is the Paris Agreement (UN, 2015). It is the first legally binding international treaty on climate change and it brings to the fore the need of international ambitious efforts in order to combat climate change and to help adapting to its effects by lowering the greenhouse gas emissions as soon as possible and to achieve a climate neutral world by mid-century. The Sustainable Development Goals (UN, 2015) were set up in 2015 by the United Nations General Assembly and are intended to be achieved by the year 2030. Sustainable Development Goal 14 ("Life below water") is aimed at sustainable development of oceans, seas and marine resources. Its ten targets outline the timeline for reaching the different aspects of ocean sustainability and impose the need of preventing and significantly reducing the negative impacts as well as increasing the knowledge and research capacity, conservation and sustainable use of oceans and their resources and providing access for small-scale artisanal fishers to marine resources and markets.

According to the World Bank (World Bank, 2020), "the Blue Economy concept seeks to promote economic growth, social inclusion, and the preservation or improvement of livelihoods while at the same time ensuring environmental sustainability of the oceans and coastal areas.
Oceans, seas and coastal areas form an integrated and essential component of the Earth's ecosystem and are critical to sustaining it. Conservation and sustainable use of oceans and seas and of their resources is vital for sustainable development, including through their contributions to poverty eradication, economic growth, food security and creation of sustainable livelihoods and decent work, while at the same time protecting biodiversity and the marine environment and addressing the impacts of climate change (UN, 2012). One of the targets of The European Green Deal, directly linked to ocean preservation, is to ratify by 2021 an action plan for achieving zero pollution for water, air and soil (European Comission, 2019).
Since 2009 there is a growth in levels of the EU Blue Economy main indicators (Table 1), but when divided by main sector, the results are not so encouraging (Table 2). Although the increase of 13-15% of turnover, GVA and gross profit and the high levels of investments for the period, there are some sectors which are lagging behind.

Table 1: EU Blue Economy, main indicators for the established sectors, 2009-2018

	2009	2018	Δ 2018-2009
Turnover, € billion	577,180	649,708	13%
GVA, € billion	153,643	176,067	15%
Gross Profit, € billion	59,573	68,067	14%
Employment, number	4 451 560	4 475 141	1%
Net investments in tangible goods, € billion	*	6,4	*
Net investment ratio, %	*	3.6%	*
Average annual salary, €	*	24020	*
Personnel costs per employee, € billion	93,598	107,499	15%

**no information*

Table 2: EU Blue Economy, change 2009-2018 for the established sectors, %

	Persons employed, Δ 2018-2009	Turnover, Δ 2018-2009	GVA, Δ 2018-2009	Gross Profit, Δ 2018-2009	Gross investments in tangible assets, Δ 2018-2009
Marine living resources	-3%	26%	29%	43%	13%
Marine non-living resources	-68%	-80%	-62%	-65%	-39%
Marine renewable energy	2246%	5621%	3582%	4114%	599%
Port activities	1%	18%	15%	8%	-6%
Shipbuilding and repair	-5%	11%	30%	93%	9%
Maritime transport	11%	31%	12%	5%	-22%
Coastal tourism	1%	20%	21%	44%	*

Source: EU Blue Economy report 2021 (Data from Annex 2, Tables A1-A6)
**no information*

As visible from Table 2, the most significant increase is observed in the Marine renewable energy sector where for the 2009-2018 period the turnover has increased by 5621 %, the gross profit – by 4114 %, the GVA by more than 3500 %, the number of employed – by more than 2000 %, all this in the context of only about 600 % growth of investments. The situation in other sectors differ as there is a huge decrease in the levels of all indicators for the Marine non-living resources sector, as well as for the number of employees in sectors of Marine living resources and Shipbuilding and repair, and in investments in sectors of Port activities and Maritime transport.

The contribution of the Blue Economy emerging and innovative sectors (EU, 2021) is significant with increasing capacity, huge investments in nature-based solutions and new opportunities like floating solar photovoltaic energy, hydrogen generation offshore, new innovations and technology for the marine minerals sector.

- The ocean energy sector has 12 GW capacity in 2020 (incl. 12 MW for wave energy and 22.4 MW for tidal energy) with expectation of increase up to at least 60 GW by 2030 and more than €78 million to R&D projects on floating offshore wind solutions via FP7 and H2020 funding programs since 2009 and €3.84 billion between 2007 and 2019, for R&D on wave and tidal energy;
- Since 2014, around €262 million have been invested through the European Regional Development Fund (ERDF) and Horizon 2020 in projects supporting Blue biotechnology;
- In January 2021, there were 2309 operational desalination plants in the European Union, producing about 9.2 million cubic meters per day and the investments for 2010-2019 period are about €630 million;
- The total defence expenditure in 2019 amounted to €186 billion, The European Maritime Security Agency (EMSA) had a budget of €81.2 million for 2020 and the whole European Defence Industry had 440 000 jobs ;
- Horizon 2020 (2013-2020) funded €79 billion to Research and Innovation and €4.9 million for skills and education were funded under the Marine Technology Skilling Strategy (MATES) project;
- In 2019, 205 out of a total of 400 submarine cable networks, responsible for 99% of international data transfer and communication, were connected to EU Member States, with a 564000 km length; and in 2019, the global underwater robotics market was valued at €2 209 million and forecasted to reach €4 390 million by 2025;

In a number of the regions, dependent of the Blue Economy sectors` development, there are not many other alternatives for livelihood and occupation. The Blue Economy activities have a great impact on the marine environment, including the effects of climate change and greenhouse gas emissions, over-exploitation and pollution which all result in biodiversity loss (EU, 2020). Many of the current activities need to reduce their carbon footprint, while new, carbon-neutral activities need to be stimulated. The Blue Economy can play a vital role in many aspects of the work to combat pollution and can benefit from new opportunities arising from that. Over the past two decades, the EU put a solid foundation for an integrated and synergetic maritime policy in order to create a sustainable Blue Economy (European Comission, 2021). Although achieving the European Green Deal objectives imposes big investments, by 2030 one third of investments in the Blue Economy could still be unsustainable (EU, 2020) and the reasons for that include focus on short-term profits, inadequate impact assessments, weak regulatory frameworks and businesses' inability to attract impact investments.

The ocean policy should be integrated into Europe's economic policy and the green and the blue policies should be better connected. The ocean, and the 'blue economy' it supports, is indispensable to achieving the transformation set out in the European Green Deal. The contribution of a healthy ocean is essential for a sustainable economy. A sustainable blue economy will create tangible opportunities for new jobs and businesses (European Comission, 2021).

Conclusion

The current state of development of the Blue Economy is a result of significant long-term work at international level. The EU is taking the necessary steps to protect water resources and ensure their sustainable use but still there is a great number of actions that should be taken on a global level so the transition towards Blue Economy could become possible. A sustainable blue economy is a global challenge that requires coordinated global action, international policies and common goals.

The Blue Economy established sectors, except Marine non-living resources, mark an increase for the last two decades. The largest increase is observed in the Marine renewable energy sector. The Blue Economy emerging and innovative sectors offer a huge number of opportunities for new activities, jobs, and nature-based solutions.

The Blue Economy activities have a great impact on the marine environment and they need to be governed in a sustainable way so the negative impacts are mitigated or eliminated. To achieve this and to reduce the unsustainable activities, EU should switch to sustainable financing in the Blue Economy sectors.

Abstract

Herbs are an integral component of the Mediterranean culture. Many farmers changed their old crops into new cultivations like herbs. This development requires investments, training programs, studies, projects in order to enrich the knowledge and skills of all the participants involved in the value chain. HEGO is a Black Sea Project, funded by the European Union and one of its main goals is the modernization of enterprises associated with cultivation, production and promotion of diversified, sustainable, value-added herb products and the enhancement of cross-border trade opportunities for local herb enterprises in participating Black Sea Basin countries (Greece, Moldova, Georgia and Armenia). During the first year of the project, Market Research survey has been performed, one in each Project country, with stakeholders from several target groups (farmers, advisors, collectors, SMEs, public authorities, organizations etc) in order to identify: (a) the current situation with reference to the collection/cultivation, processing and promotion practices used for herb products as well as legislative issues and the niche market segments for sustainable and ethical herbs products, (b) the current skills and expertise towards herbs of the participants in each country and (c) the specific future training needs of end-users of Project Outputs in relation to the above mentioned topics. The findings of these surveys provide important insights in the research field of herbs and led to conclusions, suggestions, recommendations and specific guidelines for target groups' members that will be used as feedback for the formulation of policy implementations including the development of training curricula and courses.

Keywords: *Black Sea, Extension, Herbs, Survey, Training.*

Introduction

In recent years there is a strong interest in herbs. The trend towards new alternative crops, the search for products with environmentally friendly production methods as well as the valuable properties of herbs are the main reasons for the increased interest of farmers and consumers (Papamixalopoulos, 2020). Herbs have been used extensively for their healing properties across history and cultures (Barata et al., 2016). During the Hippocratic Corpus (5th – 2nd century B.C., Greece), almost 380 medicinal herbs useful for various illnesses were recorded (Petrakou et al., 2020). Hundreds of millions of people collect plant material to fulfill their needs for substances for personal uses or for trade (Cheminal et al, 2020). The Mediterranean Basin is considered as a "Global biodiversity hotspot" and the largest of the world's five Mediterranean type climatic regions (Skoufogianni et al, 2019). According to WHO (2015), 60.000 species of aromatic and medicinal plants are used globally and more than 500.000 tons of materials from those species are traded every year. The collection and use of nature products and especially herbs is a common practice. One of the main concerns globally is the uncontrollable harvest of wild herbs which results in a severe decrease in the population of these species (Lange, 2004). Due to overharvesting and habitat loss, approximately 15.000 species are now endangered (Schippmann et al., 2006).

This paper is part of one of the main Deliverables of the project's first work package: Market Research for current situation and training needs on herb sector. The main aim of this deliverable is to describe the current situation of herb sector, in the Black Sea HEGO countries, and to identify the training needs of end-users from several target groups (farmers, advisors, collectors, SMEs, public authorities, organizations etc). During this deliverable Market Research survey has been performed, one in each Project country, using both quantitative and quantitative instruments (Michailidis et al, 2011). This research has been performed under the Deliverable "Final Cross-country Report in Market Research Surveys results" and aims at providing the final common findings, conclusions and suggestions/recommendations on training needs of herb products among Project countries.

Materials and Methods

The research in all four project countries was conducted during March and April 2021. The questionnaire was developed by the Greek team and completed: (a) in Greece by 30 responders, (b) in Moldova by 49 responders, (c) in Georgia by 33 responders and (d) in Armenia by 40 responders (Fig. 1). The sample was representative consisting of all target groups, of different age groups and of different educational background (more details are presented below). The primary collection method was face-to-face/personal interviews. But in some cases, due to weaknesses (pandemic, national reasons), interviews were done by phone, Skype, e-mail or via Google Forms. The collected national data were gathered in data excel files and were statistically analyzed using the SPSS for Windows (ver. 27). The survey instruments were based on a previous work of Valero et al. (2021).

Figure 1. Distribution of the sample by country

The following Tables 1 and 2 present a short description of the research sample. According to Table 1, Moldova had the biggest sample, followed by Armenia, Georgia and Greece. Greece's main target groups were Farmers of herbs (53,33%), whereas in Moldova, Georgia and Armenia, were SMEs (42,68%, 33,33% and 35,00% respectively), The main group of the total sample of the survey were SMEs (31,58%), followed by farmers of herbs with 23,03%.

Table 1. Description of the sample

Distribution of the sample by country	
Greece (30 questionnaires)	19,74 %
Moldova (49 questionnaires)	32,24 %
Georgia (33 questionnaires)	21,71 %
Armenia (40 questionnaires)	26,32 %

Table 2. Description of the target groups

Target groups	Greece	Moldova	Georgia	Armenia (%)
Farmer of herbs	53,33	20,41	12,12	12,50
Collector of herbs	6,67	0,00	27,27	15,00
Local public authorities	6,67	4,08	0,00	0,00
Regional public authorities	0,00	2,04	0,00	22,50
National public authorities	3,33	4,08	3,03	0,00
Sectoral agencies	0,00	2,04	0,00	2,50
Interest groups including NGOs	3,33	6,12	12,12	5,00
Education/ training centers and schools	13,33	8,16	9,09	5,00
SMEs	6,67	42,86	33,33	35,00
Business support Organisations	6,67	10,20	3,03	2,50

Results and discussion

According to all participants, current skills and expertise towards herbs are higher in processing techniques and lower in wildcrafting practices and technological expertise. Table 3 presents the mean values per country and per total survey sample.

Table 3. Grade the level of your skills and expertise today towards herbs (1: none, 5: very high)

Skills and expertise	Greece	Moldova	Georgia	Armenia	Mean	St. Dev.
Cultivation practices (planting, irrigation, fertilization, weed and pest control, harvesting, propagation)	3.57	3.15	3.00	2.80	3.13	0.33
Knowledge on cultivation needs (from planting till harvesting)	3.87	3.38	3.15	3.00	3.35	0.38
Wildcrafting practices (do you implement these methods of harvesting?)	2.83	2.46	3.58	3.30	3.04	0.50
Knowledge on ethical wildcrafting (improve the process, follow regulations and make it more sustainable and environmental-friendly)	3.37	2.38	3.61	3.20	3.14	0.53
Knowledge on the biodiversity conservation of endemic herb plant species (do you know that many endemic herb plants are forbidden to harvest as they are protected, red-listed?)	3.47	2.76	3.48	3.30	3.25	0.34
Knowledge about the ecology and sustainable management methods of herb species	3.37	3.15	3.39	3.40	3.33	0.12

Processing techniques (drying herbs, herbal mixtures, distillation, extracts, food products etc)	3.50	3.46	3.48	3.30	3.44	0.09
Technological expertise (like value chain, precision agriculture, innovations, application of technology in the cycle of production etc)	3.13	3.00	3.18	2.90	3.05	0.13
Trading skills (marketing skills, certification etc)	3.03	3.30	3.42	3.10	3.21	0.18
Business management skills (value chain development, legislative expertise, finance etc)	3.17	3.53	3.21	3.30	3.30	0.16

Future needs in training towards herbs should target the gain of plant health conditions-weed control and managerial-commercial skills (Fig.2). The next figure summarizes the averages of those mean values in an ascending order.

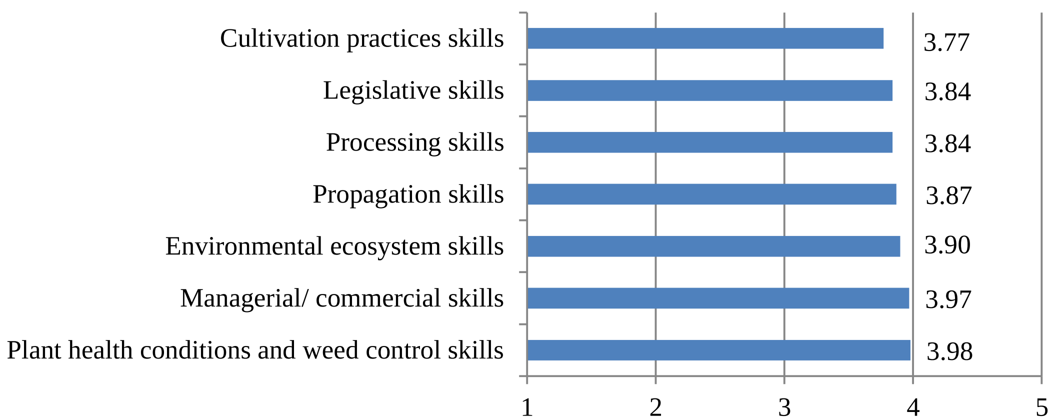

Figure 2. Future needs in herbs training

Table 4 presents the mean values per country and per total survey sample in every subcategory of skills. In Greece, training for managerial/commercial skills was seen as most needed, whereas cultivation practices skills were graded as a lesser necessity. Moreover, the most important skills that need to be developed are marketing, trading and cooperating internationally. In Moldova, training for propagation skills was more important, whereas managerial/commercial skills were less important. In Georgia, most needed skills were training for plant health conditions and weed control, while training for legislative skills seems to be a lesser necessity. Finally, in Armenia, training for plant health conditions and weed control skills seems to be very important whereas managerial/commercial skills were less important.

Table 4. Rate your need for training to the following (1:not important, 5:extremely important)

Training needs	Greece	Moldova	Georgia	Armenia	Mean	St. Dev.
a. Training for cultivation practices skills						
On planting process	3.20	4.07	3.97	3.67	3.37	0.39
On site selection like soil composition, pH level, drainage	3.40	4.15	4.27	3.82	3.91	0.39
On fertilizing	3.00	4.07	4.03	3.72	3.71	0.50
On irrigation	3.00	4.07	4.15	3.8	3.76	0.53
On relevant equipment and tools for cultivation and wildcrafting practices	3.37	3.76	4.12	3.72	3.74	0.31

Average Mean values	**3.19**	**4.02**	**4.11**	**3.75**	**3.77**	
b. Training for plant health conditions and weed control skills						
On identification of plant health problems	3.83	4.15	4.21	4.10	4.07	0.17
On weed control	3.47	4.00	4.06	3.82	3.84	0.27
On pest control	3.50	4.00	4.27	3.97	3.94	0.32
On disease control	3.83	4.07	4.39	3.97	4.07	0.24
Average Mean values	**3.66**	**4.06**	**4.23**	**3.97**	**3.98**	
c. Training for propagation skills						
On establishing and operating an herb nursery	3.23	4.23	4.06	4.00	3.88	0.44
On selection of propagation methods and materials (growing structures, cuttings, seed, separation, division)	3.30	4.00	4.27	3.77	3.84	0.41
On knowledge of each method characteristics	3.53	4.23	4.12	3.72	3.90	0.33
Average Mean values	**3.35**	**4.15**	**4.15**	**3.83**	**3.87**	
d. Training for processing skills						
On harvesting	3.03	4.00	4.12	3.87	3.76	0.49
On storage/ post-harvest practices	3.13	4.00	4.09	4.15	3.84	0.48
On distillation techniques	3.57	4.07	3.97	3.47	3.77	0.29
On drying techniques	3.53	4.15	4.24	4.05	3.99	0.32
Average Mean values	**3.32**	**4.06**	**4.11**	**3.89**	**3.84**	
e. Training for legislative skills						
On understanding legislation for products, cultivation, propagation, taxes etc	3.97	4.38	4.00	3.55	3.98	0.34
On dealing with bureaucracy	3.83	4.00	4.03	2.97	3.71	0.50
On regulations and fines about wildcrafting	3.40	3.76	3.85	3.47	3.62	0.22
On regulations about certifications	3.97	4.38	4.15	3.45	3.99	0.40
On organic certification	3.87	4.15	4.15	3.50	3.92	0.31
Average Mean values	**3.81**	**4.13**	**4.04**	**3.93**	**3.84**	
f. Training for environmental ecosystems skills						
Knowledge about the biodiversity conservation of endemic herb plant species	3.57	4.00	4.09	3.75	3.85	0.24
Knowledge about the ecology and sustainable management methods of herb species	3.60	4.23	4.18	3.67	3.92	0.33
New sustainable cultivation practices	3.97	4.08	4.09	3.75	3.97	0.16
New sustainable wildcrafting practices	3.50	4.08	4.09	3.72	3.85	0.29
Average Mean values	**3.66**	**4.09**	**4.11**	**3.72**	**3.90**	
g. Training for managerial/ commercial skills						
On business management	3.90	4.00	4.09	3.52	3.88	0.25
On innovation management	4.10	4.15	4.18	3.70	4.00	0.21
On technological management	4.13	4.15	4.15	3.65	4.02	0.25
On marketing	4.33	4.00	4.12	3.67	4.03	0.28
On trading	4.30	4.00	4.12	3.57	4.00	0.31
On evaluating market demand	4.13	4.31	4.21	3.75	4.10	0.24
On cooperating internationally (language, trade terminology)	4.17	3.15	4.03	3.62	3.74	0.46
Average Mean values	**4.15**	**3.95**	**4.13**	**3.64**	**3.97**	

However, the specification and ranking of training needs per country is of greater value. Figure 3 shows the mean values in each country.

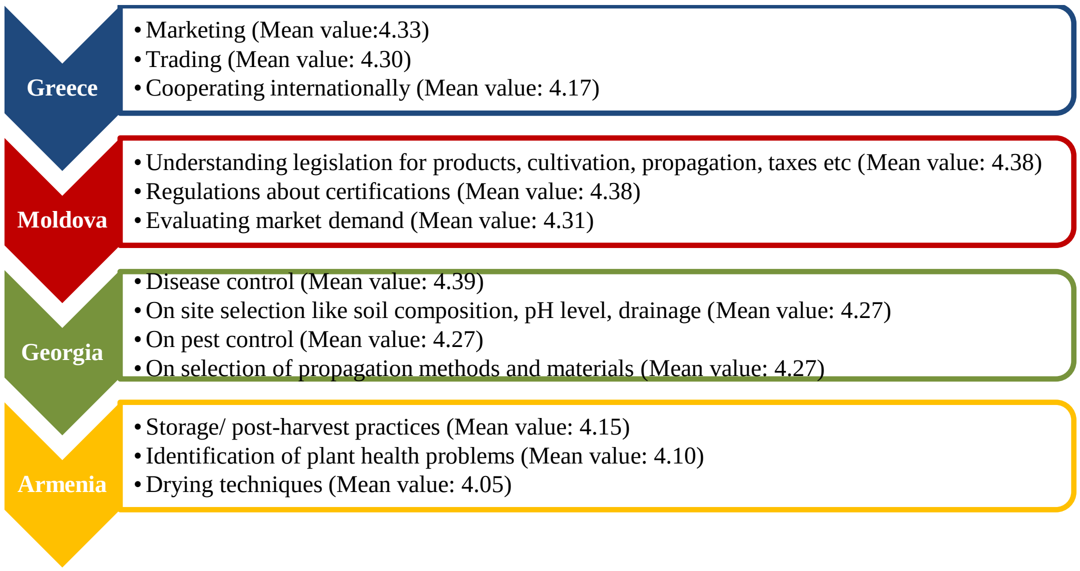

Figure 3. Most important training needs by country

From the above mentioned figure the following interesting results are obtained:

a) all three major training needs of Greek responders are included in the broader category "Training for managerial/ commercial skills",

b) major training needs of Moldavian responders are included in the broader categories "Training for managerial/ commercial skills" and "Training for legislative skills",

c) major training needs of Georgian responders are included in the broader categories "Training for plant health conditions and weed control skills", "Training for cultivation practices skills" and "Training for propagation skills",

d) major training needs of Armenian responders are included in the broader categories "Training for plant health conditions and weed control skills" and "Training for processing skills".

Figures 4-10 show the future training needs of all target groups of each country with a different color, for cultivation practices, plant health conditions-weed control, propagation, processing, legislative, environmental ecosystems and managerial/commercial skills.

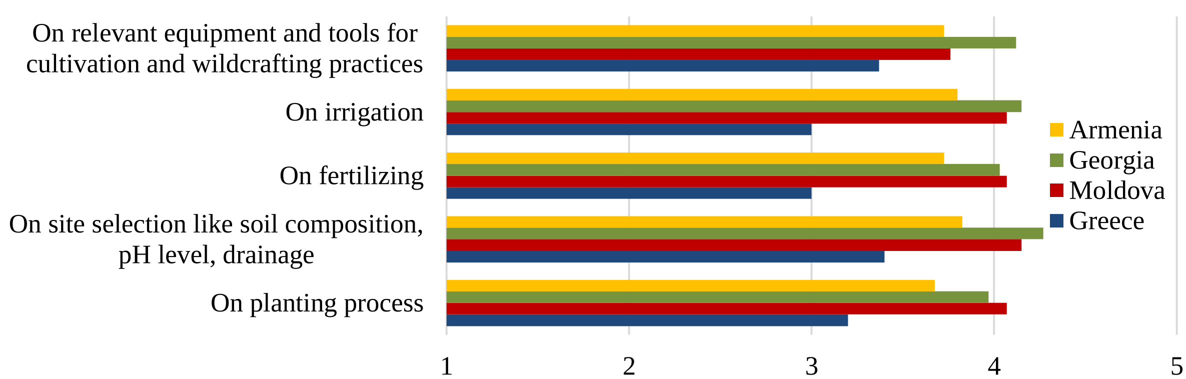

Figure 4. Future training needs for cultivation practices skills

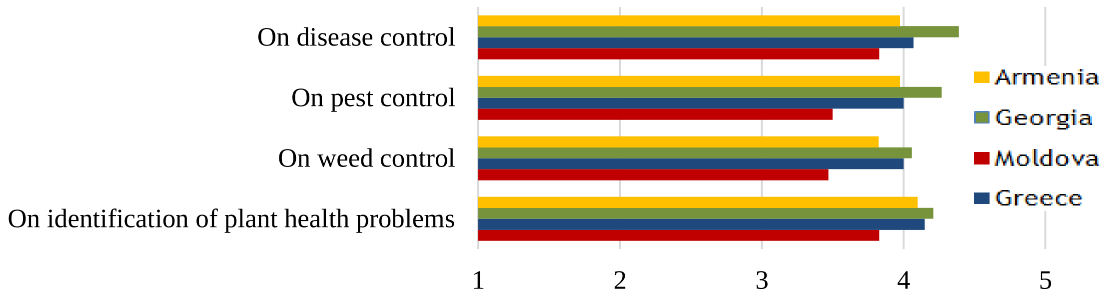

Figure 5. Future training needs for plant health conditions and weed control skills

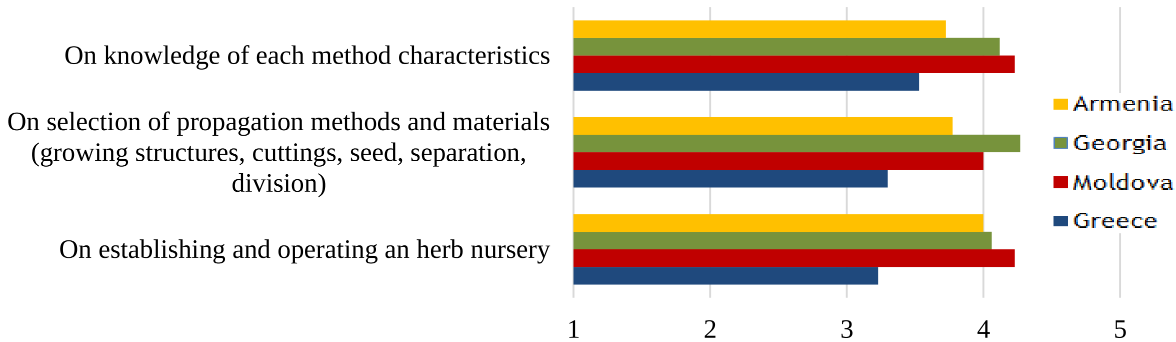

Figure 6. Future training needs for propagation skills

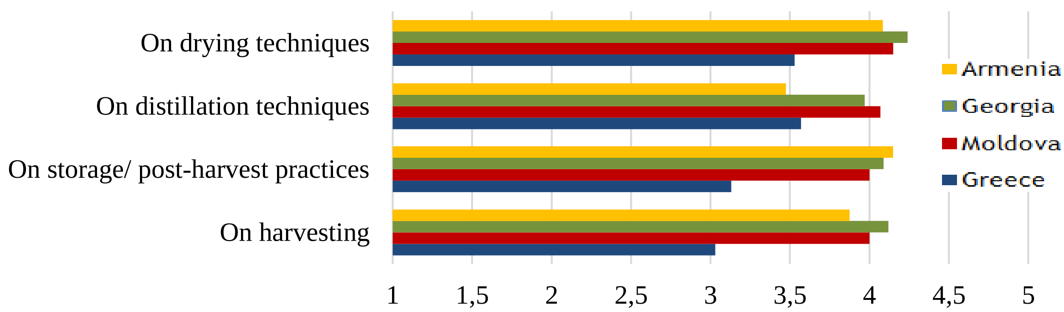

Figure 7. Future training needs for processing skills

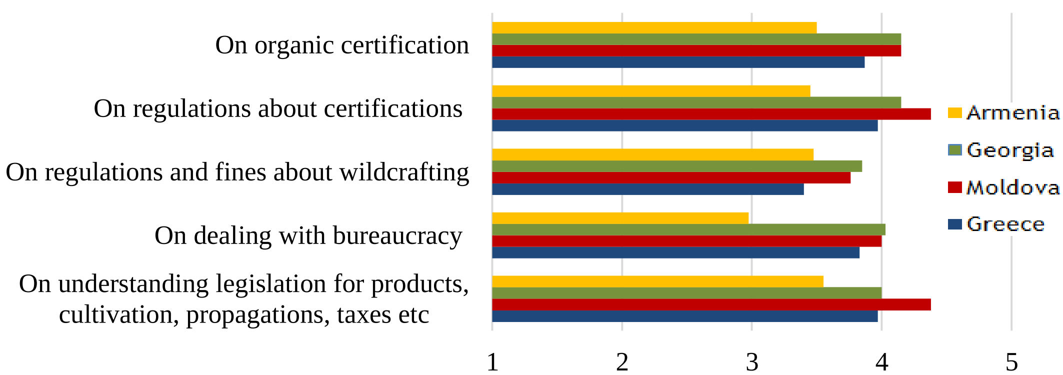

Figure 8. Future training needs for legislative skills

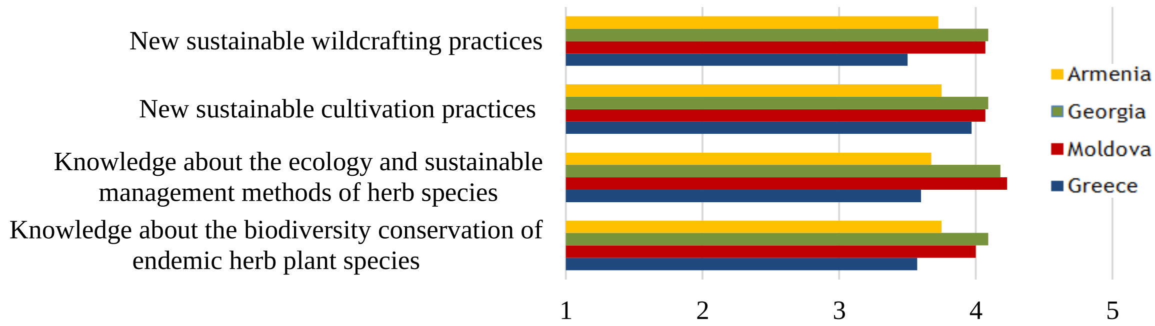

Figure 9. Future training needs for environmental ecosystems skills

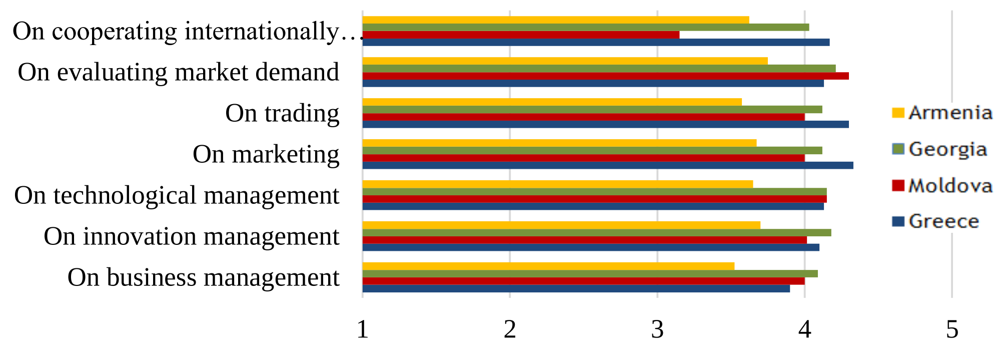

Figure 10. Future training needs for managerial/commercial skills

Conclusion

This paper provides important insights in the research field of herbs. From content point of view, this paper helps bring the sector of herbs a step closer to all different target groups participated in the survey and reduce their training gap. More specifically, results of this paper can be used to design a common training framework for all Project countries, in order to cope with the potential threats of the herb sector. The most important gap detected was knowledge/skills, especially in wildcrafting practices and technological expertise, among participants of the survey. In addition, almost all of the responders recognize the importance of education/training for herbs' cultivation. The most important skills regarding training were managerial/ commercial and plant health conditions-weed control. More specifically, the major future training needs are "evaluating market demand", which belong to managerial/commercial skills and "identification of plant health problems and disease control", which belong to plant health conditions-weed control skills. Based on the implemented questionnaire and performed analysis of the collected data from all countries, we conclude into a series of recommendations on training needs which can be the basis to design the training programme:

- Training on wildcrafting practices.
- Training on plant health conditions and weed control skills.
- Training for processing skills.
- Training on sustainable development of the business.
- Training on recognition and adoption of innovation and modernization practices current and future practices in growing, harvesting, production and trade of herbs (i.e. during the entire cycle of business).
- Training in developing skills for market review demand and supply.

- Training on product quality improvement and traceability.
- Training in accessing financing and investments.
- Training on labeling and certification.
- Training on increasing capacities to cooperate locally and internationally.
- Training in trading and commercial skills.
- Training for the development of the value chains and clusters of the herbaceous sector.
- Training for internationalization of companies and development of export activities.
- Training of new qualified specialists in herbal sector.

THE POLICY REFORMS THAT SHAPED CONTEMPORARY RURAL SOCIETY IN GREECE

Georgia KIPOUROPOULOU*, Katerina MELFOU

University of Western Macedonia, School of Agricultural Sciences, Department of Agriculture, Florina, Greece
*Corresponding author: georgkip@yahoo.com

Abstract

Rural communities remain an integral part of contemporary Greek society which is active, takes actions and resists, trying to maintain its distinctive character. These are communities in a continuous endeavor to negotiate terms and manage their integration in society, very much in the way it was envisaged in the policy reforms firstly introduced in the early decades of the 20th century. The objective of this paper is to explore and highlight the importance of policies introduced by policy makers and decisions taken by Governments of Greece at that time, in order to stimulate the agricultural economy and introduce rural education in the country. The options that were available, the radical reforms implemented during the period 1910-1920, reforms that led to the social transformation of the rural sector in Greece will be analyzed and presented. Legislative decrees and laws of 1911, the educational reform that had already begun in 1913, the establishment of new ministries and the rural reform of 1917, were the result of a dynamic relationship between the rural population and the policy initiated by the Greek Government. The decisions taken and the Bills passed in the period 1910-1920 concerning agricultural economy and rural life, particularly promoted agricultural education. The primary sector in the country, although it employed a large percentage of the active Greek population and brought sizable revenues to the state treasury, had been neglected in previous decades. It is important to point out that a result of the radical reforms that occurred in the agricultural sector was the active participation of rural population in the social and economic life of the country.

Key words: *rural economy, agriculture,20th century, agricultural education.*

Introduction

Ruralism is defined on the basis of the interaction between internal social links and external policies. In this context, a dominant role in shaping ruralism is played by the social integration processes of the rural population in modern society, which are detected at three levels: the economic, political and cultural. (Zakopoulou, 2008, p.29) At the political level, which also concerns the present study, what is being investigated is the conversion of farmers into citizens of an equal standing to others, the functionality of rural order in the current system, the importance of rural confrontations, integration policy, the importance of family agriculture, the maintenance of property by farmers and the importance of the agricultural sector in modernizing the Greek state in the first decades of the 20th century is investigated.

The rural community is an important part of the newer Greek society that acts, affects and resists. The local rural society and surrounding society developed an unprecedented two-way relationship for Greek standards in this period. The radical decisions of the Greek Governments during the first decades of the 20th century and their modernity led to the social transformation of the rural sector in Greece. The aim of the research is to investigate the contribution of the Greek Governments'' decisions to the promotion and development of the rural economy in Greece.

Materials &Methods

The agricultural sector has been the main employer of Greek working force during the period of this research (1910-1920) and its support has significantly helped both in the country's finances and in avoiding social tensions in times of social crisis.

The more general assumptions of this research are as follows: a) through the study of historical archives of the time period (Benaki Museum, Archive of Eleftherios Venizelos) a substantial promotion of the rural economy will emerge b) the decisions of the governments on the agricultural sector will be more and more substantial during the periods 1914-1917 and 1922-1924 given the historical circumstances (end of the Balkan wars and the Asia Minor disaster)

The methodology chosen for this research is qualitative. Through qualitative research, data are collected that describe problems and concepts of people's lives. The data can emanate from interviews, observations, participatory observations, stories, interactions, case studies, personal experiences, life stories, file analyzes, visual material and endoscopies.

This research uses the Grounded Theory as a methodological tool. Grounded Theory appeared in 1967 when Barney Glaser and Anselm Strauss introduced it in their book *The Discovery of Grounded Theory*. It is a systematic research method according to which the generated theory derives inductively from the study of empirical data and is not based on previous ideas or ideas of the researcher. Its basic principle is that the researcher is not encouraged to do some initial bibliographic research but to suspend his personal theoretical stereotypes in order for theory to emerge exclusively from empirical data. It is a purely inductive research approach. As its name suggests, this research method has the effect of forming a theory that is based on the empirical data it interprets. Grounded theory belongs to the qualitative methods of social research and consists in the analysis of data, the methods of production of quality material, the use of theory and ultimately the presentation of the results (Iosefides, 2006: 212) and is mainly used in research issues that have not yet been investigated or are under investigation.

Results and Discussion

The Constitution of 1911 aimed, on the one hand, to regulate relations between the large landowners and farmers and on the other to support agricultural production. These intentions can be seen through many governmental decisions such as:

- "the establishment in Athens of a Veterinary Microbiological Laboratory",
- "the establishment of a State stallion Station",
- "the establishment of veterinary regions and the appointment of veterinarians as civil servants",
- "the supply by the State of agricultural supplies to villagers",
- "the reconstruction of the agricultural service of the State ",
- "the implementation of land reclamation projects draining of swamps and rearrangement of river beds and torrents etc." (Peliouras, 2017, p.185).

The revision of the Constitution imposed arrangements (such as Article 17 which provided for the possibility of expropriation of properties not only for reasons of "public necessity" but also for "public benefit"), which opened up the way for the expropriation of estates (Patronis, 2015, p. 110). Moreover, the addition to Article 11 of the Constitution where it states that a cooperative cannot be dissolved due to a breach of the provisions of the laws, or by judicial decision,' removed from the administration the right to approve the establishment or revoke the approval of a Union.

The Interim Government of Thessaloniki 1917 proceeded to issue a series of legislative decrees that have been the first real and radical effort to resolve the agricultural issue in the country. The Agricultural reform with five legislative decrees gained force, gave impetus to the whole of the Greek state and concerned the following issues:

-2466: The transference of government properties to farmers so as to create small land ownerships

-2467: Concession of Macedonian estates to those who participated in the National great effort

-2468: Adjustment of legal relationships regarding public land, as defined by Ottoman laws

-2469: Compulsory expropriation of rural real estate

-2470: Issuing of bonds to compensate for the expropriation of farm estates which were expropriated (Tsiros, 2013, p.131).

In 1917, the Venizelos government takes a decision of crucial importance and establishes the Ministry of Agriculture. The main endeavor of the newly established ministry was to apply the agricultural reform that the prime minister had promised, but at the same time it dealts with expropriations, public estate management, land distribution, land registration and agricultural insurance (Petmezas, 2012, p.145)

An important decision and a basic principle underlying legislation were to assemble farmers in rural cooperatives to eliminate the disadvantages of small ownership. The expropriations made in the 1724 estates restored 130,000 landless families or poor farmers (Martinos, 2004, p. 245).

In addition, the agricultural reform that started in 1917 allowed the rural rehabilitation of about 600,000 refugees thus preventing social tensions, opened up the road to the development of the system of agricultural insurance, almost eliminating the usurious system of major landowners and has significantly contributed to the establishment of cooperatives (Vergopoulos, 1975, p .177).

This modernizing attitude that characterized Greek governments of this period is also detected in the field of education. Main purpose of the Prime Minister was to provide to educational programs a technical and practical content. Indicatively, we refer to the bills of the Minister of Education in 1911, that established among other things, monastery farms, a technical-vocational education network was envisaged. In the same year, the institution of the county agronomist is being introduced. The Averofio Agricultural School also contributed significantly to the improvement of agricultural production in the country. It should be noted that while the original purpose for the establishment and operation of the School was to create agronomists to fill the positions of directors in the agricultural industry, in 1911 the institutional framework changed. More specifically, two departments were established: a senior one to train agronomists to fill managerial positions in large estates and agricultural industries, and a lower one to train young farmers from rural families (Kandila, 2004, p.426).

In 1913, the Minister of Public Education submits to Parliament eight new bills. In the introductory report, it is characteristically mentioned that ' The urban school as we have said should provide the necessary general education to young people who either immediately or after their graduation and having completed their studies in vocational, commercial, agricultural, naval or other specialized school should start their profession in life.As foreseen by the 1913 bills there were six years of mandatory education and, among other things, curriculum had a direct

relationship with agricultural production with subjects such as "horticulture, arboriculture, livestock, beekeeping" (Eliades, 2010, p. 65).
In 1914, lower level agricultural schools are founded with a purely practical orientation. These schools would be founded in each county and be attended for 2 years by graduates of the elementary school aged 14-19 years as boarding school students. (Kandila, 2004, p. 426-427).
The first "senior Agricultural School of Athens" (AGSA) was established in 1920. The founding law stated amongst others things that the graduates should be able to serve as senior executives of state agricultural service departments and manage agricultural and associated businesses, to promote Greek scientific research to the various sectors of agricultural production. Moreover: "the graduates of the school will have a great qualification, such that immediately after the end of their studies they will know the conditions of Greek agriculture in contrast to graduates from foreign schools, who are ignorant of the land, its climatic, economic and social conditions, thus needing a lot of time to orient themselves and be able to beneficially apply their knowledge in Greece. "
Considering the texts of the decisions of the Greek Governments during the period 1910-1920, the projects implemented in the period 1910-1920 by the competent Ministries and Ministers, but also the Archive of Eleutherios Venizelos it is clear that the Prime Minister sought to modernize the agricultural sector and strengthen farmers and livestock farmers thus emphasizing the importance of the primary sector in the economic development of the country.
The so-called agricultural issue had preoccupied the previous Greek governments without them finding, however, ways to resolve or even address it until 1910 when the Prime Minister relieved farmers from the fear and the threat of eviction. Until then, landowners reserved the right to evict their farmers in cases where the latter did not meet the -often strict and unbearable- obligations that had been set. This prevented the impoverishment and humiliation of the rural population. In addition, the Constitution (1911) provided for the possibility of expropriating property not only for reasons of "public necessity" but also for reasons of "public benefit". This paved the way for land expropriations and rural rehabilitation of landless farmers. The result of this decision was the improvement of living conditions of the country's farmers, the increase in agricultural production and at the same time it offered motivation for future growers.
The Prime Minister's concern for the strengthening and improvement of the agricultural sector in Greece is evident from a series of decisions. In particular, the decision to send scholarship holders to study Forestry reveals that the Ministers of Agriculture and Finance realized the importance of specialization and education in order to strengthen the country's agricultural sector. Hiring trained scientists in the Forestry Service would contribute substantially and practically to the guidance and dissemination of information to farmers. Informed farmers would in turn improve both the quality of their agricultural production and their living standards.
The institution of the veterinarians is another example that demonstrates the interest of the Government to strengthen all sectors of the agricultural economy of Greece. Livestock breeding has traditionally been a main occupation of Greek farmers and the existence of scientists able to inform, help and support them with specialized knowledge has strengthened this sector of the agricultural economy. With the Veterinarians, not only would animal diseases be effectively treated but the quality and quantity of the livestock products would be improved. The establishment of a veterinary microbiological center additionally contributed to the improvement of animal husbandry in Greece. At the same time, the institution of the agriculturist introduced by the Constitution of 1911 provided the necessary advice to Greek farmers to improve their

production. The agriculturalists would act as advisors, supporters and would provide their scientific knowledge in order to improve the quality and quantity of products produced.

Conclusions

The decisions taken and the Bills passed in the period 1910-1920 concerning the agricultural economy and life particularly promoted agricultural education. The primary sector of the country, although it employed a large percentage of the active Greek population and brought huge revenues to the state treasury, had been neglected in previous decades. It is important to point out that a result of the radical changes that occurred in the agricultural sector during this period was the active participation of the rural population in the social and economic life of the country. As the rural population increased, crops important to the national economy were strengthened such as tobacco and cotton. The Law 301 of 30 September 1914 established lower level agricultural schools with a purely practical orientation. It was therefore realized that Greece as an agricultural country should care for the agricultural education of its citizens. The establishment of agricultural schools in each prefecture of the country was envisaged for children aged 14-19 to qualify to acquire knowledge and appropriate skills regarding the cultivation of the land. Knowledge was the vehicle for the development of the agricultural sector. In addition, the Constitution of 1911 provided for the establishment of model monastic farms, the establishment of a network of technical and vocational education. However, the establishment of the first School of Agriculture is the greatest proof that the intention of the Greek Government was to establish agricultural education in the country. In the founding statute of the School it becomes clear that the purpose of its establishment is to promote systematic agricultural holdings and related industries, to establish agricultural enterprises and to approach agriculture in Greece a scientific way, which was missing until then. Research, studies and scientific training of personnel in state agriculture service departments would give a new impetus to the agricultural economy, improving the living conditions of farmers and strengthening the state budget.

Abstract

The research in this paper deals with the main production characteristics of grape production in Serbia. Based on the quantitative analysis, the aim of the research was to determine the trends in the production characteristics of grapes, and to predict these movements for the following period. The production characteristicsof grapes(vineyard area, annual production and yield) were analysed for the period 2005-2019. The quantitative analysis was performed by using the methods of descriptive statistical analysis and the average annual rate of changes to determine the trends in the analyzed period and to predict the movements in the following period2020-2024. The average vineyard area in the analyzed period in Serbia was 22,173 ha;the annual change rate of the vineyard area was -1.59%. The average annual production of grapes in Serbia was 174,976t;the annual change rate was 0.64%. The average yield of grapes was 7.88t/ha;the annual change rate of the grape yield was 2.32%. According to the forecast results,it is expectedthat the vineyard area in 2024 in Serbia will be 18,917 ha, the annual production will be 168,971 t, and the grape yield will amount to 8.97 t/ha.

Keywords:*grape, production, prediction,vineyard area, grapeannual production, grape yield, Serbia.*

Introduction

Grapes have great nutritional, dietary and medicinal value in the human diet. A kilogram of grapes contains from 700 to 1200 calories, depending on the sugar content, which can provide the body with around 30% of the required daily intake of calories.
Grapes contain a large number of very important ingredients: sugars, organic acids, vitamins and minerals, aromatic substances, tannins, etc. The most important ingredient in grapes is sugar – glucose and fructose, which are easily absorbed by the human body. In the right proportion with sugar, acids in grapes providea pleasant and refreshing taste. In the form of salts, they have an important physiological role in the body.
Minerals found in grapesare also very important for the human body. In addition, because of a small amount of nitrogenous substances, extremely small content of chloride and absence of fatin grape juice, grapes have a special role in the treatment of some diseases. Grapes contain a higher number of vitamins, which also contribute to their value in the human diet.
Owing to the beneficial effects of grapes on the human body, consumption of fresh grapes in the world is constantly increasing. Only a small amount of grapes is consumed fresh, while they are

most commonly used as raw material for the production of wine, grape juice, raisins, grape honey and other food products. The largest amount of grapes is processed into wine (Golovic,2021).

Grape pomace, which remains after processing of grapes and extraction of must or wine, is used for the production of komovica brandy or pure alcohol, which is used in the chemical industry, for medicinal purposes, etc. After the production of brandy, pomace can be used as animal feed or for production of organic fertilizers, by composting.

In terms of labor needed for establishing and maintaining vineyards, grapevine is one of the most intensive crops.

Theresearch in this paper analyzes the trends forthe production characteristics of grapes –the vineyard area, annual production and yield of grapes in the Republic of Serbia and the Autonomous Province of Vojvodina (AP Vojvodina).

The aim of the research is to perform analysis for the previous period and determine the trends for the observed characteristics using the quantitative methods, as well as to predict the analyzed production characteristicsfor the following period. Based on the results of the implemented forecasts, it will be possible toplan appropriate measures which would lead to improved grape production. The aim of the paper is also to perform a comparative analysis of the obtained results for Serbia and Vojvodina.

The authors of this paper have recently studiedsimilar problems. Novković et al. (2011) analyzed changes in the sown areas, yield and total production of several important vegetable crops in Vojvodinafor the period 2000-2009. The study results indicated that owing to increased yields per hectare, the total production increased, despite reductions in the total sown area.

A great number of authors have published findings concerning analyses and forecasts for production of different crops (Novković et al. 2013, 2014, 2014a, 2015, 2018; Miljanović et al. 2014; Mutavdžić et al. 2013).

Material and Methods

The methods applied in this study are quantitative methods. The data used for analyzing the grape production from the previous period include data on the vineyardarea, total production and yield of grapes in the Republic of Serbia and AP Vojvodina for the period 2005-2019. The research data were acquiredfrom the official publications of the Statistical Office of the Republic of Serbia.

Analysis of the grape production was performed by using the methods of descriptive statistical analysis, which includedthe basic statistical indicators: arithmetic mean, i.e. average value of occurrence, extreme values of occurrence (min and max), coefficient of variation (Cv) and annual rate of change (r).

Given the values of a time series Y with length n, the average index of change is:

$$G = \left(\frac{Y_n}{Y_1}\right)^{\frac{1}{n-1}}$$

and the average rate of change:

$$r = (G - 1)$$

where:

- r is the average annual rate of change
- G is the average annual index of change

- Y_1 is the absolute value of the first member of the time series
- Y_n is the value of the last number of the time series
- n is the length of the series (number of years)

By applying the calculated rates of change to the production characteristics in the last year of the analyzed period (2019), prediction (extrapolation) was conductedfor the period of the following five years (2020-2024).

Results and Discussion

Tendencies and prediction of grape production characteristics in the Republic of Serbia

The results of the descriptive statistics for the grape production characteristicsare presented in **Table 1**. The parameterwith the greatest variability in the period 2005-2019 in Serbia wasthe annual production. High variability was determined also for the yield, while it was significantly lower for the vineyard area. The area showed a decreasing trend, while the yield hada more pronounced growth rate, so the annual production of grapes showed a tendency of increase.

Table 1. Basic indicators of grape production characteristicsin Serbia (2005-2019)

Production parameters	Average value	Variation interval		Coefficient of Variation (%)	Rate of change (%)
		Minimum	Maximum		
Area (ha)	22,174	20,333	25,676	6.79	-1.595
Yield (t/ha)	7.88	5.8	10.6	15.78	2.324
Production (t)	174,976	122,489	240,369	30.94	0.637

Source: Authors' calculations

The results of the forecast for the area, annual production and yield of grapes in Serbia for the period 2020-2024 are presentedin **Table 2**. The vineyard area will decrease and in the last year of the observed period (2024)it will occupy less than 19 thousand hectares, which is by1,584 ha or 7.7% less than the vineyard area in 2019.

Table 2.Predictionsfor the vineyard area, annual production and yield of grapes in Serbia (2020-2024)

Year	Area (ha)	Production (t)	Yield (t/ha)
2020	20,174	164,558	8.18
2021	19,852	165,606	8.38
2022	19,536	166,661	8.57
2023	19,224	167,722	8.77
2024	18,917	168,791	8.97

Source: Authors' calculations

In the forecast period 2020-2024, the grape production will increase. In 2020, the production will reach 164.6 thousand tons, which is only 1 ton more than in the previous year (2019). In the last year of forecasting, the annual production of grapes in Serbia will be close to 169 thousand tons, which is by 5,200 tor 3.2% more than the production in 2019. The forecast for the grape yield on the territory of Serbia indicates that the yield will increase, so in 2024 it will be around 9 t/ha, which is significantly higher than the average value of 7.88 t/ha. The difference is around 1.1 t/ha or 14%.

Tendencies and prediction of grape production characteristics in AP Vojvodina

The results of the descriptive statistics forthe grape production characteristicsin AP Vojvodina (**Table 3**) showed that the average vineyard area was slightly more than 4.8 thousand hectares. The annual production of grapes in the analyzed period was around 42 thousand tons, while the yield was more than 8.5 tons per hectare. There were great variations in the annual production, caused primarily by variations in the yield, and significantly less by variations in the area. The highest yield was achieved in 2009, while the lowest yield was in 2005.

Table 3. Basic indicators of grape production characteristics in the region of Vojvodina (2005-2019)

Production parameters	Average value	Variation interval		Coefficient of Variation (%)	Rate of change (%)
		Minimum	Maximum		
Area (ha)	4,838	3,267	5,693	10.79	-3.889
Yield (t/ha)	8.65	5.4	11.9	18.85	1.521
Production (t)	41,920	25,546	59,705	22.5	-2.423

Source: Authors’ calculations

The vineyard area and annual production hada decreasing tendency, while the yields hada tendency of increase.

Table 4 presents the results of predictions for the vineyard area, annual production and yield of grapes on the territory of AP Vojvodina for the period 2020-2024.

The vineyard area will decrease, so it is expectedthat in the last observed year (2024) the vineyard area in AP Vojvodina will be around 2.7 thousand hectares, which is by 588 haor 18% less than in 2019.

Table 4.Predictions for the vineyard area, annual production and yield of grapes in AP Vojvodina (2020-2024)

Year	Area (ha)	Production (t)	Yield (t/ha)
2020	3,140	26,710	8.53
2021	3,018	26,063	8.66
2022	2,900	25,431	8.79
2023	2,788	24,815	8.92
2024	2,679	24,214	9.06

Source: Authors’ calculations

In the forecast period, the annual production of grapes will also decline. According to these forecasts, the grape production in 2024 will decline to around 24.2 thousand tons, which is by 3,159 tons or 11.5% less than in 2019.

Unlike the areas and annual production, the yield of grapes will grow. By the end of 2024,the yield of grapes will be over 9 tons per hectare, which is higher by 410 kilograms per hectare or 4.7% than the average value achieved in the analyzed period 2005-2019.

Comparative analysis Serbia-Vojvodina

The vineyard area in the period 2005-2012 was constantly decreasing, both in AP Vojvodina and in Serbia.The area stagnated in the period 2012-2017, butthen continued to decline in Vojvodinain 2018 and 2019. In the Republic of Serbia, a decline in 2018 was followed by an increase in the vineyard area in 2019 (compared to the previous year) for the first time in 15 years.

During the period 2005-2017, the percentage share of the vineyard area on the territory of AP Vojvodina in the total area at the national level was constant, amounting to around 22%.

In 2018, there was a slower decline in the area in AP Vojvodina in relation to Serbia, so itsshare in the total area in Serbia slightly increased. In 2019, this percentage dropped to less than 16%.

Table 5 shows the predictions for the vineyard area in AP Vojvodina and Serbia, as well as the percentage share of the areain Vojvodina in relation to Serbia for the period 2020-2024.

The vineyard area in AP Vojvodina will decrease at 2.4 times higher annual rate than in the Republic of Serbia. The share of the vineyard areain Vojvodina in the total vineyard area in Serbia will constantly decrease and in 2024 it is expected to be around 14%, which is as much as 36% less than it was in 2005.

Table 5. Predictionsfor the percentage share of the vineyard area in AP Vojvodina inthe total vineyard area in Serbia for the period (2020-2024)

Year	**AP Vojvodina (ha)**	**Percent (%)**	**Republic of Serbia (ha)**
2020	3,140	15.56	20,174
2021	3,018	15.20	19,852
2022	2,900	14.84	19,536
2023	2,788	14.50	19,224
2024	2,679	14.16	18,917

Source: Authors' calculations

The average share of the grape production in Vojvodina in relation to Serbia was 23.96%. The highest production, both in Vojvodina and in Serbia, was achieved in 2009. The lowest production in Vojvodina and Serbia was achieved in 2014.

The largest share of the grape production in Vojvodina in the total grape production in Serbia was in 2011, while the lowest percentage share was recorded in 2019.

The production in Vojvodina will decline, while at the national level it will increase. The percentage share of the grape production in Vojvodina in the total grape production in Serbia will constantly decrease and in 2024 it is expected to amount to 14.35%.

The highest yields recorded in both Vojvodina and at the national level were achieved in 2009 (11.9 t/ha in Vojvodina, 10.6 t/ha in Serbia). In the period 2005-2019, the yield in Vojvodina was two times below the national average (in 2014 and 2015). In addition, 2014 was also the year in which the lowest yields were recorded (Vojvodina 5.4 t/ha, Serbia 5.8 t/ha).

By analyzing the predictionsforthe grape yield for the following five years in Vojvodina and Serbia, it can be concluded that the yield will increase over the years, both in Vojvodina and in Serbia. If this trend continues, it can be expected that in 2025 the yield in Vojvodina will be almost identical to the yield in Serbia, amounting to approximately 9.2 t/ha.

Conclusions

Based on the presented research results, the following conclusions can be reached:
- In the Republic of Serbia, there is a trend of increasing the grape yield and grape production, while the vineyard area shows a decreasing trend. The average area was 22,173 ha, the average yield was 7.88 t/ha, and the average production was 174,976 t in the period 2005-2019. In 2024, the expected vineyard area in the Republic of Serbia will be around 18,900 ha, the production will be approximately 168,800 t, and the yield will be 8.97 t/ha.
- On the territory of AP Vojvodina,there is a trend of decreasing the vineyard area and grape production, but also atrend of increasing the grape yield. The average vineyardarea was 4,838 ha, the average yield was 8.65 t/ha, and the average production was 41,920 t. In 2024, the area is expected to be around 2,700 ha, the yield will be around 9.06 t/ha, and the production will be around 24,200 t.
- The vineyards area in Vojvodina will decrease at a faster rate than in Serbia. The yield shows an increasing trend both in Vojvodina and in Serbia, but a largerincrease is expected at the national level. Unlike the yield and area, which have the same trends in Vojvodina and Serbia, the grapeproduction in AP Vojvodinais expected to fall, while at the national level the grape production shows an increasing trend.

ANALYSIS OF THE PARTICIPATION OF INCENTIVES IN LIVESTOCK IN RELATION TO THE AGRICULTURAL BUDGET OF THE REPUBLIC OF SERBIA

Nikola STOLIĆ*, Bratislav PEŠIĆ, Nebojša ZLATKOVIĆ, Žarko KOPRIVICA

Academy of Southern Serbia, Department of Agricultural and Food Studies, Prokuplje, Serbia
*Corresponding author: nikola.stolic@gmail.com

Abstract

One of the most difficult chapters in the EU accession negotiations, based on the experience of other members, is the chapter on agriculture and rural development. The agrarian budget is a joint and consolidated form of state support for agriculture, which is implemented through subsidies for agricultural production. The subject of research in this paper is the analysis of agricultural policy and formed incentive measures in various areas of agricultural production in Serbia. Also, the budget of the Republic of Serbia, the agrarian budget of the Republic of Serbia and the planned and implemented incentive measures in agriculture for the period 2016-2020 will be compared. Based on the budget of the Republic of Serbia for 2017, the funds distributed to the Ministry of Agriculture amounted to 43.8 billion rsd, which is 3.3 billion rsd more than in 2016. On the other hand, the share of the budget of the Ministry of Agriculture in the total budget of the Republic of Serbia shows a decreasing trend and in 2017 it amounted to about 4.8%. Budget funds for agriculture in 2018 amounted to 44.1 billion rsd, which is approximately the level of the previous year (0.7% more), but with the trend of decreasing the share of the budget of the Ministry of Agriculture in the total budget of the Republic of Serbia, which reaches a value of 4.46% in 2018. The financial resources determined by the agrarian budget in 2019 were lower for 0.3%, while the difference in 2020 was 3.13%, with the announced possibility of rebalance and increase of funds as in 2019. Solving the problem of financing has a direct impact on the development of agriculture, observed from the aspects of primary agricultural production, agriculture in a broader sense, multifunctional agriculture, as well as rural development.

Key words: *agrarian budget, incentives, agriculture, animal husbandry, development*

Introduction

A very important economic activity that has economic, social and political significance is agriculture. In market developed economies, agriculture is "privileged", ie it has financial support, whether viewed in a narrower sense, as primary agricultural production or more broadly as multifunctional agriculture. Examples of this are the measures of the Common Agricultural Policy (CAP) of the European Union, which are mostly based on incentive (non-refundable) funds, as well as the way of financing agriculture in the United States based on favorable farm loans.

The Common Agricultural Policy (CAP) is one of the oldest policies of the European Union. Agrarian policy developed in parallel with the development of the Union during long-term processes, continuous changes, integration of a large number of entities that took place within it. The common agricultural policy has influenced: increasing agricultural production and productivity, changing the production structure, stabilizing the internal market, increasing exports, independence from imports, protecting and increasing producers' incomes, security of supply.

All of the above has led to the fact that the European Union is today at the very top of the list of the largest importers and exporters of agricultural products in the world. The Common Agricultural Policy has always played an important role in the EU budget. Large funds were allocated for financing agriculture and rural development of the EU (about 43% of the EU budget). The CAP is also the largest expenditure in the EU budget.

The agricultural sector in the Republic of Serbia in the past decades, after all the negative challenges it has faced in the past, has experienced a serious economic downturn and economic crisis. Serbian agriculture has significant comparative advantages due to its strategic position, favorable geographical terrain, favorable climatic conditions, good education of the population, etc. The Republic has large areas of arable land that is of high quality (80% belongs to the good and 20% to a high supply of humus). By implementing the EU agricultural policy and applying its laws in Serbian agriculture, a safe business environment would be created, and the highest level of efficiency and competitiveness would be achieved. There would be an increase in the process of food production and processing, and thus, there would be a recovery and development of the entire economy.

One of the most difficult chapters in the EU accession negotiations, based on the experience of other members so far, is the chapter on agriculture and rural development. The EU's agricultural policy is constantly evolving, quite complicated and subject to constant change. It takes a lot of time and effort, good coordination around policy harmonization. Therefore, the chapter on agriculture should be focused on priorities, ie work on the implementation of all regulations related to the accession of Serbian agricultural policy to the common agricultural policy of the EU.

The Ministry of Agriculture, Forestry and Water Management (MAFWM) has the largest role in the integration and association of agriculture in Serbia and the EU. However, due to the seriousness and scope of work, it is necessary to involve other bodies and institutions in the cooperation.

The agrarian budget as a source of financing for agriculture was established by the Decision on the formation of the agrarian budget, which was adopted at the end of 1995, and practically became an integral part of the state budget in 1996. "The agrarian budget is a joint and consolidated form of state support for agriculture, which is implemented through subsidies for agricultural production" (Miličić et al., 2018).

The Republic Government, at the proposal of the Ministry of Agriculture, Forestry and Water Management and in accordance with the Law on the Budget of the Republic of Serbia, determines the amount of the agrarian budget every year. By analyzing the quantitative data on investments in the agricultural budget in the period from 1996 to 2015, it can be concluded that in the observed period, the average share of agriculture in the total state budget was only 4.8%. The Law on Incentives in Agriculture and Rural Development stipulates that the agrarian budget cannot be less than 5% of the budget of the Republic of Serbia starting from 2014 (MAFWM, 2017).

The term "incentives" in the Law on Incentives in Agriculture and Rural Development is defined as funds provided in the budget of the Republic of Serbia, as well as funds provided from other sources allocated to farms and other persons in accordance with this law in order to achieve agricultural policy goals and rural development policy Živadinović, Milovanović, 2011).

The intention of this law was to directly affect all agricultural producers, who will be motivated to invest in agricultural production by establishing legally regulated standards for transparent use of budget funds, and thus improve production in terms of quantity and quality. In order to plan the production cycle, it is necessary for agricultural producers to be informed in advance about the possibility of subsidizing their production by the state. In this way, the planned volume of production in the next production cycle is significantly influenced, and thus the final offer of final products on the market after the completed production cycle (Pejanović et al., 2011).

This law has achieved a higher level of harmonization with the regulations of the European Union, given that the Republic of Serbia is in the process of joining the European Union and that in accordance with the obligations arising from that process, is working to harmonize its legislation with EU legislation. A higher degree of harmonization of the agrarian policy of the Republic of Serbia with the Common Agricultural Policy of the European Union is being achieved. This law defines the obligation of users to comply with regulations governing environmental quality standards, public health protection, animal and plant health protection, animal welfare protection and protection of agricultural land, which are also requirements that must be met by a farmer in the European Union. would exercise the right to use incentives (MAFWM, 2018).

The agrarian budget of the Republic of Serbia is conceived in accordance with the overall real financial possibilities of the country, and with the assumed macroeconomic parameters for the same year. In difficult economic conditions, where the funds of the agrarian budget are not enough to meet the real needs of domestic agriculture, the Ministry of Agriculture is forced to redefine the priorities of its activities, and at the same time provide basic conditions for achieving strategic goals in the livestock sector. The funds in the limit are distributed by first planning funds for the IPARD program, then for incentives for rural development measures, special incentives and, finally, the remaining funds are directed to direct payments. Of the total funds planned for direct payments, funds for incentives for plant production are planned first, because they can be precisely planned (Pejanović et al., 2013). Then, funds are planned for outstanding obligations from the previous period, and the remaining funds are directed to incentives in animal husbandry. The Law on Agriculture and Rural Development established the Directorate for Agrarian Payments and Article 8 defines its activities. The Law on Ministries defines the competence of the Ministry of Agriculture in creating agricultural policy, and as a direct user of the budget of the Republic of Serbia, it is responsible for the process of planning, providing, implementing and monitoring the effects of realized funds for livestock incentives (Popović, 2014). The budget planning process starts from the Proposal of priority areas of financing, information on the realization of funds for incentives in livestock in the current year and projections of funds for requests submitted in the current year, which will be resolved in the next year. The input parameters in the process of planning the necessary funds for incentives in animal husbandry are: realization from the previous period; the situation in the processing of received requests, the projection of the number of requests that will be submitted by the end of the current year and the necessary funds for them, and the projection of obligations under the requests from the current year that will be transferred to the next year; the total potential of requests that can be processed in one year (Stojanović et al., 2017).

The aim of this paper is to apply modern knowledge and economic measures from the new agricultural and rural economy in order to create a basis for long-term planning of agricultural production by direct beneficiaries of incentives and define new types of incentives, incentive beneficiaries, minimum levels of incentives and conditions of their use.

Material and methods

The subject of research in this paper is the analysis of agricultural policy and created incentive measures in various areas of agricultural production in Serbia. Also, the budget of the Republic of Serbia, the agrarian budget of the Republic of Serbia and the planned and implemented incentive measures in agriculture for the period 2016-2020 will be considered comparatively.

Results and discussion

Funds intended for incentives in agriculture and rural development are determined by the Law on the Budget of the Republic of Serbia for the current year, and are distributed through the Decree on the distribution of incentives in agriculture and rural development for the current year. The financial basis for the implementation of incentives in agriculture and rural development is the Decree on the distribution of incentives in agriculture and rural development for the current year, which defines the amount of funds, types of incentives and maximum amounts per type of incentives for the current year. Detailed conditions and criteria for exercising the right to incentives in agriculture and rural development for certain types of measures are prescribed by the regulations and the Law on Incentives in Agriculture and Rural Development.

Table 1. Share of the agrarian budget in the budget of the Republic of Serbia in the period 2016-2020

Year	Total RS budget (in 1.000.000 dinars)	RS agrarian budget (in 1.000.000 of dinars)	The share of the agricultural budget in the total RS budget (%)
2016	1,659.678	40,466	4,89
2017	1,951.754	43,788	4,80
2018	1,854.185	50.955	4,46
2019	1.246.200	51.700	4,14
2020	1.314.500	40.500	3,08

Source: Work newsletter, Documentation of the Ministry of Agriculture of the Republic of Serbia. Author's calculation

For each budget year, the Government prescribes the amount of funds, types and maximum amounts by type of incentive, in accordance with this law and the law governing the budget of the Republic of Serbia, within 30 days of the law governing the budget of the Republic of Serbia. The amount of funds is determined within the budget of the Ministry of Agriculture, and the Law prescribes that the budget of the Ministry of Agriculture cannot be less than 5% of the budget of the Republic of Serbia for a given year in terms of the law governing the budget system.
The maximum amount by type of incentive depends on: available funds determined by the law governing the budget of the Republic of Serbia, the volume of these funds by type of incentive, the number of beneficiaries and the unit of measure depending on the type of incentive (Karajović et al., 2020). Based on the Law on Budget for 2016, the funds distributed to the Ministry of Agriculture amounted to 40.5 billion dinars, which represented 4.9% of the budget of the Republic of Serbia for 2016. Based on the Law on the Budget of the Republic of Serbia for 2017, the funds distributed to the Ministry of Agriculture amounted to 43.8 billion dinars, which is 3.3 billion dinars more than in 2016. On the other hand, the share of the budget of the Ministry

of Agriculture in the total budget of the Republic of Serbia shows a decreasing trend and in 2017 it amounted to about 4.8%.

Budget funds for agriculture in 2018 amounted to 44.1 billion dinars, which is approximately the level of the previous year (0.7% more), but the trend of decreasing the share of the budget of the Ministry of Agriculture in the national budget, which in 2018 reaches the value of 4.46%.

Budget funds for agriculture in 2019 amounted to 51.7 billion dinars, which is approximately the level of the previous year (0.3% less), but the trend of decreasing the share of the budget of the Ministry of Agriculture in the national budget, which in 2019 reaches the value of 4.14%.

Budget funds for agriculture in 2020 amounted to 40.5 billion dinars, which is approximately the level of the previous year (1.06% less), but the trend of decreasing the share of the budget of the Ministry of Agriculture in the national budget, which in 2020 reaches the value of 3.08%.

Of the total funds allocated by the budget of the Republic of Serbia for the Ministry of Agriculture in 2017, 28.6 billion dinars are planned for incentives in agriculture and rural development, while in 2018, 30.4 billion dinars are planned. The right to incentives have: agricultural holdings and family agricultural holdings that are registered in the Register of Agricultural Holdings, local self-government units, and other persons and organizations (Pešić, 2020). In order to initiate the procedure for exercising the right to incentives, it is necessary for the beneficiary of the incentive to submit a request to the Directorate for Agrarian Payments. Also, the procedure can be initiated through a competition, a request to the bank for approval of credit support, etc. The decision on exercising the right to incentives is made by the director of the Directorate for Agrarian Payments by a decision. The beneficiary of the incentive is obliged to: adhere to the regulations governing environmental quality standards, protection of public health, protection of animal and plant health, protection of animal welfare and protection of agricultural land; acts in the manner and under the conditions provided by a special regulation which regulates certain types of incentives in more detail; provides accurate data and documentation for exercising the right to incentives; purposefully uses incentive funds as well as to purposefully use, not alienate and not enable another person to use the object of incentives, within the period determined in accordance with a special regulation; keeps documentation related to the exercise of the right to incentives for at least five years from the day of their collection; return the paid funds if the obligation from the law is not complied with; return unjustifiably paid funds due to an administrative error; return excess funds in accordance with the law. The National Strategy for Sustainable Development defines development as a long-term and goal-oriented, comprehensive and synergistic process that affects all aspects of life - economic, social, environmental and institutional. Sustainable development is oriented towards the formation of a model that does not have a quality way to meet the socio - economic needs and interests of citizens, while reducing the impact that poses a threat to the environment and natural resources. For these reasons, the Budget of the Republic of Serbia for 2020 will undergo certain changes. These changes will be reflected through an appropriate rebalance of funds that will be directed to agricultural producers, sustainable development and improvement of agricultural production.

The expected amount allocated for agricultural production, after the budget rebalance, will be increased by approximately 1.13%, which is a steady amount that is determined for agricultural producers in the territory of the Republic of Serbia.

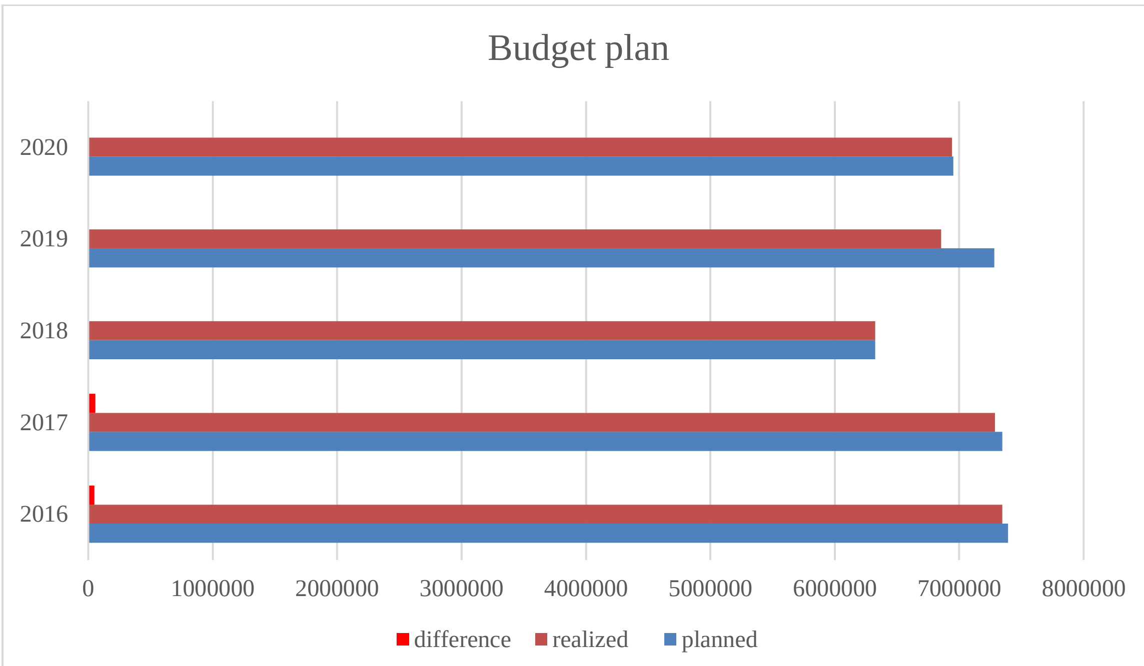
Source: Work newsletter, 2016-2020 year, Ministry of Agriculture (http://uap.gov.rs/wp-content/uploads/2021/03/informator-februar-2021.-god.pdf

In the period 2016-2020, the level of planned funds for incentives in animal husbandry is declining. Based on the data of the Ministry of Agriculture, in the observed three years in 2017, there was a slight decrease in the level of funds compared to 2016, but in 2020 that amount is one billion dinars less than in 2017. In the following years, in 2019 and 2020, the funds for financing livestock production were increased, regardless of the structure of planned and realized funds.

A graphical representation of these assets is shown in Graph 1. Livestock production in the Republic of Serbia is facing numerous problems that result in a decrease in the number of head and a decrease in livestock production.



Graph 1. Incentives in livestock 2016-2020
(Izvor: http://www.minpolj.gov.rs/dokumenti/2021)

Conclusion

In Serbia even today, agriculture provides about 12 percent of the gross value added of agriculture. Natural potentials are insufficiently used and there is still accelerated deagrarization, a high level of senilization of the active agricultural population and a low level of motivation of employees due to low average wages.

In the past period, Serbia has started structural reforms of agricultural policy by implementing various strategies and programs and has made significant steps. Harmonization of the standards of the common agricultural policy and the agrarian policy of Serbia is not only a condition for membership in the EC. Its application would increase production, improve product quality, market competitiveness, increase imports and exports, modernize equipment and introduce new technologies, etc.

Solving the problem of financing has a direct impact on the development of agriculture, observed from the aspects of: primary agricultural production, agriculture in a broader sense, multifunctional agriculture, as well as rural development.
In the current period in the Republic of Serbia, financing the development of all aspects of agriculture, as well as financing rural development, is necessary to be realized with the dominant support of the state. The need for a dominant role of the state is also caused by the underdevelopment of financial markets and financial institutions that would enable greater activation of market mechanisms in the system of financing agriculture. The financial support of the state should be manifested in a larger allocation from the state budget for the agrarian budget, and it is necessary to redefine its structure in order to increase the participation of incentives aimed at rural development.
The agricultural sector is large and very demanding, it brings with it a lot of laws and regulations, the implementation of which takes a lot of time and a large organization. Participation in the reform and harmonization of the standards of the common agricultural policy is not only in the power of the muscles of the Government and the Ministry, but of all those involved in agricultural and rural development and production.

ASSESSING THE IMPACTS OF COVID-19 ON AGRICULTURE FROM THE PERSPECTIVE OF AGRICULTURAL ORGANIZATIONS: A CASE STUDY FROM GÜMÜŞHANE, TURKEY

Nilgün DOĞAN[1]*, Hakan ADANACIOGLU[2]

[1]Gumushane University, Aydın Dogan Vocational School, Kelkit, Gumushane, Turkey

Abstract

The main purpose of this study is to determine the impact of the COVID-19 outbreak on agricultural production from the perspective of agricultural organizations in Gümüşhane province in Turkey. Agricultural organizations in the province include provincial and district agriculture directorates, agricultural credit cooperatives and the chamber of agriculture. The survey was conducted in February and March of 2021. Simple descriptive statistics were used in the analysis of the data. Agricultural change in the research area compared to the period before the COVID-19 outbreak was shown with proportional distributions. Findings show that the COVID-19 outbreak has not had a negative impact on agriculture in many ways in the study area. However, the increase in agricultural input prices during the pandemic period is the most unfavourable situation encountered. As expected during the pandemic period, the demand for crop and animal products increased. However, the supply of agricultural products did not increase at the same level as expected. Another finding from the study is that the COVID-19 outbreak has not reduced the sown area in the region. The reason why producers do not reduce their production areas despite the increase in production costs can be attributed to the increase in agricultural subsidies provided by the government during the pandemic. However, it is important for governments to work on structural reforms in order to overcome the shocks that occur in COVID-19 and similar epidemics.

Keywords: *Agricultural organizations, COVID-19, impact, production, Turkey.*

Introduction

There is no beneficial truth that besides its impact on human health, COVID-19 and the lockdown that was done beginning in March 2020 in an effort to hold its spread have had a major economic impact that has affected whole sectors including the agricultural sector and agricultural market in the world. The Anatolian geography meets the important needs of Turkey with its arable land. The agricultural population in Turkey is quite high and it plays an important role in feeding, rural development and providing raw materials to the industrial sector. The agricultural sector covers 1/4 of the national income. Like many other developing countries, this sector in Turkey is the single largest source of livelihoods. Varshney et al. (2020) stated that the agricultural sector in India accounts for 60% of all rural employment.
According to the Turkish Statistical Institute (TurkStat) data; growth in the agricultural sector was 4.8% in Turkey in 2020. But, as agriculture grew, per capita income fell to 8 thousand 599 dollars, the lowest level in the last 11 years (TurkStat, 2020). During the pandemic; farmers, agricultural workers, food producers, just like healthcare workers have been at work 24 hours a

day. Even if there is a curfew, agricultural production activities continued to be carried in the fields, vineyards, gardens and barns. Yavuz (2020) emphasized that with the COVID-19 outbreak, the strategic importance of the agricultural sector increased and created social awareness in the country. On the other hand, Kayabaşı (2020) pointed out that although there were gradual transitions, those working in both agriculture and industry would be under the risk due to the COVID-19. The impact of the pandemic can manifest itself in the form of agricultural production and yield decrease as well as supply shocks. During the pandemic, stabilizing agricultural production and ensuring farmers' incomes became important tasks for governments (Hai-ying and Chang-wei, 2020). To minimize the impact of the outbreak on agricultural production, Turkey has introduced incentives to encourage farmers to produce.

Some issues need to be addressed regarding the impacts of the outbreak on agriculture: one is to ensure the production and supply and the other is to stabilize farmers' incomes. At this point, it is very vital to analyse its sustainable impacts before and after the pandemic in Turkey, because the Turkish Republic Ministry of Health is still reporting a continuous rise in the number of cases, with the outbreak now spreading to virtually in the country. Although there is an increase in agricultural production according to the data of 2020, the full impact of the outbreak on agriculture is not known in future production periods. The impacts of the outbreak on agriculture is a big risk especially in rural areas in Turkey. For this reason, it is clear that much bigger improvements with the right agricultural policies will cause new developments during the pandemic. No doubt, while COVID-19 is influencing agriculture such as crop harvest, plantation, transportation, marketing of agricultural products, labour mobility, exporting and the food system in the world (Hai-ying and Chand-wei, 2020; Varshney and Meenakshi, 2020; Jambor et al., 2020; Pan et al., 2020; Kayabaşı,2020; Doğan and Doğan, 2020), in Turkey, reaching internal and external input and output markets, lack of temporary labour, changing marketing channels have been the main problems (Ceylan and Özkan, 2020). The main agricultural product in crop production is grain and wheat is the main stable grain. The lockdown and social distancing did not create a significant problem for wheat production because, it was already planted before the outbreak and it can also be harvested by machinery (Ceylan and Özkan, 2020). Nevertheless, the case of the production in fruit and vegetables is different due to the seasonal/migrant labourers. So, urgent measures have affected production of fruit and vegetable. In some periods, there has been permanent lockdown in Turkey and this affected seriously district bazaars. Thus, family farmers have been affected since they sell their products regularly in these bazaars.

As mentioned in the literature above the impacts of this virus in the world and on Turkey's agricultural economy must be taken seriously now and in the near future. The studies relating to the impact of the pandemic on Turkey's agricultural economy are not in detail. These studies give macro data about agricultural products in Turkey and the world. Qualitative analysis or surveys are not used to understand the real problem in the field. Then, the results are similar in the current literature. Moreover, the results do not reflect the situation at a certain point, which can trace the vital impacts of the virus on Turkey's agricultural economy. This study goes beyond these constraints in the literature with the oriented research questions relating to the perspective of agricultural engineers on the impact of COVID-19. We explore COVID-19's impacts on Gümüşhane province which is in the north of Turkey. By providing impacts of COVID-19 on breeding and crop production, makes an appreciable contribution to the public authorities, NGOs, etc. Gümüşhane is a province where most of the sectors cannot exist due to its geographical conditions so livestock has been a source of livelihood for most households for many years. As can be understood from the preliminary study conducted on the province, although the time-honoured tradition of animal production offers potential, it does not currently reach the desired level due to recent problems experienced in the sector. Thus we search the impacts of COVID-19 in light of the ongoing and widespread of the virus in the province. In our paper on the COVID-19 impacts, we have a specific focus on the agricultural production in Gümüşhane through the eyes of the agricultural organizations.

Materials and Methods

Primary data in this study were obtained from Gümüşhane, face-to-face interviews with the agricultural engineers were carried out to collect qualitative and quantitative primary data. Agricultural organizations in the province of Gümüşhane include provincial and district organizations affiliated with the Ministry of Agriculture and Forestry, Agricultural Credit Cooperatives and the Chamber of Agriculture. During the survey, fifteen agricultural engineers were interviewed. The agricultural engineers interviewed consist of the managers of the organizations they work with or the experienced people in these organizations who have information about the agricultural structure of the region. Surveys were conducted in February and March 2021. To address the impacts on the Gümüşhane agriculture, we developed a survey that consists of two parts. In the first part of the survey, we have used the questions which reflect the impact of the pandemic using three criteria ("Increased", "Decreased", and "Unchanged") on the production in the province.

Input and product prices, production cost, demand and supply, amount of production, sown area, number of animals, access to agricultural information and credit opportunities, migration movements, agricultural supports and farmer income are some of these indicators. In the second part, the perceptions of the fifteen agricultural engineers working in the agricultural organisations in Gümüşhane regarding the impact of the COVID-19 outbreak on agriculture were presented. We developed a survey using a 5-point scale, from 1= "strongly disagree" to 5= "strongly agree" and its design followed standard implementation in the field.

Simple descriptive statistics were used in the analysis of the data. Agricultural change in Gümüşhane compared to the period before the COVID-19 outbreak was shown with proportional distributions. In the introductory instructions to the survey, the experts were informed that participation was voluntary, that the information they shared would not be linked to them and that the data would be reported in aggregate form only. These instructions were followed by the first part, which asked participants to what extent they agree regarding the impact of the pandemic. Overall, the content of the survey was designed to capture perceptions regarding their agronomic, breeding, horticulture practices. As it is, we used the spread of the virus (using data on caseloads in each district), as distinct from the lockdown itself, to provide the impacts. So, the agricultural experts' perceptions, concerns and expectations from COVID-19 were based on a merger of access to data, media and other information in Turkish society, as well as their own experiences because of the outbreak.

Results and Discussion

Change in agricultural indicators compared to the period before COVID-19

In this section, the aspect of agricultural change in Gümüşhane compared to the period before the COVID-19 outbreak was analysed with some indicators. In this context, the aspects of the change in main agricultural indicators were presented such as input and product prices, production cost, demand and supply, amount of production, sown area, number of animals, access to agricultural information and credit opportunities, migration movements, agricultural supports and farmer income. The opinions of the agricultural engineers working in the agricultural organisations in the region about the aspect of the change in the agricultural indicators are shown in Table 1. As the table reflects, a significant number of agricultural engineers participating in the survey stated that agricultural input prices had increased compared to the period before the COVID-19 outbreak. All of the participants (100%) stated that fertilizer prices had increased. While the rate of those who stated that the prices of seeds and pesticides increased was 93.3%, this rate was 86.3% for fuel and 93.3% of the participants stated that the prices for feed, which is an important input for animal production, had also increased. At the same time, 86.7% of the participants stated that the cost of energy (electricity) used in irrigation increased. From this standpoint, we can say that in general, the increase in agricultural input prices compared to the period before the COVID-19 outbreak can be considered as a negative change. This has led to an increase in production costs. As a matter of fact, all of the participants said that the cost of both crop and livestock production had increased. As it was found by Pan et al. (2020), COVID-19 had the most significant impact on the livestock after the crop production and they also indicated in their study that the shortage of crop production materials had become one of the main obstacles in agricultural production during the outbreak of this pandemic. It was mentioned in a similar study by Middendorf et al. (2021) that in three farming systems (cropping, livestock, and horticulture) significant majorities expressed concerns, especially related to input prices.

The rate of participants who stated that the demand for crop and animal products increased compared to the period before the COVID-19 outbreak was 60%. The remaining participants reported that the demand had not changed much. It was reported in the study published by Lioutas and Charatsari (2021) that the pandemic experience taught us that the restrictions posed by governments during major crises, in combination with the changing consumers' behaviour, can cause market fluctuations with considerable effects on agri-food production. The situation is slightly different in terms of supply. Varshney et al. (2020) searched the impact of the pandemic by type of commodity and their results point to considerable resilience in agricultural markets in dealing with COVID-19 shock. One case study (Bereir, 2020) found that the restrictions of COVID-19 were hindering the Sudanese farmers especially small-scale farmers in their supply of agricultural products. In our study, the rate of the participants stating that the supply of crop and animal products had increased was 46.7% and 40%, respectively. On the other hand, more than one-third of the participants stated that the supply had fallen. The rise in demand more than supply is a reason for the increase in prices of agricultural products compared to the period before the COVID-19 pandemic. As a matter of fact, 80% of the participants stated that the price of the crop products had increased, and this rate was 85.8% for the animal products.

In considering the access to credit it was seen that there was no negative development. In fact, nearly 50% of the participants stated that access to credit opportunities had increased. More than 50% of the participants stated that there was not much change in terms of access to agricultural information for the farmers compared to the pre-COVID-19 outbreak period.

It can be said that there is a positive development in terms of the sown area. Because 53.3% of the participants stated that the sown area had increased. This can be attributed to the increased agricultural subsidies provided by the government due to COVID-19 restrictions. So that, 73.3% of the participants stated that agricultural supports had increased compared to the period before the COVID-19 outbreak. However, in the study by Kumar et al. (2020), it was emphasized that farmers of high-value commodities had suffered higher losses due to the pandemic in India, so they suggested that supporting SMEs like credit opportunities would help the farmers to survive.

Regarding the amount of the crop production in the study area, 60% of the participants reported that the amount of crop production had increased compared to the period before the COVID-19 pandemic. It can be said that the increase in crop products is mainly due to field crops. As a matter of fact, more than 50% of the participants claimed that there was not much change in the amount of fruit and vegetable production. A different conclusion was found in a study by Hai-ying and Chang-wei (2020) that stated the pandemic had an impact on all stages of the vegetable supply chain in Shanghai. In our study, according to the opinions of the participants, we can say that the rate of increase in the amount of animal production is less than crop production. While 42.9% of the interviewed participants found that the amount of animal production had increased compared to the period before the COVID-19 epidemic, 35.7% of them said that it did not change. The opinion of the participants for milk, red and poultry meat, eggs and honey production is similar to the general average. On the other hand, according to Pu and Zhong (2020) in China, the marketing quantity of agricultural products dropped dramatically during the pandemic.

In terms of productivity, there is no negative development for the crop and animal production in the study area. While 60% of the participants indicated that the productivity in the crop production was increasing, this rate was 50% in the animal production. A similar result was found in Andrieu et al. (2021) in Burkina Faso, France and Colombia. They reported that surveyed crop farmers in rural areas were not affected in their productive activities as in our study. When an evaluation was made in terms of the number of animals in the research area, there was not much change. Only 35.7% of the participants expressed that the number of cattle and small ruminants (sheep and goats) had decreased compared to the period before the COVID-19 outbreak. However, the remaining participants argued that the number of cattle and small ruminants had either increased or had not changed. In terms of the number of poultry and beehives, there was no negative development compared to the period before the COVID-19 outbreak. Conversely in the study of Seleiman et al. (2020) was stated that livestock farmers already suffer from a shortage of labour concerning both farms and packing plants, since animals need to be fed daily and the production cycle is short for some animals.

One of the most curious issues in the period before the COVID-19 pandemic is migration movements. A more positive development had been experienced in terms of the migration movements compared to the pre-pandemic period. 60% of the participants remarked that the reverse migration from the city to the rural areas had increased, and 40% pointed out that there had been no change. On the other hand, 40% of the participants said that the migration from the rural areas to the city decreased compared to the period before the COVID-19 outbreak, and 53.3% reported that it did not change. The findings of this research also partially confirm this. A similar finding was stated in the study by Kayabaşı (2020) that less prevalence of the pandemic in rural areas would further increase migration to rural areas. What kind of change occurred in terms of the farmer income compared to the period before the COVID-19 pandemic was another curious issue. In print and social media, statements about the decrease in the income of the farmers are frequently encountered in this period. 40% of the participants stated that the income of the farmers decreased, 26.7% of them reported that it did not change. The rate of participants who stated that the income of the farmers increased compared to the period before the COVID-19 outbreak was 33.3%.

Table 1. The opinions of the agricultural engineers on the change in agricultural indicators compared to the period before COVID-19

Agricultural indicators	Increased (%)	Decreased (%)	Not changed (%)
Seed prices	93.3	-	6.7
Fertilizer prices	100.0	-	-
Agricultural pesticide prices	93.3	-	6.7
Petrol prices	86.7	-	13.3
Water prices	40.0	6.7	53.3
Cost of energy (electricity) used in irrigation	86.7	6.7	6.7
Feed prices	93.3	6.7	-
Crop production cost	100.0	-	-
Animal production cost	100.0	-	-
Demand for crop products on the market	60.0	-	40.0
Demand for animal products on the market	60.0	13.3	26.7
Amount of crop products supplied	46.7	33.3	20.0
Amount of animal products supplied to the market	40.0	33.3	26.7
Crop product prices on the market	80.0	13.3	6.7
Animal product prices on the market	85.8	7.1	7.1
Access to credit	46.7	6.6	46.7
Access to agricultural information	20.0	26.7	53.3
Sown area	53.3	20.0	26.7
Number of crop products produced	33.3	13.3	53.4
Total amount of crop production	60.0	20.0	20.0
Field crops production amount	60.0	20.0	20.0
Fruit production amount	20.0	13.3	66.7
Vegetable production amount	33.3	13.3	53.4
Overall productivity in crop production	60.0	13.3	26.7
Total amount of animal production	42.9	21.4	35.7
Milk production	35.7	21.4	42.9
Red meat production	35.7	14.3	50.0
White meat production	45.5	9.0	45.5
Egg production	35.7	7.1	57.2
Honey production	30.8	15.4	53.8
Overall efficiency in animal production	50.0	21.4	28.6
Number of cattle	35.7	35.7	28.6
Number of small ruminants	50.0	35.7	14.3
Number of poultry	38.5	23.0	38.5
Number of beehives	23.1	23.1	53.8
Reverse migration from urban to rural areas	60.0	-	40.0
Urban migration from rural areas	6.7	40.0	53.3
Agricultural supports	73.3	6.7	20.0
Farmer Income	33.3	40.0	26.7

Perceptions on the agricultural impact of the COVID-19

In this section, the perceptions of the agricultural engineers in the region regarding the impact of the COVID-19 outbreak on agriculture were presented. In this context, various proposals were directed to the participants. Likert scale averages of the responses to the proposals are shown in Table 2. The perceptual responses of the participants to the proposals confirm their views in the previous section. As it was indicated in the previous section, the participants were asked about the absolute direction of the agricultural change in Gümüşhane. In this section, perceptual expressions are included. According to the findings in Table 2, the proposals that most of the participants agree with the increase in input prices. It was understood that the participants mostly agreed with the proposals that "prices of agricultural pesticides and animal feed have increased", followed by the propositions about the increase in fertilizer and seed prices, respectively. Participants underlined that they strongly agreed with the proposals regarding the increase in the cost of agricultural production due to the COVID-19 outbreak.

It can be said that the participants agree with the proposal that "there has been immigration from the city to rural areas" significantly. In the previous section, it was stated by the participants that the reverse migration from urban to rural areas had increased in the region. It is possible to say that the participants agree, but do not strongly agree, with the proposal regarding the increase in agricultural subsidies compared to the period before the COVID-19 outbreak. As it was indicated in the previous section, more than 70% of the participants stated that agricultural subsidies were increased. Participants were undecided about the decline in income of farmers compared to the period before the COVID-19 pandemic. This result is consistent with the findings in Table 1. Compared to the pre-COVID-19 outbreak, it was seen that the participants had an undecided attitude in their proposal regarding the increase in the cost of energy (electricity) used in irrigation and fuel prices. However, according to the findings in Table 1, a significant majority of the participants stated that both the cost of energy used in irrigation and fuel prices increased. Participants have been in an undecided attitude regarding the COVID-19 outbreak causing problems in finding workforce, access to agricultural information, and transportation of products to market places after harvest, product storage, and the number of small ruminants. As it was found in the research of Cariappa et al. (2021), the pandemic-induced lockdown exacerbated food loss at production, marketing, distribution and wastage on the Indian agricultural system. On the other hand, according to the perceptions of the participants; the COVID-19 outbreak did not pose a significant problem in terms of planting and harvesting times, access to credit opportunities, the number of beehives, animal and plant product prices, migration from rural areas to cities, demand for animal and plant products and the amount of plant products supplied to the market.

Table 2. Perceptions of agricultural engineers in agricultural organizations about the impact of the COVID-19 outbreak on agriculture

Statement	Mean	SD
Agricultural medicine prices increased	4.13	1.3558
Animal feed prices increased	4.07	1.3870
Production cost increased	4.00	1.3628
Fertilizer prices increased	3.93	1.4376
Seed prices increased	3.87	1.5523
Urban migration to rural areas happened	3.60	1.3522
Agricultural supports increased	3.40	1.2421
Farmers' income decreased	3.27	1.2799
Cost of energy (electricity) used in irrigation has increased	3.20	1.4243
Fuel prices increased	3.13	1.4075
There were problems in finding workforce	2.93	1.3848
Producers had problems in accessing agricultural information	2.93	1.5796
Problems occurred in transporting products to market places after harvest	2.87	1.5055
There were problems with product storage	2.67	1.4960
Number of cattle decreased	2.64	1.6919
Number of small ruminants decreased	2.57	1.6968

Quality seed has become harder to find	2.43	1.2839
Problems occurred in fertilizer supply	2.43	1.4525
Agricultural areas decreased	2.40	1.4541
Problems occurred in procurement of agricultural pesticides	2.36	1.3927
Number of poultry decreased	2.36	1.7805
Productivity fell in animal production	2.21	1.6257
Productivity fell in crop production	2.14	1.4601
Amount of animal products supplied to the market decreased	2.13	1.3020
Farmers changed their production pattern during the pandemic period	2.13	0.8338
Animal production decreased compared to the pre-pandemic period	2.13	1.5976
Water prices increased	2.07	1.4376
Crop production decreased compared to the pre-pandemic period	2.07	1.5796
Problems in accessing water resources for irrigation	2.00	1.4142
Sowing or planting delayed	1.93	1.2688
There was a delay in the harvest	1.93	1.1411
Access to credit facilities decreased	1.93	1.2799
Number of beehives decreased	1.93	1.5424
Animal products prices fell in the market	1.87	1.3558
Crop product prices fell in the market	1.73	1.3345
Rural to urban migration ??	1.73	1.4376
Demand for animal products fell in the market	1.60	0.9856
Demand for herbal products fell in the market	1.53	0.9155
Amount of crop products supplied to the market decreased	1.53	0.9155

Mean: mean score of likert scale (1: Strongly Disagree - 5: Strongly Agree); SD: standard deviation

Conclusions

This study was carried out to determine the impacts of COVID-19 on agricultural production in Gümüşhane province in Turkey and also compared to the pre-pandemic period. Findings show that the COVID-19 outbreak has not had a negative impact on agriculture in many ways. However, the increase in agricultural input prices during the pandemic period is the most unfavourable situation encountered. Restrictions during the epidemic period have a significant effect on the increase in agricultural input prices. Thus, this rise increased the cost of farmers. As expected during the pandemic period, the demand for the crop and animal products has increased. However, the supply of agricultural products did not increase at the same level as expected. This has contributed to the increase in prices of agricultural products.
COVID-19 outbreak did not reduce agricultural production area in the region. The reason why producers do not reduce their production areas despite the increase in production costs can be explained by the increase in agricultural subsidies provided by the government. This shows that the shocks that occur in COVID-19 and similar epidemics can be prevented with government support. However, it is controversial that government support can be a sustainable solution. Not every country in the world has a strong budget to afford such epidemics. The World Health Organization (WHO) points out that there may be a hunger problem in many countries in the coming period. For this reason, it is important for governments to work on structural reforms in order to overcome the shocks that occur in COVID-19 and similar epidemics.

Acknowledgement

We would like to thank Provincial and District Directorates of the Ministry of Agriculture and Forestry for their valuable help to gather the data of this study.

INVOLVEMENT OF FARMERS IN LOCAL PARTNERSHIPS: STUDY OF LOCAL ACTION GROUPS STRUCTURE IN THE CZECH REPUBLIC

Ondřej KONEČNÝ*, Pavla SADLOŇOVÁ, Zdeněk ŠILHAN, Marie JÍLKOVÁ

Department of Regional Development, Mendel University in Brno, Brno, the Czech Republic
*Corresponding author: ondrej.konecny@mendelu.cz

Abstract

The contribution aims to evaluate the importance and role of farmers in 78 local action groups (LAGs) in the Czech Republic. The LAGs have gradually established themselves as important players in the EU's rural development. Therefore, it is a question of how active the farmers are in these local partnerships. Farmers represent one group of actors (non-profit organizations, municipalities, schools, non-agricultural entrepreneurs), which create the LAG. The research is based on the analysis of the created database of LAG partners (3,960 entities) (1) and the database of supported projects in LAGs in the period 2007-2013 (2). The database of LAG partners contains information on: sector of the partners, role in the LAG or localization. The database of projects supported by the LAG contains information about the applicant, the aim of the project, the focus and priority of the support. The results show that 61-70% of the partners of all LAGs are members of a private sector (including agriculture). Behind representatives of municipalities, farmers are the second most frequently represented group, as they accounted for between 12 to 23% of LAG partners. However, decision-making powers are most often held by representatives of the public sector. Supported projects (2007-2013) of LAG partners were most often implemented by the private non-profit sector (45%). Farmers, together with other entrepreneurs who were partners of the LAG, were also significantly supported (40% of projects).

Keywords: *Farmers, Local Action Group, Rural Development, Community-Led Local Development, Partnership Structure.*

Introduction

Local Action Groups (LAGs) are well-established institutions in local development, composed of public and private sector partners. This private sector can be further subdivided into the non-profit, business, and private sectors. And it is often farmers who are part of this sector. The initial involvement of farmers in LAGs in the Czech Republic was examined by Delín (2012). Research focusing on the partnership structure of LAGs is then primarily oriented towards the involvement of the partners in the board and the relationships between them (Thuesen, 2010; Zajda, 2014; Patkós, 2018).

Local partnership is one of the principles of the LEADER method (*Liaison Entre Actions de Développement de l'économie Rurale*). Therefore, the development of the territory should be addressed by the LAG based on the principle of endogenous development and so-called bottom-up approach, whereby it is an effort to activate the local potential of the territory through local actors. As many studies reveal, the implementation of bottom-up principles is often very limited (Hudečková and Balzerová, 2010; Chevalier and Maurel, 2013; Konečný *et al.*, 2021). The motivation of local actors to be part of partnerships is sometimes criticised, as Pátkos (2018, p.

97) shows in the example of Hungary: *"Action groups were motivated to involve as many actors as possible since the amount of subsidy mostly depended on the size"*.
Getting support from the LAG is very important for many actors in the LAG and the distribution of support is a key role for many LAGs (Binek *et al.*, 2020). Therefore, the topic of LAG support for local projects is widely represented in the literature (Lošťák and Hudečková, 2010; Volk and Bojnec, 2014). As farmers are an important target group of LAG support for rural development, their involvement in partnerships is welcome (Furmankiewicz, Thompson and Zielin, 2010; Volk and Bojnec, 2014).
We want to ask how different types of partners are involved in LAGs and what role they play here. For this paper, we want to consider the role of farmers. The main objective of the paper is therefore to assess the current structure of LAG partners and to uncover the representation of different types of partners in LAGs and decision-making bodies, with an emphasis on the role of farmers. A sub-objective is to reveal the influence of the partnership structure of LAGs in supporting projects in the 2007-2013 programming period. We are therefore interested in the extent to which active and successful farmers are among the supported applicants among the LAG partners.

Materials and Methods

The data needed for the key analyses of the partnership structure of 78 Local Action Groups (as of 2020) from five selected regions of the Czech Republic (South Moravian, Moravian-Silesian, Olomouc, Pardubice and Zlín regions) were collected individually from the websites of the Local Action Groups and their mandatory published information. It was drawn both from the traceable information on the websites and from the annual reports or minutes of the meetings of the LAGs' bodies. In total, a database of 3,690 LAG partners was created containing the following information:

- Name of partner.
- Legislative form.
- Sector (public sector and private sector (further subdivided into non-profit, business and individuals)).
- Role in the LAG (participation in the LAG bodies (an audit committee, a selection committee, or a board)
- Interest group/topic of focus (primarily identified agriculture).

We were also interested in who is the chairperson of the decision-making body (committee/council) of the LAG. Identification was made for 75 out of 78 LAGs. It was possible to classify partners by interest group/theme of focus for 2,312 partners (63% of partners).
We further assessed the importance of farmers in the partnership structure according to their representation among successful applicants of projects funded through the LAG. Therefore, we had to link the partner database of selected LAGs (11 LAGs) with the database of projects supported by Local Action Groups in the 2007-2013 programming period (it contained 854 projects). The databases were linked through the organisation identification numbers (IČO) of the partners. In terms of interpretation of the results, it should be noted that we are fully aware that the actual number of identified partner projects varied to some extent. This is because the project support is related to the partnership structure of the LAG in 2020 (we do not have the partnership structure from 2013 and it is not possible to find out additionally). However, we know from partial research that the partnership structure changes only gradually over time and

rather there is a slight increase in the number of partners (Binek *et al.*, 2020). Sadloňová (2021) published comprehensive research on the issue.

Results and Discussion

LAG partnership structure

A higher proportion of private sector partners in the LAG is expected, as it is already specified in the LAG standards that the number of public sector partners in the LAG must not exceed 49%. However, the rules over time in different EU countries vary (Thuesen, 2011; Chevalier, 2012). In all analysed regions, the dominance of private sector LAG partners was evident, accounting for between 60-70% of LAG partners in the study areas. This means that the average representation of the public sector is comparable to the situation in Hungary (Pátkos, 2018).
However, the composition of the private sector in LAGs varies across the regions studied. In three regions (Olomouc, Pardubice and South Moravian Region) it is possible to see a significant share of the private non-profit sector. However, the business sector, also represented by farmers, accounted for at least one-third of the private sector (35-49%). Individuals who are not representatives of non-profit organizations or in business have the smallest share of representation in all regions. Although these are lower proportions of representation of individuals in the LAG membership base, it means that the individuals are interested in influencing the development of the area in which they live. Based on the additional information, which we know for the 2,312 partners (63%), farmers are very common representatives of the private business sector. They accounted for 12-23% of LAG partners in the regions analysed.
The average number of LAG partners in each sector in the regions shows slight differences between the formed LAG partnerships. Representatives of the public sector had the largest average number of partners (13-24 partners), while the non-profit sector had on average between 11-21 partners in LAGs in each region. The number of entrepreneurs and among them, farmers in LAG partnerships was lower (11-15). Czech LAGs are much smaller in terms of the average number of partners than e.g. in Hungary (Pátkos, 2018).
However, the key information is to find out how active the partners are in the LAG bodies, as by serving in them they have the greatest opportunity to influence the functioning and direction of the LAG (Thuesen, 2010). Zajda (2014) show that there can be considerable mistrust between private and public sector representatives, which affects the functioning of LAGs. Of the 3,690 LAG partners in the analysed regions, 1,395 (38%) are part of the LAG bodies: the council/committee, the control committee, and the selection committee. These are mandatory bodies whose organisational structure must be published on the LAG website according to the standards.
The LAG partners are expectedly represented in the bodies mostly from the private sector, except for the Zlín Region, the largest share of partners is from the private non-profit sector. For the only Zlín Region, the private business sector dominates the private sector in the LAG bodies. Partners from the public sector were represented in the bodies between 32-42%. Their representation is thus slightly higher than could be inferred from their representation within the overall partnership. From this perspective, we can say that the risk of public sector dominance highlighted by Pollermann et al. (2013) has been minimised.
Public sector representatives play an even greater role in the role of LAG leaders. In all regions, at least half of the LAG chairpersons were representatives of the public sector, predominantly municipal representatives (mayors). They were chairpersons in 54-75% of LAGs in each region.

Thus, we confirmed the findings of other studies (Furmankiewicz et al., 2010; Marquardt et al., 2012; Chevalier and Maurel, 2013) that show the key role of this sector in the decision-making functions of LAGs. The reason for this lies in:

- Efforts to control financial flows and support local projects (1) (Furmankiewicz et al., 2010).
- historical inertia, as municipal representatives were the most frequent initiators of the establishment of LAGs (2) (Pátkos, 2018), and,
- the natural roles of sectors/actors in the region, as for mayors, concern for the development of municipalities is an integral and key role in their performance (3).

On the other hand, Thuesen (2010), who examined the composition of 55 Danish LAGs, showed that there was no predominance of the public sector on the boards (14% of the partners in this body were from the public sector).

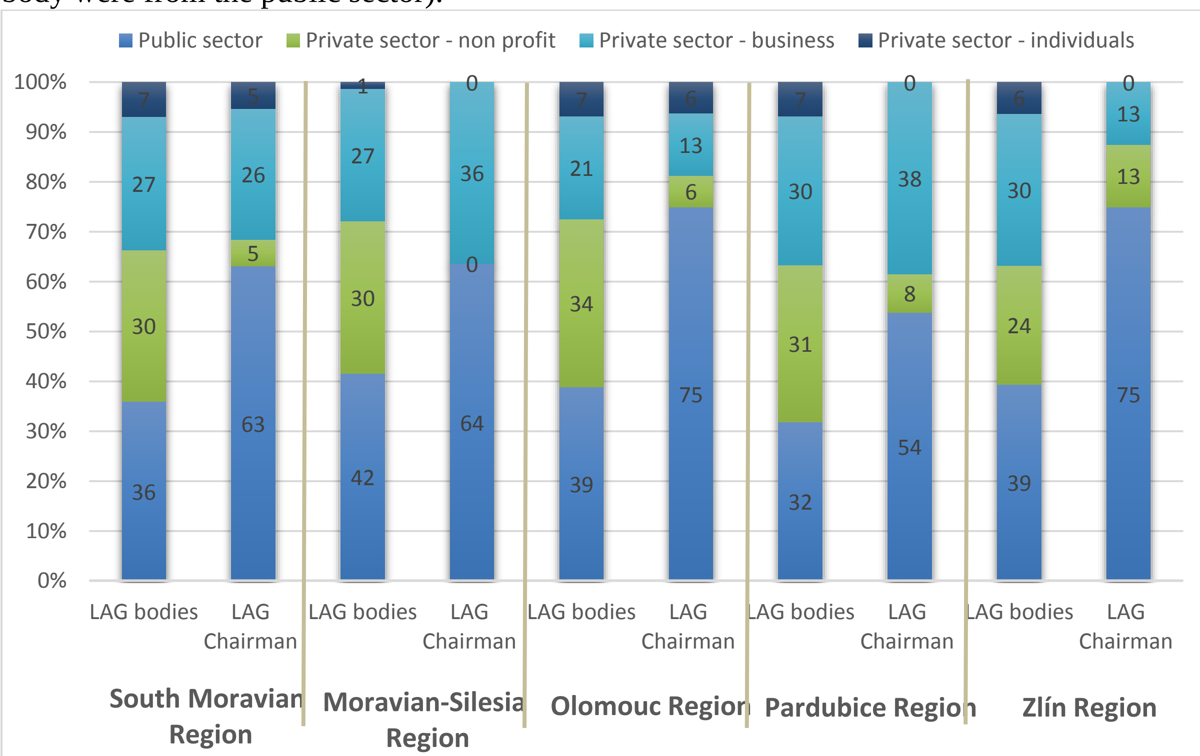

Figure 1. Representation of selected types of partners in bodies of LAGs and among the chairmen of LAGs in selected Czech regions

Source: Author's elaboration based on the created database.

The results showed that the second most frequent representatives as chairpersons were entrepreneurs. Compared to their representation within partnerships or bodies, their role as chairs is much greater. In 13-39% of the LAGs surveyed, entrepreneurs were the chairperson of the LAG executive body. However, in only five LAGs out of 75, we identified that they were farmers. Thus, we confirmed the persistence of the trend of weaker representation of farmers in key roles and support of LAGs in the Czech Republic, as previously pointed out by Lošťák and Hudečková (2010) or Delín (2012), given the influence they have in other countries, such as Italy or Spain (Chevalier, 2012).

LAG supported projects

We want to evaluate the role of farmers in the LAG not only based on their representation in the LAG, its bodies and decision-making functions. We will focus on the projects supported through the LAG in the period 2007-2013 and look at how successful farmers were among the applicants from among the LAG partners. It should be noted that the LAG supports not only projects of LAG partners, but also individual applicants outside the partnership structure who are within the territorial scope of the LAG. There were significant differences between the 11 LAGs surveyed in the total amount they could use to support local applicants (a total amount of EUR 0.8-3.6 million). In total, the LAGs supported 854 projects with a total of EUR 25.5 million in total project expenditure (of which EUR 14.3 million in subsidies).

Among the successful applicants for projects supported through LAGs, actors outside the LAG partners were significantly predominant, accounting for 77% of applicants and their projects accounted for 4/5 of the total expenditure of supported projects. In terms of differences across LAGs, the share of LAG partners in supported projects ranged between 7-37% and between 4-58% of total project expenditure.

If we focus on the 172 supported projects of the 11 LAG, the largest representation is of applicants-partners from the non-profit private sector (47%). The private business sector was on average 41% represented. Although public sector representatives are very important in the structure of LAG partners, representation in the decision-making bodies and leaders of the LAG, they accounted for only 9% of the projects. It should be added that the actual dimension of municipalities as applicants is much larger, as municipalities are often part of the LAG partnership structure as part of a micro-region (institution) but apply for projects independently. Therefore, they are not found in the results. This is a common practice, which is often required by LAGs themselves to meet the prescribed quota of a maximum of 49% public sector representation within the partnership (Binek *et al.*, 2021). For example, even thirty municipalities can be represented in a LAG through one micro-region that has one representative in the partnership. Micro-regions are an important part of LAGs, as studies from different countries show (Hudečková and Balzerová, 2010; Marquardt et al., 2012).

A review of the overall spectrum of applicants clearly shows that municipalities were very dominant among applicants outside the LAG partners. Supported municipal projects accounted for 42% of all projects outside the LAG partners. In all LAGs, it was at least 30% and in three LAGs more than half of the LAG projects were supported by municipalities. Using Slovenia as an example, Volk and Bojnec (2014, p. 368) showed that *"in the years 2008 and 2009, the final beneficiaries in 58% of all projects approved for co-financing with the LEADER funds were from the public sector, 27% of the final beneficiaries were civil societies and only 15% of the final beneficiaries came from the private sector"*.

The importance of farmers among the successful applicants among the LAG partners can be inferred by knowing the distribution of partners within the interest groups/theme of focus that the LAG partners represent and the project name. We assume that the projects of these partners will themselves be linked to the interest group to which the partner belongs. The largest number of projects of the partners of the analysed LAGs can be seen in the interest group Agriculture and Environment, with 58 out of 172 projects (one-third of the projects). It is the relative success of farmers and the good absorption capacity of the territory in supporting agriculture that was reflected in the 2014-2020 period, as almost every LAG included support for agricultural entrepreneurship in its strategies (Konečný et al., 2021).

The results show the surprising finding that in most cases projects of partners without any official role in LAGs (not represented in the LAG bodies - control committee, selection committee or committee/council) were supported. The proportions of these partners with supported projects ranged between 38-90% in the LAGs addressed. Only eight projects were implemented by partners belonging to a committee/council (5% of partners' projects).

Conclusion

The results of a study of 78 LAGs in five Czech regions show that farmers are an important part of local partnerships. The business sector, also represented by farmers, accounted for at least one-third of the private sector in all regions (35-49%). On average, one to two LAG partners out of ten were directly farmers. The private sector accounted for at least one-fifth of the representatives in the LAG bodies in the regions. However, key positions in the LAG are held by the public sector and this is most evident in the LAG committee/council chair. Indeed, the public sector partner was chairperson in 54-75% of LAGs in each region. The second most common representatives among the chairpersons are entrepreneurs, as the non-profit sector holds few of these positions. However, farmers at the head of LAGs are very rare (only in 5 LAGs).

Even so, farmers can be very active in terms of subsidy support for projects for their activities. The claim can be supported by the fact that about one-third of the partner projects supported by the LAG were implemented by farmers. Farmers were an important group of beneficiaries targeted by LEADER support under the 2007-2013 rural development program (RDP). In conclusion, however, it should be said that although municipalities were insignificant applicants among the LAG partners (only 9%), projects of municipalities as non-partners of the LAG prevailed. They accounted for 42% of all non-LAG partner projects.

Abstract

Bioeconomy is becoming increasingly one of the most popular topics on the agenda of policy and research worldwide. Its importance has been demonstrated by the immediate strategic goals and resources that have been provided to finance its implementation at international, regional, and local levels. Our planet faces great environmental, social, and economic challenges. The livestock sector is a fundamental element of the global economy as it maintains and supports the economy of urban and marginal areas. Meanwhile, it supports human demands for food, clothing, numerous other essential products for human survival, and contributes to the recycling of nutrients, and enhances biodiversity and resource sustainability. This paper provides a thorough review of the scientific literature on the bioeconomy of livestock production. By means of bibliometric network analysis (i.e. software VOSviewer), 550 relevant documents were identified in publications between 2004 and 2021 and used in the analysis. This research visualizes the strongest links with bioeconomy with emphasis on livestock production, main research domains, most influential countries, as well as research collaborations among countries and organizations. Among the findings of this research, 5 keywords with the highest frequency during 2020 were identified. These outcomes would be useful for understanding the latest development of global research about the bioeconomy in the livestock sector and guiding future research in this subject.

Keywords: *Bioeconomy, livestock production, bibliometric analysis, VOSviewer.*

Introduction

The world's population is expected to exceed 9.7 billion by 2050 and 11.2 billion by 2100 (United Nations, 2015). This increase in population combined with the emergence of the COVID-19 disease, has led to a worsening of global food insecurity (Kusmayadi et al., 2021). There are three big challenges that the humanity is facing today in relation to the future of our planet: (a) reducing dependence on fossil fuels, (b) mitigating the effects of climate change, and (c) achieving a sustainable, adequate and safe food chain (Papadopoulou et al., 2018). To overcome these challenges, bioeconomy has to play a key role for the reconciliation of the environmental and social difficulties and the enhancement of the economic development within the primary and secondary production sectors (D'Amato et al., 2020). Bioeconomy is based on the use of research and innovation in the biological sciences to create economic activity and benefits for the society (Staffas et al., 2013). Focusing on the agri-food sector, by 2050 food production will have to increase by 50% to meet demand from the growing global population (Rodias et al., 2021). Intensified global food production contributes to the greenhouse gas emissions and utilizes large amounts of natural resources and contributes to the loss of biodiversity, given the fact that it is based on monocultures and aims for high yields (Benton et al., 2021). While livestock production also contributes to these aspects, there is undoubtedly many sustainable ways to mitigate its negative effects, including the use of agro-ecological approaches, adoption of principles of organic farming, modern technology and increased circularity (Mbow et al., 2019). The aim of bioeconomy practices for agriculture includes: a) minimizing the use of primary natural resources (such as water and energy) throughout cultivation and animal production, b) minimizing polluting activities and unsustainable practices (such as the use of synthetic fertilizers and unsustainable use of chemicals), and c) recycling, transformation and reuse of agricultural waste for the production of bioenergy, nutrients and bio-fertilizers (Rodias et al., 2021). In this context, a transition from a fossil-based economy to a circular bioeconomy is the way to secure a sustainable future (Tsimitri et al., 2018).

Although the importance of the bioeconomy has been recognized worldwide, in Greece it has not yet received the appropriate attention. This is evidenced by the complete lack of an implemented national strategy for bioeconomy, despite the fact that the Greek government seems to recognize the need for resource efficiency and low carbon emissions (Papadopoulou et al., 2018). The agri-food sector in Greece is one of the most important sectors in exports, with a strong presence in Europe and a growing presence in the American food markets (BRIDGES, 2017). The livestock production sector in Greece is one of the two main sectors of primary production and represents about 25% of the total gross agricultural production of Greece (Zervas et al., 2015).

Given its location, the formation of the landscape, the rich water resources and the vast coastline, Greece has considerable prospects to develop an economy based on agro-ecological approaches for sustainable food production and agri-tourism. Indeed, there is an enormous potential of the agricultural sector for development and Greece can claim a significant role in the development of the bioeconomy both in local and European level. Bioeconomy is the central theme of the 21st century which will ensure the prosperity of our planet.

One of the most critical methodologies which are widely used to show the research development in a field concerned is the literature review (Zhang & Yuan, 2019). The objective of this paper is to visualize the definition of bioeconomy towards livestock production, through the bibliometric networks of international scientific literature.

Materials and Methods

The bibliometric analysis is defined as the process of identifying, analyzing and measuring the scientific productivity of individuals, groups, institutions and countries on a specific topic (Konstantinis et al., 2018). For the purpose of this study, bibliometric analysis was performed using VOSviewer version 1.6.16 (Van Eck & Waltman, 2014). The VOSviewer software was developed by Van Eck and Waltman (2014) for the creation, visualization, and exploration of maps based on the bibliometric network data (Biancolillo et al., 2020).

The literature review was made with the aim of analyzing peer-reviewed publications (books, book chapters, articles, and papers published in conference proceedings) concerning the livestock production bioeconomy issue. The peer-reviewed publications were retrieved from the Scopus database (https://www.scopus.com) on May 29th 2021 using *("animal production" OR "livestock production") AND bioeconomy* as the search keyword. This search keyword was selected, firstly because there wasn't any other literature on this subject and secondly, both terms "animal production" and "livestock production" are used in literature, so they were both included as keywords. This keyword was searched in all fields of the publications. The time frame was set from 2004 to 2021 (May 29th). All the data were exported as "comma-separated values" (csv) files and processed through a bibliometric network analysis using the VOSviewer software.

Results and discussion

Comprehensive search in the Scopus database on the bioeconomy of the livestock production resulted in 550 publications. There is a notable, almost linear increase, in scientific publications on bioeconomy from year 2014 onwards, achieving the highest peak in year 2019 for about 150 publications (Figure 1).

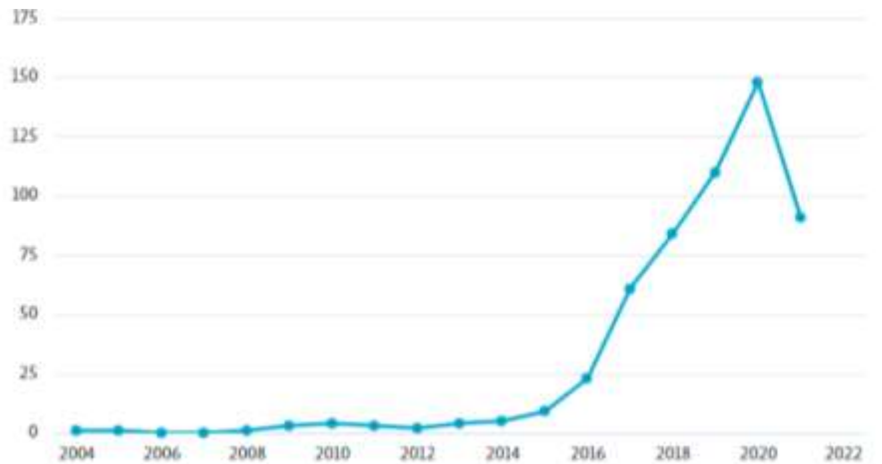

Figure 1. Scopus publications on the livestock production bioeconomy at the international level (2004-2021)

These publications, based on their research area that deal with can be categorized as follows: a) agriculture and biological sciences (288 papers, 26.8%), b) environmental science (193 papers, 18.0%), and c) veterinary (113 papers, 10.5%). Although the bioeconomy of the livestock production has attracted an international interest, the intensity of the research seems to vary among countries. It is therefore important to demonstrate its distribution to research globally through an analysis of papers published in different countries. This can also serve as an indicator to imply the demand of more studies in the regions concerned. It is easily observed that Poland, Germany, Norway and Italy are the most active countries with 151, 91, 84 and 62 papers, respectively (Figure 2). Similar research on the bioeconomy of the livestock production in Greece seems to be less frequent, as currently there are only 6 scientific publications available. Based on the inter-connections among different countries, this proves that cooperation is prevailing in Europe when research is conducted.

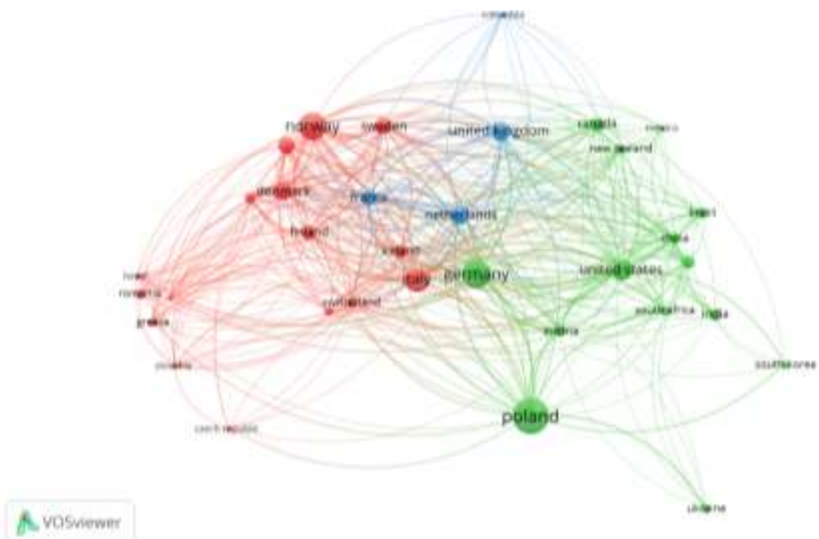

Figure 2. Network demonstration of main countries in livestock production bioeconomy research (Minimum number of documents of a country: 5)

The number of publications produced within the period 2004-2021 on the bioeconomy of the livestock production is derived from 160 research organizations (universities and research institutes). Specifically, the 5 most productive organisations are the University of Life Sciences in Lublin, Poland (112 documents), The Norwegian Institute of Bioeconomy Research (67 documents), Leibniz Institute for Agricultural Engineering and Bioeconomy in Potsdam, Germany (46 documents), Wageningen University & Research in the Netherlands (33 documents) and Norwegian University of Life Sciences (28 documents).

According to Zhang & Yuan (2019), keywords are used to identify the aspect/topic of each paper and are useful for readers to comprehend the researching contexts. Author keywords in our research sample were also explored and analyzed by using the VOSviewer software to demonstrate the keywords with a high frequency as well as keyword relationships. The analysis of the keywords generated 2,003 results. However, only 54 keywords have at least five co-occurrences. The most important keywords are bioeconomy (1.20%), agriculture (1.10%) and sustainability (1.10%) (Table 1).

Table 1. Top ten keywords related to the livestock production bioeconomy

Keyword	Occurrences	Frequencies (%)	Total link strength	Links
Bioeconomy	24	1.20	28	15
Agriculture	22	1.10	26	16
Sustainability	22	1.10	38	25
Anaerobic digestion	11	0.55	8	7
Circular economy	11	0.55	16	9
Climate change	11	0.55	16	10
Biomass	10	0.50	11	8
Dairy cow	10	0.50	4	4
Microalgae	10	0.50	11	10
Bioenergy	9	0.45	11	8

It is also very interesting to find out the development of high-frequency keywords in the past decades, which will help researchers to understand the main trends in this research topic. The co-occurrence network map of keywords related to the livestock production bioeconomy (Figure 3) shows the 51 most used keywords. The size of the circle is relative to the co-occurrence of that item, the shorter the distance is among the items, the stronger their relation is. The color of the circle shows the happened time slot. Keywords with lighter colors are highlighted more recent. It is easily observed that researches started to pay more attention to the terms "sustainability" and "bioeconomy" from 2019. The three red arrows show the lighter areas with 5 keywords, "air pollution", "waste management", "biorefinery", "manure", "circular economy". Those have the highest frequency among all the keywords analyzed in our research during 2020, indicating the new focusing directions in livestock production bioeconomy research.

Figure 3. The overlay visualization map of high-frequency keywords in livestock production bioeconomy research (Minimum number of occurrences of a keyword: 5)

Conclusion

This study presents publications that deal with the bioeconomy of the livestock production sector, through a bibliometric network analysis. The main advantage of this method is that it is capable to analyze the multidimensional nature of bioeconomy through a large literature database. On the other hand, the main disadvantage lies with the fact that some publications may be missing in our study because they do not precisely use our search keywords. Furthermore, the publications analyzed with this method do not include literature such as working papers, Masters' and Bachelors' thesis, project reports and deliverables.

During the last decades, publications on the research area of bioeconomy have increased rapidly confirming that both research community and international policies have recognized bioeconomy as an important activity for the production of goods, services, and energy and as one of the main solutions towards sustainable economic growth of the livestock sector. This paper summarized the main research topics in livestock production bioeconomy and revealed the most important keywords that can be the new directions in livestock production bioeconomy research. However, it revealed limited studies and projects that will be able to support and diffuse the bioeconomy development with particular focus on Greece. It is necessary to further intensify research towards this direction and attempt a deeper content analysis in the future on the bioeconomy of the livestock production. From the political side, new legislation and national policies are needed to address challenges that the livestock production sector is going to encounter, protect national resources and introduce efficient waste management. Finally, we suggest that policy directions in Greece should encourage multi-disciplinary programs, innovation and knowledge developments, to provide skilled experts in the field of the livestock production and its associations with bioeconomy. This may contribute to addressing the acceptability and legitimacy of issues that are central to sustainability science and practice.

Abstract

The study focuses on the constraints and potentials of irrigation in three municipalities crossed by the Telwa valley in the department of Tchirozérine, Region of Agadez. The valley passes through the towns of Agadez, Dabaga and Tchirozérine. It is one of the Aïr valleys that carry significant amounts of rainwater collected from the Aïr Mountains. The article highlights the constraints potential of irrigation in this Telwa valley. The study involved a sample of 48 producers chosen from 12 villages in the three communes. It appears that the total areas of irrigable land are variable with an average of 1.66 ha. Likewise, the average cultivated area is 0.92 ha. The availability of irrigated land takes 47% of producers operate an area of less than 1 ha, around 31% of producers operate more than 1 ha per year. The municipalities have 46% of the irrigated sites in the region. There is an experienced human capital in irrigation management formed by 12.908 producers in 2018, including 4.427 for the three municipalities studied, which represents more than 34% of the region's workforce. Among the producers, we find both sexes but largely dominated by men 97% against 3% of women. Access to groundwater for irrigation is through two main systems, shallow PVC wells and boreholes (varying at varying depths). The dewatering is provided by motor pumps and the crops are irrigated according to the gravity and Californian type.

Introduction

Niger, due to its location, is subjected to Sahelian - arid type of climate, the main characteristics of which are low rainfall, variable in time and space, high temperatures and strong winds, tending to accentuate its aridity (Aliou *et al.*, 2014). Mainly rain-fed, Nigerien agriculture is practiced in very hostile conditions, due to the country's arid climate regime characterized by low rainfall, a short rainy season and high temperatures. Despite these unfavorable constraints, agriculture remains the most important sector of Niger's economy. More than 80% of the population is active in agriculture (INS, 2012), while the primary sector represents around 45% of the Gross Domestic Product (GDP).

This primary sector dominated by agricultural activities has in fact grown faster than other sectors of the economy. It is also the second sector contributing to export earnings after mining (Ministry of Agriculture, 2014). However, cereal yields in Niger have declined in recent decades due to climate change causing flooding, erratic rains and poor distribution in time and space. Irrigated crops such as vegetable production are therefore considered as an alternative to food

security in the face of climate change (Yacoubou, 2009). As water is the first limiting factor for agricultural production in most of the country, the long-term development of irrigation in Niger has always been considered as an essential aspect which makes it possible to stabilize yields, especially in the event of irregular rainfall (Alizee *et al*., 2011; Patrick and Issa, 2009).
In the region of Agadez located in an arid zone where the climate of the arid type (with very low rainfall averages hardly exceeding an annual cumulative of 200 mm (PRODEX, 2013), only irrigated crops are practiced, provided from the surface water table, which is fed by runoff from wadis or *koris* during the short rainy season, water collection being done through wells and manual drilling, the depth of which generally varies from 0 to 18 meters depending on the area (Moumouni, 2014).
Irrigated agriculture is developing more and more in the Aïr mountain areas, thanks to the intensification and the orientation of production towards national and regional markets. However, this vegetable production faces enormous constraints associated with biophysical factors which unfortunately slow down its development. Despite these constraints, the Agadez region, particularly the communes of Agadez, Dabaga and Tchirozerine crossed by the Telwa valley, have great potential in terms of irrigation. The paper aimed to assess the main constraints and potentialities of irrigation along Telwa *kory* stream in three municipalities of Tchirozerine Department, Agadez Region.

Materials and Methods

The main materials used in this study consists of list of all irrigation sites in the region, including their respective area coverage provided by the regional directorate of agriculture; a GPS for the geo-referencing of sites and surface measurements; individual discussion and focus group questionnaires for the field survey and a smart phone for taking pictures. The study relies on the use of primary and secondary data. Primary data was collected through field observations and interviews with public technical services and staff of Non-Governmental Organizations (NGOs) working in the field of irrigation in the study area. Questionnaires were administered to farmers and market gardeners to assess the constraints and potential of irrigation in the area. Secondary data comes from documentary that deals with themes and subjects related to the issue of irrigation. Also, the use of GPS made it possible to collect the geographical coordinates of all the villages and gardens sampled in order to measure the total surface area of all the gardens representing the samples to highlight the irrigated land potential of the area of 'study.

Sample size

The study carried out in the department of Tchirozérine concerned three (3) communes of the region of Agadez which are the commune of Agadez; of Tchirozerine and of Dabaga. In each commune, four (4) villages were selected on the basis of the importance of market gardening activity and the size of the cultivated areas. Then, four (4) producers were surveyed in each village, which resulted in a sample of twelve (12) villages and forty-eight (48) farmers/producers questioned (table 1).

Table 1. Sample frame and distribution of respondents for interview and Focus Group Discussion (FGD)

Municipalities	Villages	Sample for individual interviews	Sample for FGD
Agadez	Tchiguefen	4	8 farmers
	Eladeb	4	
	Toudou Bila	4	
	Azamalan	4	
Tchirozerine	Azzelkelawey	4	8 farmers
	Azzel Ecole	4	
	Tchimbiram	4	
	Emassaknan	4	
Dabaga	Baital	4	8 farmers
	Intatat	4	
	Tassalamsalam	4	
	Babaré	4	
Total	**12**	**48**	**24**

For the purposes of the study, individual interviews and collective discussions with the operators (48) were carried out in order to obtain detailed and precise information. The selection of respondents was made at random, a list of all the producers in the village was drawn up, then the respondents were drawn at random. However, criteria attributable to age; the experience and level of responsibility of the irrigator were considered. That is, each respondent must be an active gardener at least twenty (20) years old and have at least five (5) years of experience in market gardening. both qualitative and quantitative analysis. The qualitative data were discussed and interpreted by the research team. To determine the extent and area of Kory-Telwa, a supervised classification map was produced using ARCGIS software and the watershed was digitized from Google Earth. To assess the potentials of irrigation in this area, quantitative data from the questionnaire results were analyzed and interpreted using descriptive statistical techniques including percentage, ratio, average and analysis presented in tables and graphs. This analysis is performed using Microsoft Excel software.

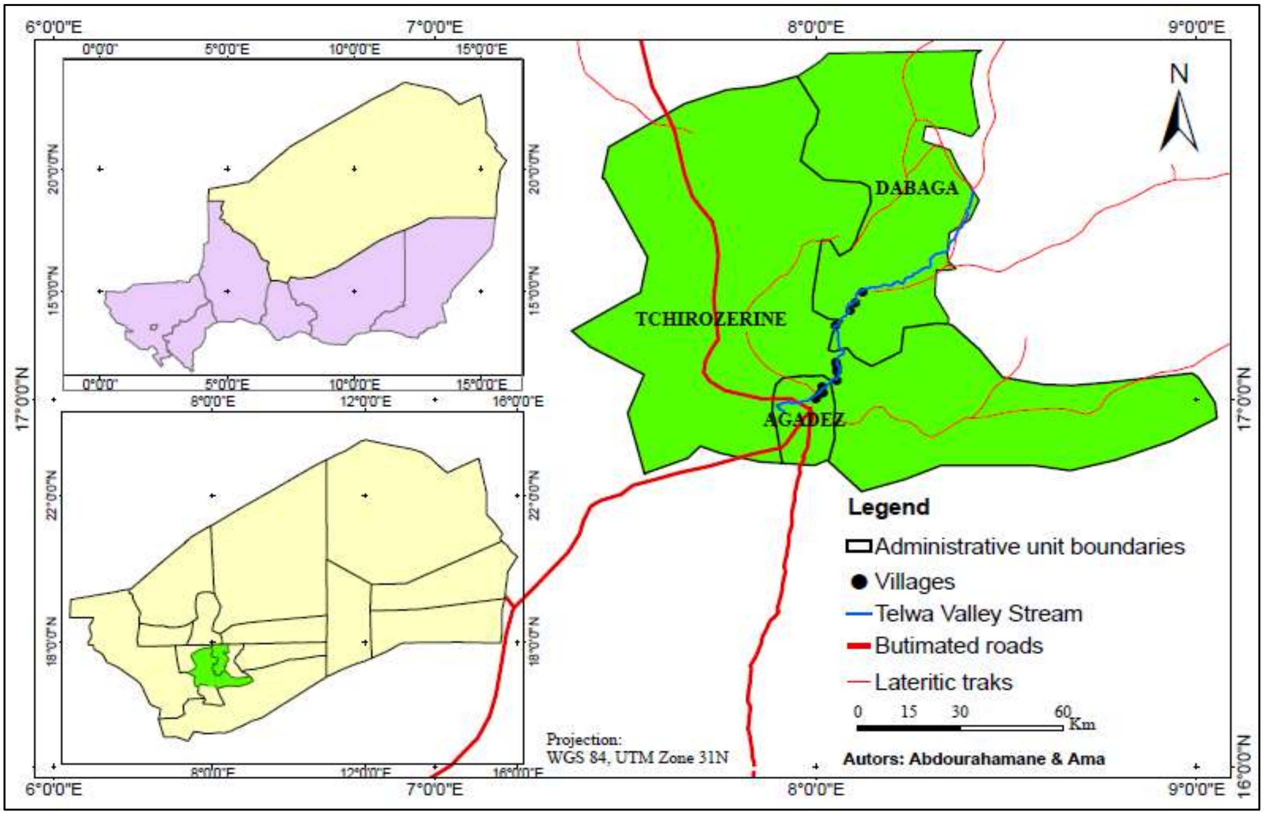

Figure 1. The Study location, the three municipalities and the selected villages

Results and discussion

Potentials of irrigation

Despite the various constraints encountered by irrigation production in the area, which are common biophysical constraints hindering the development of irrigation farming in the area. They can be divided into two: the biotic such as parasitic and pest attacks, weed infestations and diseases associated with insects, birds and rodents; for abiotic constraints, these relate mainly to water erosion, siltation, leaching, soil gullying and destruction of crops during floods. Others include early drying up of the wells, the presence of bedrock. The latter contains (abiotic) retard enormous potential which, if developed, could boost the development of vegetable production and the income of producers.

Land potential

The irrigable land potential of Niger is estimated at 270,000 ha on the basis of exploitable water and soil resources (FAO-AQUASTAT, 2015 and Moussa, 2016). Agriculture of Agadez in 2018, the irrigable areas are estimated at 21,510 ha for the whole region with about 7,000 hectares cultivated areas which represents 32% of the regional irrigable potential. Most of the region's land resources (51%) are concentrated in the department of Tchirozérine where irrigated production seems to be developing well with more than 50% of cultivable areas being developed.

Table 2. Sample characteristics

	Mean	**Median**	**Minimum**	**Maximum**
Total surface (ha), N=48	1.66	1.3	0.4	6
Exploited surface (ha), N=48	0.92	0.8	0.3	2

One can therefore note from table 3, as an indication, that the size of the areas used for irrigation in this zone is very random and varies considerably from one farmer to another. Table 3 also presents the distribution of exploitable and exploited areas of the zone.

Table 3. Distribution of Exploitable and Cultivated Farmland in the Study Area

Size class (ha)	Frequency	Relative frequency (%)	Cultivable land (ha)	(%)	Cultivated land) (ha)	(%)
< 1	13	27.1	9.1	11	20.6	47
1-1.99	19	39.6	24.8	31	19.5	44
2-2.99	10	20.8	21.6	27	4	9
3-6	6	12.5	24.4	31	0	0
Total	48	100	79.9	100	44.1	100

The table (3) shows that gardens with less than one (1) ha represent 27% of all gardens, then 11% of the total exploitable area of the sample studied. Gardens with areas between 1 to 1.99 occupy approximately 40% in number and 30% in area. Farms with an area greater than two (2) hectares represent 33% in workforce and approximately 58% in area. It is noticed that the largest areas occupy more of the cultivated areas. This proves the presence of significant land potential that could be developed. However, for the areas actually exploited, more than 64% of farmers interacted, cultivate an area of less than one (1) ha per year, corresponding to 47% of the total area exploited, approximately 31% of producers have an average holding of more of one (1) ha and only 4% manage to exploit two (2) ha per year. These figures show a predominance of small-scale irrigation despite the importance of land availability in the area. This depends on the one hand on the financial resources of the operator (financial capacity for investment in development) and on the other hand on the availability of water, which remains a limiting factor along the valley.

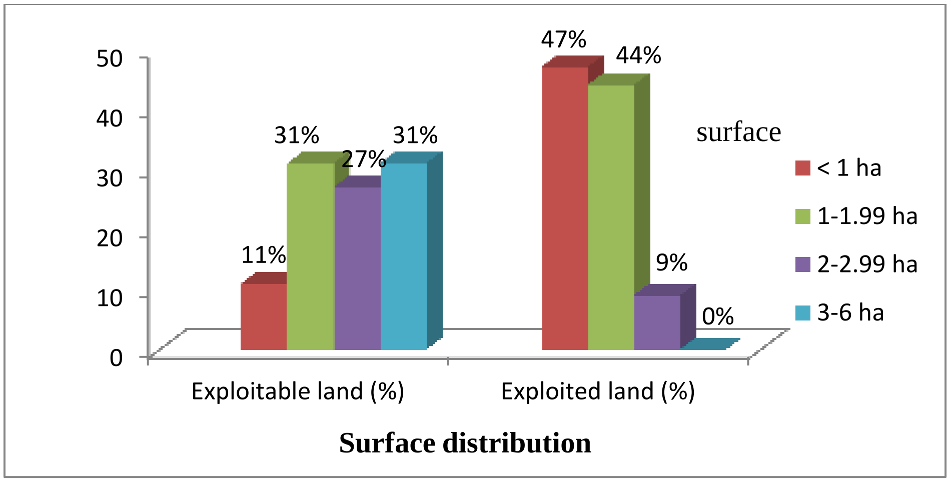

Figure 2. Exploitable and Exploited land (%) in the three Communes as farmland distribution

Water potential

The water potential of the study area consists of the water resources used in the Aïr, especially in the Telwa valley, mainly come from alluvial acquires which are in turn supplied by the floods received from the watersheds during the rainy season. These shallow aquifers, whose recharges already depend on the quantity and duration of the flows, have recently suffered from early exhaustion which could be linked to the intense drawdowns of water for irrigation, which remains the main activity of the populations of the area. . The development of irrigation encouraged by the advent of the use of motor pumps has influenced the balance of this alluvial water table. In the vast majority of cases, the latter no longer ensures the water supply necessary for irrigation for the entire agricultural season in the area.

In addition, the presence of deep water tables in this area was noticed, though not very much known. There is lack of reliable scientific data that could help in estimating the water potential or in understanding how the aquifer works. The presence of the base in places and the lack of technical and financial means limit access to deep water tables for farmers, whose average depth of wells does not exceed twelve (12) meters. However, deep boreholes have recently been tested in the Aïr with depths varying from twenty-five (25) to one hundred and fifty-two (152) meters, but these holes show a weak relationship between the depth and the magnitude of flow (Illias, 2018). As for the alluvial aquifers of the Telwa valley, although superficial, they have the potential to store large quantities of water, the recharge of which is sometimes spontaneous, following the first flows depending on the proximity of the water and this well relative to the minor *koris* bed (Illias, 2018).

With each irrigation time, thousands of cubic meters (m3) of water flow and infiltrate through this valley. The latest estimates of the water potential of this valley come from studies carried out by scientific experts from the Office for Overseas Scientific and Technical Research (ORSTOM) who spent several years in the Aïr. Indeed, for the hydrological studies of the Telwa valley, hydrometric stations had been installed along this *kory* and the data were collected and analyzed for each rainy season (Gallaire, 1995). Table 3 shows the volumes sold in Dabaga and the volumes lost between Dabaga and Azzel (village in the municipality of Tchirozerine) from 1980 to 1988 were considered.

The number of producers constitutes a human potential, one of the real factors of production at the level of a farm. Indeed, the region of Agadez has 278 irrigated cultivation sites spread over fifteen (15) municipalities, of which 128 sites are located in the municipalities of Tchirozerine, Dabagaet and Agadez, i.e. 46% of the irrigated sites in the region (table 3). There were 12,908 producers in 2018, including 4,427 for the three municipalities mentioned, which represents more than 34% of the region's workforce. These farmers are represented by both sexes but largely dominated by 97% men against 3% of women.

Table 3. Farmers and Irrigation Sites Proportions in Agadez Region

Communes	Number of sites		Number of producers	
Tchirozerine	80	(28.8%)	2613	(20.2%)
Dabaga	36	(12.9%)	1566	(12.1%)
Agadez	12	(4.3%)	248	(1.9%)
Autres communes	150	(54%)	8481	(65.7%)
Total	278	(100%)	12908	(100%)

Socio-demographic characteristics of farmers

The study area is characterized by a large demographic representation as shown in table5. The household size of the sample studied varies from 3 to 15 people with an average of 8 people per household. The age of the producers surveyed varies from 24 to 74 years, with an average age of 44 years. Market gardeners are generally married (93.75%). Market gardening constitutes the main activity for all the producers surveyed (100%), 27% of whom have a secondary activity. The average experience of practicing irrigation is 28. In addition, 58% of these respondents have at least once received agricultural training, which testifies to the good mastery of agricultural practice in the area. This signifies a good workforce in the region.

Market Gardening as labor activity

Representing the main activity in the Aïr zone, market gardening is a major employer of labor, mainly coming from the southern part of the country. The laborious tasks, especially manual weeding, require the use of hard labor which often works for the entire crop season. Most producers do not work alone, family labor is the first to be called upon, but in the absence of this, farmers employ easily accessible external manpower, although most often without agricultural experience. In some cases, depending on the importance of the work and farmers' uses, both family and hired manpower are involved (figure 3).

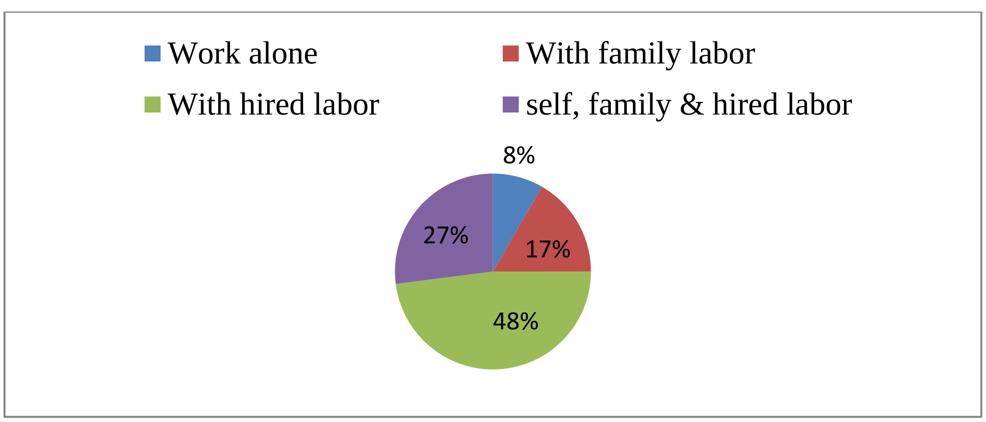

Figure 3. Relative Labor (manpower) Proportion for Irrigation Farming in the Three Communes

Irrigation system
Due to the absence of surface water in the study area, only groundwater is used for irrigation. Access to groundwater for irrigation is through two main systems, shallow PVC wells and boreholes (varying at varying depths). The watering is provided by motor pumps and the crops are irrigated according to the gravity and Californian type.

The diversity and Importance of Cultivated Crop Species

Irrigated crops are characterized by a large number of cultivated species in the Aïr zone. This study identified 24 species of market gardening and 2 species of cereal crops divided into 11 families. The most represented families are *Solanaceae* (5 species), *Cucurbitaceae* (4 species), *Apiaceae* (4 species), *Malvaceae, Liliaceae, Fabaceae* and *Poaceae* (with 2 species each).
For the most cultivated crops, it was considered of those with a relative frequency greater than 30%. Fruit vegetables, with the exception of eggplant, are among the most widely cultivated crops. They have the advantage of giving rise to several harvests per crop cycle. Indeed, these crops are produced during the period of high water availability in the area. Salad, cabbage and moringa are the most widely cultivated leafy vegetables. The salad has a very short cycle (less than 40 days) and shares with moringa the advantage of being well produced in all seasons and as for cabbage, it is generally appreciated for its good yields. For root vegetables, carrots and beets are better represented. Onions, on the other hand, dominate bulb vegetables and generate significant economic value.

Conclusion and Recommendations

This study allowed us to highlight the irrigation potential along the Telwa Valley in the northern part of the Agadez region. Thus, it emerged that there is an important land potential which is not significantly exploited, as farmers are unable to grow large areas of land (more than 3 ha). Despite the importance of water flows, farmers are not effectively exploiting this water potential due to the lack of water retention structures. A part this, there is also significant irrigated crop biodiversity and human potential in the area.
As a recommendation, technical support in terms of training (organic fertilization, biological control, etc.) and infrastructure (water retention and mobilization structures) is necessary for these irrigators.

Abstract

In order to achieve the set tasks to increase the level of GDP growth, a significant increase in investments is required, while the agribusiness faces the challenge of increasing exports to USD 45.0 billion by 2024, which is also impossible without serious investments in the development of foreign trade activities of enterprises. The existing measures of state support for the development of foreign trade activities do not provide the required level, as well as the existing investment mechanisms have not lead to a significant increase in the volume of agricultural exports. At the same time, the potential of private investment in the agribusiness development directly or indirectly through funds and stock exchanges is estimated at the level of 10% to 12% of the population of Russia. Currently, Russia has only 1.7% of private investors or about 2.5 million people, while this figure is 11% of private investors in China, it is an average of 39% in Japan, and it is more than 52% of private investors from the total population in the USA. Therefore, the recent years' reforms in the sphere of the Russian agribusiness have led to an increase in agricultural production, profitability of enterprises and the development of export activities. The necessity of analyzing and substantiating the essence of the economic category of competitiveness, which is largely based on the external manifestations of the competitiveness of agricultural products, in particular the cost, has been justified. The measures to increase competitiveness at the economic level are substantiated based on the use of high-tech, nature and soil-protective agriculture and new technologies in animal husbandry and crop production in terms of the development of export potential. Some reasons have been identified that impede the development of the agricultural sector, in particular, the insufficient level of investment activity in the agricultural sector and the weakness of the economic positions of agricultural enterprises. It has been proposed to apply budgetary support to normalize their financial situation. The risks that must be taken into account when bringing agricultural products to foreign markets have been identified.

Keywords: *Agricultural enterprises, Products, Competitiveness, Export activities, Development.*

Introduction

A number of studies have identified the export of agricultural products as a driving force of economic growth. Stimulating the development of exports is the primary task of national economies (Ayob Freixanet, 2014; AboagyeGunjal, 2000; Khanal et al., 2020; Altukhov et al.,

2019). Mania and Rieber (2019) found that export baskets have different potential for growth and economic development and that the quality of export diversification should be assessed according to a country's ability to develop its production structure.
In recent years, significant institutional and functional reforms have taken place in the Russian agribusiness that are focused on changing the structure of agricultural production, its re-equipment, diversification and development of agricultural exports. At the same time, these years were a period of development of agriculture and obtaining competitive products of the industry. The most important result of this work should be considered an increase in agricultural production and the profitability of agricultural enterprises including those through the implementation of export activities (KhokhlovaYushina,2019; Deloitte Survey, 2019).
A chronically unprofitable industry has become profitable. The aggregate level of profitability of agricultural organizations increased almost 3 times, although incomes are not high enough to ensure the maintenance of expanded reproduction in most farms. It is known that profit stimulates business to make investments while the industry becomes more attractive for Russian and foreign investors. Nevertheless, the overall level of investment activity in the agribusiness remains low. However, their share in the total volume of investments in the Russian economy is slightly less than 3%, while the share of agriculture in the gross domestic product is much higher and is equal to about 5.5%. Investments in the country's agribusiness has resulted in the growth of the labor productivity being the most important economic indicator. If an agricultural employee produced products worth 72,000 rubles in 2010, then currently, it is 1.5 times more then that in 2010 (On the progress and results of the implementation…, 2020, ShagaidaUzun, 2020). However, the dynamics of development of the agribusiness industries suggests that most of them have exhausted their reserves of internal growth and cannot develop further at the existing rates without a radical change in the investment and government policy of regulation. Over the past three years, state support for the agribusiness has increased 1.4 times. However, the positive effect of state support for the agricultural economy is significantly brought to naught by its insufficient volume and lack of solutions to all existing problems. The state of affairs in the agricultural sector of the economy can be corrected only by increasing its investment and innovation attractiveness. An example of this is the development of food and processing sectors of the agribusiness economy, where production fixed assets have been actively updated in recent years, i.e. good conditions have been created there for domestic and foreign capital. It is necessary to achieve the same situation in agriculture. Further development and growth of the Russian agribusiness (at least 4% to 5% annually) is possible only within the framework of the implementation of strategic target programs for effective and accelerated reform of agriculture and increasing the competitiveness of products of the industry's.
The purpose of the study is to analyze the factors hindering the development of the agricultural sector and export activities of agricultural enterprises, as well as to develop measures to increase competitiveness at the economic level in terms of developing export potential.

Materials and Methods

The materials for the study were those of the State Program for the Development of Agriculture and Regulation of the Markets of Agricultural Products, Raw Materials and Food, the priority project titled 'Export of Agricultural Products', regulations governing the export of agricultural products, data from the Ministry of Agriculture of Russia and other federal and regional authorities. In the course of the research, the methods of system and structural-dynamic analysis, expert assessments, extrapolation and others methods were used.

Results and discussion

In recent years, the competitiveness of agricultural products has become more significant. The transition to the model of export-oriented development of agricultural enterprises presented them with a fait accompli: a significant difference in prices for agricultural products when selling them in Russia and abroad and insufficient demand due to the low purchasing power of the Russian population. It should be borne in mind that even before the recent transformations, the level of labor productivity in agriculture, the material and technical base of product processing and its implementation lagged behind those level of the developed countries, which determined the higher cost of production of the agricultural industry of this country. Of course, at the same time, it should be noted that the bioclimatic potential of domestic agriculture is relatively worse. However, there is a certain part of the farms that successfully compete in the domestic and foreign markets, and their products are in constant demand (Kovaleva, 2019 Kovalenko Chekuno, 2019).

Such a contradictory situation requires analysis and substantiation of the essence of the economic category of competitiveness and search for ways to improve it for domestic producers. In the current market, one should not absolutize in many respects the external manifestations of competitiveness or non-competitiveness of agricultural products, which are mainly determined by the price factor. It is necessary to clearly find out which market one is talking about and where the competitiveness of the products should and can be shown. It goes without saying that the domestic market of Russia features extremely low paying capacity of the bulk of the population. In addition, the food market is practically not regulated by the government, which allows the trade sector to dictate its terms to agricultural producers and contributes to the growth of the disparity in prices for agricultural products. Agricultural exports are not adequately supported and imports are not sufficiently limited.

Measures to improve competitiveness at the economic level follow from the experience of profitable agricultural enterprises. The basis of their success is the use of high-tech, nature and soil-protective agriculture and new technologies in animal husbandry and crop production. The increase in the number of such agricultural enterprises is the key to the competitiveness of the industry. After all, intensive technologies are designed for deeper knowledge, require active involvement in the production of agricultural products of mineral fertilizers (150 kg of active agent per 1 ha or more), low-volume use of plant protection products against diseases, pests and weeds, differentiated application of agents in different phases of plant development and equipment operation along the tramline. At the same time, a programmed product quality can be obtained that meets the requirements of both processing and the domestic and foreign markets.

The next step is high (high-intensity) technologies. This is the strategic future of competitive agriculture in Russia. These technologies not only require high-quality varietal crops and seed varieties, but also need to take into account various aspects of their natural and climatic growing conditions, soil cultivation and seeding systems, fertilization and protection against diseases, and requirements for determining the parameters of cultivated areas and product quality. High-techs have been created and in many respects provide accurate (precise) control of the production process of growing and storing competitive products. As a rule, these technologies take into account and control the quality of performed process steps based on changing landscape conditions and optimize the use of intensification resources. Many elements of these technologies require revision or adaptation of their European counterparts to local conditions.

Obviously, the task of intensifying production in agriculture with the use of new technologies requires a sharp, 3-4 times, increase in labor productivity by way of transferring the production of the agricultural sector to the use of agricultural machinery of new generations and then precision technology that accurately fulfills the production processes specified. In general, one can conclude that each agricultural enterprise needs to turn to the technical design of production of specific types and with given parameters of competitive products for sale in the foreign market.

It should also be added that agricultural enterprises should pay more attention to marketing and look for the most profitable channels for selling products in the foreign market. These channels should have a stable financial position and the ability to pay for purchased goods on time. The implementation of cluster strategies will also contribute to increasing the competitiveness of agricultural enterprises (Kovshov et al., 2019; Cherkesova et al., 2019; Voytyuk et al., 2021).

In the regions, the increase in the competitiveness of agricultural products is due to the fact that the regional market develops on specific types of products and their sale profitability is associated with the costs of transporting products to foreign markets. In Russia, transporting agricultural and food products are required, because the conditions for growing some types of agricultural products are very different. However, due to the lack of an extensive infrastructure for the distribution of products and high tariffs for the transportation of products, agricultural enterprises cannot take full advantage of the opportunity for their products to enter the foreign market at the lowest cost. As a result, there was a huge difference in prices for agricultural products in different regions of Russia.

Considering the issue of the competitiveness of the products of agricultural enterprises in the industry in the domestic market, it is necessary to predict possible changes in export-import activities associated with the dynamics of the world market. Thus, ensuring the competitiveness of agribusiness products and foodstuffs cannot be considered only as a function of an economic entity, agricultural or other producer in the agricultural sector.

Federal and regional state authorities are responsible for the current processes and regulation of domestic and foreign markets. The measures used for these purposes include the organization of information support and the formulation of forecasts, subsidies and compensations to support profitability and reduce costs in the production of competitive products of agricultural enterprises, as well as interventions to keep prices in a certain range; the formation of reserves, including strategic ones, when the world market conditions are undergoing major changes. At the same time, the most important source of risks for the implementation of the agricultural development policy is the low competitiveness of the industry in its economic relations with other sectors of the Russian economy, i.e. unsatisfactory competitive position of agricultural producers in their relations both with processors of raw materials, trade, infrastructure and transport enterprises, and with manufacturers of industrial products necessary for the reproduction of fixed assets and ensuring current production activities.

The price proportions of the Russian economy were formed mainly during the period of price liberalization and foreign trade at the initial stage of reforms. At the same time, a number of sectors of the country's economy used market advantages and achieved an outstripping rise in prices for their products in comparison with prices for agricultural products. The price proportions that changed as a result of the abovementioned came into conflict with the existing technological structure of production and the structure of its distribution throughout the country, which determine the level of current material costs and capital intensity in the agricultural sector.

The weakness of the economic positions of agricultural enterprises in their relations with enterprises of related industries allows them neither to resist the rise in prices for the resources they consume, nor to adapt to it by increasing the selling prices of agricultural products. The growing lag of the selling prices of agricultural products from the prices of consumed production resources leads to a shortage of financial resources in agriculture and a reproduction crisis. Consequently, while maintaining the prevailing prices for the industry's products, the problem of normalizing the financial situation of an agricultural enterprise cannot be solved and the industry cannot switch to a mode of sustainable export-oriented development without any budgetary support.

In addition, there is a lack of effective tools and scientific methods to ensure the competitiveness of enterprises. Inattention to the issues of restructuring and modernization of most production subsectors lead to low efficiency of agricultural production (Ushachev, 2009).

To reduce the influence of negative factors, the Strategy for the development of the agricultural and fishery sectors of the Russian Federation for the period up to 2030 has been approved, one of the purpose of which is creating a high-performance export-oriented sector that develops based on up-to-date technologies and is provided with highly qualified personnel. The State Program for the Development of Agriculture and Regulation of Markets for Agricultural Products, Raw Materials and Food for the Period of 2013-2020, the Federal Scientific and Technical Program for the Development of Agriculture for 2017-2025, and the Doctrine of Food Security are also being implemented.

However, the agricultural production management mechanisms used in the framework of development programs are focused on solving individual local problems and turn out to be insufficiently effective (Bakhtin et al., 2017; Kotov et al., 2017).

The "International cooperation and export" national project is implementing the "Export of agricultural products" priority project, within the framework of which the regional authorities develop programs with appropriate funding and set targets. So, the "Export of agricultural products" project of the Saratov region sets the task of increasing the supply of regional agricultural products to USD 773 million by 2024, the project for the development of exports in Udmurtia assumes an increase to USD 49.1 million, Kurgan region also plans an increase up to USD 49 million, Moscow region plans an increase up to USD 1.7 billion, Stavropol Territory plans an increase up to USD 1.093 billion, and Bashkiria plans to increase up to USD 230 million.

The goal of the regional project in the Kaluga region is to triple the volume of exports of agricultural products of the region until 2025. The "Volume of exports of agricultural products" target indicator for 2024 is planned in the amount of USD 72 million (Ministry of Agriculture of the Kaluga Region…, 2020).

Two hundred and fifty six agricultural enterprises represent the agrarian sector of the Kaluga region, more than 150 of which are involved in export activities (Voytyuk Marinchenko, 2021). They sold products worth over 107 billion rubles in 2019. The industrial production index was 110.0% (Export of agricultural products…, 2021).

The total amount of financing for the activities of the regional export development project amounted to 9.33 million rubles in 2019, of which 8.96 million was from the federal budget and 0.37 million was from the regional one.

The indicator of the program implementation is the volume of export products sold (Table 1). The indicator exceeded USD 52.1 million (130.3% of the target) in 2019.

Table 1. Indicators of the implementation of the Export of Agricultural Products project of the Kaluga region

Item	Export volume, USD million	Period / year							
		2017	2018	2019	2020	2021	2022	2023	2024

When planning the entry of agricultural products into foreign markets, one should take into account risks, including macroeconomic ones. These include, for example, uncertainty regarding:

- Prospective conjuncture of the foreign energy market (return of oil prices to the corridor of normal values can sharply reduce the financial capabilities of the budget);
- Prospective trends in the real ruble exchange rate (strengthening the ruble will help weaken the effect of measures to protect the domestic market);
- Ways and rates of implementation of reforms in the social sphere and housing and communal services (under some scenarios, these reforms may lead to a sharp reduction in the growth rate of real incomes of the population).

With the industrialization of the livestock sector, the risks of epizootics objectively increase. It is necessary to develop and implement a system of preventive measures to damp social risks that may be generated by the uneven development of agriculture in the constituent entities of the Russian Federation, therefore, the different severity of the socio-economic crisis caused by the ousting of inefficient economic entities from the market, or the transformation of modern hidden unemployment into open.

It is also necessary to consider the following risks:

- Institutional risks (uncertainty of the actual timing of the formation and establishment of viable unions and associations of producers, which will provide an opportunity for intra-industry and inter-sectoral coordination of development programs);
- Legislative risks (uncertainty of the timing of the formation of the legal and regulatory framework for agricultural activities and state regulation of agriculture);

Man-made, ecological and natural-climatic risks (the possibility of large-scale disasters, the elimination of which requires the diversion of funds from all sectors of the national economy, including that from the agricultural sector of the economy).

This is the main range of issues and tasks to be solved in the country in order to increase the competitiveness of the agribusiness and bring the industry to the dynamics of sustainable development.

Conclusion

There are a number of unresolved problems in the industry that impede the development of the agricultural sector, such as the inability to reduce the shortage of financial resources resulting from the constant rise in prices for consumed resources and the insufficient level of investment activity through higher prices for products. At the same time, the relatively low competitiveness in comparison with developed foreign countries is due to lower labor productivity in agriculture because of the less developed material and technical base of enterprises in the agricultural sector, as well as processing and product selling enterprises. In recent years, thanks to government support, many enterprises have been upgraded, which has increased the competitiveness of agricultural products and has a positive effect on the export potential of enterprises.

To increase the competitiveness of the agribusiness and individual economic entities, as well as bring the industry to the dynamics of sustainable development, it is necessary to take into account the macroeconomic risks associated with the international situation and the risks associated with socio-economic development within the country.

To reduce the negative impact of factors hindering the development of the agricultural sector, as well as to ensure further enterprise modernization that increases the competitiveness of enterprise products and export potential, it is necessary to expand government support measures. The main area of increasing the competitiveness of enterprises is their modernization using high-tech production in animal husbandry and crop production, which are based on up-to-date agricultural machinery, varieties, breeds, types and hybrids of an intensive type and modern technologies based on the engineering of programmed products for the domestic and foreign markets. That will allow reaching the specified levels of production and export.

LIVELIHOODS OF SMALL FARM HOUSEHOLDS IN COVID-19 PANDEMIC: A CASE STUDY IN THE RED RIVER DELTA OF VIETNAM

Nguyen Thi HAI NINH*

Faculty of Economics and Rural Development, Vietnam National University of Agriculture, Hanoi, Vietnam
*Corresponding author: haininh.hua@gmail.com

Abstract

The COVID-19 pandemic has been affecting the entire food system, especially small farm households. Border closures, trade restrictions and confinement measures have been preventing farmers from accessing markets, including for buying inputs and selling their produce, and harvesting crops, thus disrupting domestic and international food supply chains and placed millions of livelihoods at risk. With more than two-thirds of the population living in rural areas, rural Vietnam is strongly affected by the COVID-19 pandemic in terms of losing jobs of many agricultural labourers, reducing income sources of small farm households due to the interruption of agricultural exported products market, and the decline of domestic market spending on food. This paper aims to provide empirical evidence about the impact of the COVID-19 pandemic on the livelihoods of small farm households in Northern Vietnam. Using data collected from sample farm households in the Red River Delta in Northern Vietnam, this paper investigates the effects of the COVID-19 pandemic on livelihoods of small farm households including livelihood resources, livelihood activities, and livelihood adaptation strategies. Results from 120 farm households show that a wide decrease in their income since the COVID-19 pandemic occurred in Vietnam, in which non-farming income dropped the most in households relying on crop production and wage-earning. Farm households relying on aquacultural productions and tourist services are the most affected by the COVID-19 pandemic when total income is reduced by more than 32 percent. For more pandemic resilient livelihoods, most of the farm households expected to receive government support in forms of financial provisions, preferential loans, market opening.

Keywords: *livelihood, small farm household, COVID-19 pandemic, Vietnam.*

Introduction

The COVID-19 pandemic has led to a dramatic loss of human lives worldwide and presents an unprecedented challenge to public health, food systems and the world of work. The economic and social disruption caused by the pandemic is devastating: tens of millions of people are at risk of falling into extreme poverty, while the number of undernourished people, currently estimated at nearly 690 million, could increase by up to 132 million by the end of 2020 (ILO, 2020). The pandemic has been affecting the entire food system, especially small farm households. Border closures, trade restrictions and confinement measures have been preventing farmers from accessing markets, including for buying inputs and selling their produce, and harvesting crops, thus disrupting domestic and international food supply chains and reducing households' income. The pandemic has decimated jobs and placed millions of livelihoods at risk (FAO, 2020).

Vietnam's agricultural sector plays an important role in the economy. With its strength in agriculture production, Vietnam has the advantage of ensuring national food security and

contributing to food security in other countries. In addition, Vietnam's agricultural sector has also created many high-value export items. With more than two-thirds of Vietnam's population living in rural areas, rural Vietnam is strongly affected by the COVID-19 pandemic in terms of losing jobs of many agricultural labourers, reducing income sources of small farm households due to the interruption of agricultural exported products market, and the decline of domestic market spending on food. In this context, small farm households are vulnerable to the impacts of the COVID-19 pandemic on livelihoods, income and welfare (Tran et al., 2021).
This paper aims to provide empirical pieces of evidence about the impact of the COVID-19 pandemic on the livelihoods of small farm households in Northern Vietnam. In this paper, the COVID-19 pandemic is assumed to affect the livelihood of small farm households in terms of livelihood resources, livelihood activities, income and livelihood strategies. The following sections of this paper include material and methods, results and discussion and conclusion.

Material and Methods

Hai Phong is a coastal province in the Red River Delta, Northern Vietnam. The livelihood of small farm households in Hai Phong is mainly based on agricultural farming, aquacultural farming and fisheries catching, and tourism services. However, the COVID-19 pandemic has strongly affected the livelihoods of smallholder farmers due to the disruption of the supply chain of agricultural and aquatic products and especially the absence of tourists. Therefore, this study was conducted in 2 districts of Hai Phong province to clearly identify the impact of the COVID-19 pandemic on the livelihoods of smallholder farmers.
In order to get an overview of the livelihood transformation of small farm households under the impact of the COVID-19 pandemic, this study collected data from 120 small farm households based on 3 main livelihood groups: 30 farm households depend on agricultural production and wage earning (hereinafter referred to as agriculture - wage earning group); (2) 30 farm households depend on agricultural and aquacultural farming (hereinafter referred to as agriculture - aquaculture group); (3) 60 farm households depend on aquaculture and tourism services (hereinafter referred to as agriculture – tourism service group). These households have their own farm land of less than 0.36 ha per household, so they are identified as small farm households in Vietnam (GSO, 2019). Primary data from 120 small farm households were collected through direct interviews with household heads using semi-structured questionnaires. The content of the interview included: information on the head of the household as age, gender, education level; the number of family members, number of labour, livelihood resources, livelihood activities, income and livelihood strategies in response to the COVID-19 pandemic.
Primary data from small farm households are synthesized and analyzed using descriptive statistical methods combined with T-test and Mann Whitney U-test to examine the difference in the mean of household's income pre and during the pandemic (Dinh, 2011).

Results and Discussion

Description of the surveyed households

This section provides demographic information about the surveyed households including the age, sex and education of the household head and the number of family members as well as gender structure of the family. In small farm households in the Red River Delta of Vietnam, the age of the household head has a significant influence on the livelihood activities of the household because of the strong influence of household head on household's members (Hoang, 2009). The long production experience of the elderly householders helps them to quickly adapt to market risks and diseases in agricultural and aquacultural farming; thereby making reasonable changes in the livelihood activities of their households. Basically, the age of the household head in the agriculture - aquaculture group is the highest with an average age of 50.9 years old; the age of the household head in the aquaculture-tourism service group is lowest at 47.5 years old (Table 1). The author's observations during household interview show that young householders are less experienced but more dynamic, creative and have many bold ways of thinking for business. They have many business ideas suitable for tourism activities. This is very necessary for the group of aquaculture-tourism service households to develop livelihood activities and increase income.

Table 1 Statistical description of small farm households

Description	Unit	Agriculture – Wage earning (n=30)		Agriculture – Aquaculture (n=30)		Aquaculture- Tourism services (n=60)	
		No of HH**	Percentage (%)	No of HH	Percentage (%)	No of HH	Percentage (%)
Household member	Persons	4.3	-	4.8	-	4.6	-
- Male	Persons	2.3	56.7	2.5	50.0	2.4	58.3
- Female	Persons	2	43.3	2.3	50.0	2.2	41.7
Family labourers	Persons	2.3	-	3.0	-	2.8	-
Age of household head	Years	50.7	-	50.9	-	47.5	-
Education of household head	Years	8.7	-	9.6	-	10.3	-

*Source: Authors' own calculations from survey data in 2021; ** HH: Household.

Besides age, a high level of education is also an advantage for the household head to easily access agricultural and fishery market information as well as tourism service market information. Based on these market information, small farm households can diversify their livelihood activities. Statistical data show that the heads of households in the group of aquaculture - tourism services have the highest level of education (more than 10 years of schooling), in the remaining two groups, the heads of households have lower education levels.

Livelihood resources of small farm households during the COVID-19 pandemic

Farm land

The Red River Delta of Vietnam has a history of agricultural cultivation for thousands of years. However, with a high population density, the average farm land area per person is the lowest (500m2) compared to other regions in the country (Bergstedt, 2012). Figure 1 illustrates the area of farm land used for crop farming and aquacultural farming of the three small farm household groups. Compared to 2019, the area of land used for crop and aquacultural farming in 2020 is lower in all three groups of households. Householders believe that the decline in domestic consumption of agricultural and aquatic products is the main reason why they narrow their farming area. With the declining demand, farm householders cannot sell their products. Amongst these three groups of households, agriculture – wage earning households have the lowest decrease in land use, the householders think that they try to make full use of their farm land area to serve livelihood activities and to avoid wasting natural resources.

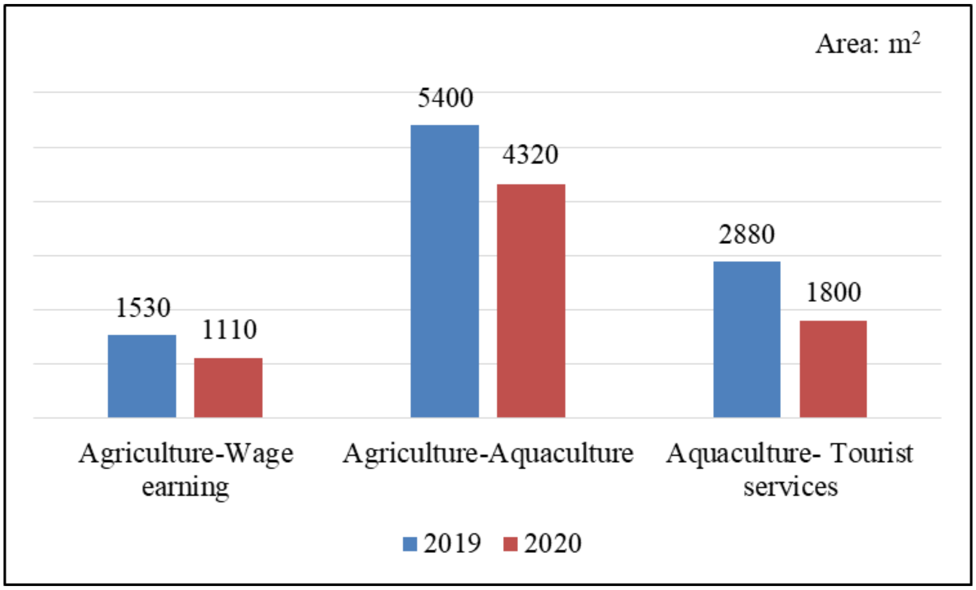

Figure 1. Land use for agriculture and aquaculture of small farm households
*Source: Authors' own calculations from survey data in 2021

Financial resource

Not only farm land, financial resource for production is also an important livelihood resource of smallholder farmers. In rural areas of Vietnam, farmers can access official loans from banks and credit institutions through farmers' union and women's union. In this study, the sources of loans for all three groups of households are mainly from banks and relatives. The group of agriculture-wage earning households has the lowest number of households with loans (10% of the households), and the group of aquaculture - tourism service households need more capital for business, so 60% of households have loans (Table 2). Some householders believe that accessing financial resources at banks is still difficult due to the requirements of mortgage of property rights such as land use rights or housing property rights, so they tend to borrow from relatives if the loan amount is small. In contrast, householders borrow money from banks mainly with large amounts. Some households borrowed to invest in production before the pandemic, so they cannot afford to pay now.

Table 2. Loan of small farm households in 2020

Description	Agriculture – Wage earning (n=30)		Agriculture – Aquaculture (n=30)		Aquaculture- Tourism services (n=60)	
	No of HH	Percentage (%)	No of HH	Percentage (%)	No of HH	Percentage (%)
Number of HH loan	3	10.0	15	50.0	36	60.0
Amount of money loan	10 (mils VND**/HH)		44 (mils VND/HH)		40 (mils VND/HH)	
Comparison to the loan of 2019						
Increase	1	33.3	3	20.0	5	13.9
Keep stable	0	0.0	2	13.3	4	11.1
Decrease	2	66.7	10	66.7	27	75.0

*Source: Authors' own calculations from survey data in 2021; **VND: Vietnam Dong, 23 thousands VND equals to 1 US dollar

In order to better understand the impact of the COVID-19 pandemic on the livelihood resources of smallholder farmers, householders were required to compare loan amounts in 2020 with the pre-pandemic period. As a result, the majority of householders answered that they reduced their loans compared to 2019. Especially the group of aquaculture - tourism services with 75% of households reduced loans in 2020. Farm households working as tourism services face the most difficulties during the COVID-19 pandemic when their livelihoods were frozen. Householders in this group reported that they must completely change their livelihoods. Some households have not fully paid off their bank loans, then they have a crisis.

> *"I just hope the COVID-19 pandemic is quickly defeated to stabilize the country's socio-economics, through which the lives of people like me can stabilize. I still owe the bank a loan before, I have to pay a lot of interest every month, the epidemic has severely reduced income from tourism services, so it is even more difficult to pay bank interest." (Interview with a head of small farm household, female, 49 years old)*

Labour resource

For smallholder farmers in the Red River Delta of Vietnam, in addition to farm land, family labour is also a resource that plays an important role in livelihood activities (Le Thai, 2011). To analyze the impact of the COVID-19 pandemic on the change in labour use, this study compared the change in family working days in 2020 compared to the time before the pandemic occurred. There are 3 levels of assessment of working days in 2020 for household heads to answer including an increase compared to 2019; remain the same as in 2019; and decreased compared to 2019. Statistical results show that aquaculture - tourism service households have the largest number of working days decrease by 33.3%; the decrease was mainly due to the frozen tourism service activities. In the group of agriculture – wage earning households, labour only decreased by 10% and mainly because tourism service households did not need to hire labourers anymore. In any group of households, this decrease leads to a decline in the income of households in general and of labourers in particular. This decrease, therefore, makes farmers' lives extremely difficult during the pandemic.

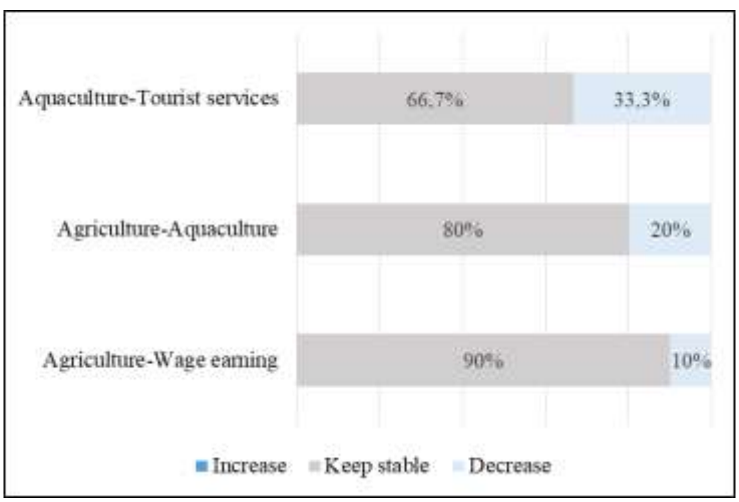

Figure 2. Labour use in small farm households in 2020 compared to 2019

*Source: Authors' own calculations from survey data in 2021

Livelihood activities

Many studies on the livelihoods of smallholder farmers in Vietnam in general and the Red River Delta in particular have come to the conclusion that diversifying livelihood activities is a way for farmers to increase their income and risk reduction (Nguyen 2015, Hoang 2009). In this study, the results show that a small farm household can simultaneously carry out different livelihood activities such as crop cultivation, animal husbandry, aquacultural farming, trade, tourism services and wage earning, etc. Nevertheless, in order to clearly identify the impact of the COVID-19 pandemic on the livelihoods of three groups of small farm households, this study only focuses on analyzing the changes of the main livelihood activities which account for the majority of households working time and main contribution to household income.

In the group of agriculture – wage earning households, before the pandemic (2019), the majority of them (over 83%) carried out all 3 main livelihood activities, namely crop farming, breeding and wage earning. However, when the pandemic occurred, the number of breeding and wage earning households decreased, especially the number of households engaged in wage employment decreased from 100% (in 2019) to 60% (in 2020) (Table 3). According to the surveyed households, livestock in this area is mainly large one such as buffaloes, cows, goats and pigs to supply restaurants to serve tourists. Therefore, when the restaurants were almost closed, the consumption market for livestock meat was a limitation, some households with insufficient capital gave up raising livestock and only focused on crop cultivation (vegetables and rice) to self-serve household consumption. In addition, the number of households with non-farm workers, such as serving at restaurants, decreased due to the social distancing. So that, only seasonal jobs such as construction workers remain, causing a significant decrease in the job supply.

Table 3. Livelihood activities of small farm households

Livelihood activities	2019		2020		Mann-Whitney U Test (2020/2019)
	No of HH	Percentage (%)	No of HH	Percentage (%)	
Agriculture – Wage earning (n=30)

*Source: Authors' own calculations from survey data in 2021

*** Confidence 99%; ** Confidence 95%; * Confidence 90%

In the group of agriculture - aquaculture households, aquacultural farming and fisheries catching are the main livelihood activities, especially fisheries catching is the livelihood of more than 86% of the surveyed households before the pandemic. Besides, many households still maintain crop farming activities (rice, vegetables) to provide food for their families (over 66%), and very few households still have wage labourers in their leisure time. Since the COVID-19 pandemic occurred, the structure of livelihood activities of this group has also changed significantly. The number of aquacultural farming households remains the same but the area of aquacultural ponds is reduced because aquacultural farming requires large financial investment, households have to borrow capital from banks or relatives. So that in the difficult situation of epidemics, no household intends to invest more. Similarly, the number of fisheries households also decreased due to the decline of the domestic market and the social distancing orders of the Government that made it difficult to sell seafood. On the contrary, the number of households cultivating rice and vegetables, and wage earning has increased significantly because households consider crop farming as a lifeline during the pandemic, which helps households to be self-sufficient in food and cut down living costs. Moreover, the number of households looking for non-farm jobs increased by nearly 40%. Despite the increase in wage employment, the income for these kinds of jobs is not high because the work is only seasonal. The wage employment only helps the household to slightly improve their income during the epidemic period.
It can be said that the group of aquaculture-tourism service households is the group that suffers the most losses due to the COVID-19 pandemic. Before the epidemic, 100% of the surveyed households did services and tours along with trading seafood products for tourists. Tourists to the locality number in the millions. This is a relatively large source of income for households in each holiday and summer vacation. Nonetheless, the epidemic caused a serious decrease in the number of visitors while the tourism service business required a large amount of money to invest, so nearly 40% of surveyed households had to close their businesses, even some. Householders think they are on the verge of bankruptcy. There were householders who reported that they rented a shop for a period of 5 years, but had encountered nearly 2 years of epidemics. The tourism business faced many difficulties, so they were in danger of bankruptcy. In parallel with the difficulties in the tourism service business, the fisheries catching activities of farmers are also difficult because of the lack of consumption markets, so the number of fisheries catching households also decreased by nearly 10%. Under such difficult conditions, 30% of households with surplus labour had to switch to wage employment to earn a living and pay debts. However, the amount of money earned is only enough for daily living, this group of households also has to spend a large amount of money to pay bank interest, so life becomes more and more difficult.

Household income and livelihood strategies

Compared with 10 other provinces in the Red River Delta of Vietnam, the average income of smallholder farmers in this research site is relatively high because of diverse sources of livelihood, especially the development of agricultural activities and tourism services before the time COVID-19 occurred. The source of household income comes from the main livelihood activities mentioned above. These are incomes from tourism services, wage employment, agricultural farming, aquacultural farming, fisheries catching and seafood trading. Compared with the other two groups of households, the average income of agriculture – wage earning household is the lowest both pre and during the COVID-19 pandemic. In this group, household's income from cattle breeding and wage earning accounted for a higher proportion than income from crop farming before the pandemic. However, during the pandemic, income from wage

employment decreased by more than 16%, instead, households grew more crops, causing the share of income from crop farming to increase to nearly 30% (Table 4). This shows a reasonable shift in the households' livelihood strategies of this group to cope with the impact of the pandemic.
The group of agriculture - aquaculture households has diversified sources of livelihood, especially since the pandemic occurred. The COVID-19 pandemic changed the livelihood strategy of this household group with the increase of crop farming and wage earning activities, and the reduction of aquaculture farming and fisheries catching activities due to the inability to find a consumer market as well as a large financial investment. With this movement, income from crop farming and wage earning accounted for more than 20% of the household income during the pandemic (compared to more than 6% before the pandemic). The timely diversion helps this group of households maintain a higher total income than the other two groups of households.

Table 4. Average household's income from different livelihood strategies (millions VND per household per year)

Income sources	2019		2020		T-test (Income)
	Household income	Income share (%)	Household income	Income share (%)	
Agriculture – Wage earning (n=30)

*Source: Authors' own calculations from survey data in 2021
*** Confidence 99%; ** Confidence 95%; * Confidence 90%

If the group of agriculture – wage earning and agriculture - aquaculture households are affected by difficulties in lack of consuming agricultural and aquatic products during the epidemic period, the group of aquaculture - tourism service households has to face the heavy impact from the orders of social distancing that led to no visitors. Income from tourism services decreased by up to 90%, forcing households to increase other livelihood activities such as seafood trading (especially online trading) and wage work. With the agility of young household heads, this group of households has taken advantage of information technology to serve their livelihoods. Selling seafood online is a new and effective idea during the epidemic. Consumers also prefer this form because it is both convenient to buy and ensures the health of themselves and their families.

Conclusion

The COVID-19 pandemic has caused changes in the livelihoods of smallholder farmers in the Red River Delta, Northern Vietnam, in many different directions. In order to adapt to the difficulties caused by the disruption of the consumption chain of agricultural and aquatic products, most households tend to further diversify their livelihood activities to create multiple sources of income. In addition, the COVID-19 pandemic has also changed the structure of crops for farming households and changed the form of fisheries catching and aquacultural farming.

Changes in livelihood activities and livelihood strategies depend not only on the group of the household as analyzed above, but also on the age, sex and education level of the household head. In addition, livelihood resources such as farm land, financial resource, and labour resource are also factors affecting the household's livelihood strategies. The analysis results show that in general, the group of agriculture – wage earning, agriculture - aquaculture households are less affected by the COVID-19 pandemic than the group of aquaculture - tourism service households. In order to adapt to the change of livelihood during the pandemic, each group of households has different difficulties such as lack of production capital, lack of market support and production techniques support from local authorities.

In view of the difficulties and challenges faced by smallholder farmers during the COVID-19 pandemic, this study makes a number of policy recommendations to help households stabilize their livelihoods as follows:

- Firstly, the bank simplifies procedures so that households can easily borrow capital to invest in redirecting or expanding livelihood activities in line with the ongoing epidemic situation in Vietnam.
- Secondly, local authorities need to have solutions to support people in selling agricultural and aquatic products through distribution channels such as cooperatives, local businesses, online agricultural product sales floors, etc.
- Thirdly, it is necessary for small farm households to take advantage of idle time to improve the quality of labour by learning more production techniques and market information to be able to adapt to changes in the market and consumption trends during the pandemic.

CONSUMERS' BEHAVIOR TOWARDS FOOD WASTE: A CASE STUDY OF FAYOUM, EGYPT

Mahmoud A. A. MOHAMED

Department of Agricultural Economics, Faculty of Agriculture, Fayoum University, Egypt
Corresponding author: maa16@fayoum.edu.eg

Abstract

This paper aims at exploring consumers' behavior towards food waste in Fayoum city, Egypt, through identifying the causes and degree of awareness of Food waste. A survey was collected in January 2021 where 200 respondents from Fayoum Governorate, Egypt. Who each one of them represents a family or household; they were randomly selected and interviewed online. A structured questionnaire was used to investigate whether respondents know about the concept of food waste or not, moreover, who is responsible for food purchasing and the amount of food wasted by the family. The reasons for food waste and the degree of awareness of food waste were investigated, food waste reduction practices. Finally, the impact of some explanatory variables such as Age, Sex, Education, Marital status, Job, Residence. The results showed that among respondents, there are significant differences between age groups, sex, job categories and frequency of purchase regarding knowledge of food waste. The results clarified that respondents considered offers and discounts in supermarket a first cause of high Food waste, they think it's important that I don't waste food and food waste creates economic damage to the society, where, preparing a list of purchases is considered a first practice of food waste reduction. The results of multinomial logistic model revealed that there is a significant effect of education level, residence, shopping frequency, and sex on the knowledge of food waste. The study recommends organizing campaigns to promote food waste reduction among families and students at universities, encouraging food waste recycling for its environmental, social and economic importance and impacts.

Key words: *Consumers' behavior, Food waste, Multinomial logistic model.*

Introduction

Food is considered a necessity for the resumption of people's life, and the issue of food came to be one of the biggest concerns for all countries and governments. Commonly, food consumption is influenced by economic, social, and cultural factors, economic factors comprise individual income, population, prices, availability, etc., where social factors include family size, education level, location, etc., and culture includes beliefs, ideologies, unwritten norms, motivations, attitudes and knowledge about food (Mohamed et al., 2012). Resulting from decisions and actions by retailers, food service providers and consumers, a decrease in the quantity or quality of food is called food waste. Food is wasted in many ways, for example, fresh produce that deviates from what is considered optimal, for example in terms of shape, size and color, is often removed from the supply chain during sorting operations, foods that are close to, at or beyond the "best-before" date are often discarded by retailers and consumers, and large quantities of wholesome edible food are often unused or left over and discarded from household kitchens and eating establishments. According to FAO, around one third of the world's food was lost or wasted every year. Food loss and waste has become an issue of great public concern. The 2030 Agenda for Sustainable Development reflects the increased global awareness of the problem (FAO, 2011). Pervious researches have shown interest to the issue of food loss and waste, in many of them knowledge about food waste and its causes was investigated, the study of (Barr, 2007) stated that individuals with a good knowledge of the problems caused by food waste are more likely to be aware of food waste issue and avoid it. As for demographic and socio-economic variables, many previous studies stated that the higher the income of households, the higher the food wasted and vice versa with poorer households (Buzby and Guthrie, 2002, Brook Lyndhurst, 2007; Koivupuro et al., 2012). The study of Barr (2007) showed that females more careful to reduce waste than males, while other studies found that women waste more than men (Gallo, 1980; Buzby and Guthrie, 2002). This paper focuses on household food waste, which includes food purchased from shops or takeaways and consumed within the home, and it aims at exploring consumers' behavior towards food waste in Fayoum city, Egypt, through identifying the causes and degree of awareness of Food waste, Food Waste Reduction Practices, and the relationship of independent variables and the knowledge of food waste.

Materials and methods

<u>Sampling and Sample Size</u>

The information produced in this research is based on extensive fieldwork, A survey was collected in January 2021 where 200 respondents from Fayoum Governorate, Egypt. Who each one of them represents a family or household; they were randomly selected and interviewed online. A structured questionnaire was used to investigate whether respondents know about the concept of food waste or not, moreover, who is responsible for food purchasing and the amount of food wasted by the family. The reasons for food waste and the degree of awareness of food waste were investigated, food waste reduction practices. Finally, the impact of some explanatory variables such as Age, Sex, Education, Marital status, Job, Residence, having children under 14 years old, Monthly income, shopping responsibility, and shopping frequency on the knowledge or awareness of food waste.

<u>Data Analysis</u>

To describe socioeconomic characteristics of respondents, descriptive statistics was applied. A multinomial logistic model was applied to analyze factors determining food waste knowledge and awareness, in this model, the independent variables can be either dichotomous (i.e., binary) or continuous (i.e., interval or ratio in scale). Multinomial logistic regression is a simple extension of binary logistic regression that allows for more than two categories of the dependent or outcome variable (Starkweather and Moske, 2011, Mohamed and Mahmoud, 2019).

Multinomial logistic regression is a simple extension of binary logistic regression that allows for more than two categories of the dependent or outcome variable (Starkweather and Moske, 2011).

The empirical multinomial logistic model for this study is specified as (Sofoluwe. et al, 2011):

$Y_i = f(X1, X2, ..., X10)$

Where yi, the dependent variable is polychotomous and it is the knowledge or awareness of food waste; (yi) is defined as 1 for (yes I know or I am aware), 2 for (I know or I am aware to some extent), 3 for (I don't know). Xs are the explanatory variables, where: X1 = Age, X2 = Sex, X3= Education, X4= Marital status, X5= Job, X6= Residence, X7= having children under 14 years old, X8= Monthly income, X9= shopping responsibility, X10= shopping frequency.

Results and Discussion

Socioeconomic characteristics

Results showed that 41% of the respondents' age range of 30-39 year, 35% of 40-49 year, and 15% were between 20-29 year, while only 9% of the respondents were in the age of more than 50 years. 5% of respondents' Monthly household income were less than 2000 L.E, 29% 2000 L.E to less than 4000 L.E, 33.5% 4000 L.E to less than 7000 L.E, 32.5% more than 7000 L.E. Results showed that 49% of the respondents interviewed get rid of food debris throw put in basket, 34.5% Transfer the surplus as food for birds, and 16.5% recycle food. Results showed that 62% of the respondents interviewed were Male, 38% were Female. As for the level of education 63% of the respondents interviewed had obtained Postgraduate qualification, 33% had obtained bachelor's degree and 4% had obtained middle certification. 74% of the respondents interviewed are working in Governmental job, 16% free work, while 10% in Private sector. Referring to Residence 28% of respondents live in Rural, 72% live in urban. 59% of the respondents have knowledge of food waste, 30% maybe have knowledge of food waste while 11% don't have knowledge of food waste. 69% of the respondents buy their needs weekly and 31% daily. For source of food waste knowledge 57% was from culture, 32% from Education, 8% from Social Media, and 3% was from Family. As for Most of the food has a percentage of waste Vegetables it the first with 50%, second was baked goods with 36%.

Table 1. Respondents' Socioeconomic Characteristics

Variable		Frequency	Percent
Age	20-29	30	15
	30-39	82	41

Graph (1) Information about Knowledge of Food Waste

Causes of high Food waste

Respondents interviewed were asked to rank the Causes of high Food waste according to the degree of approval. Offers and discounts in the supermarket is considered a first Causes of high Food waste which ranked by respondents with a percentage of 65.7%, I drop off items that are nearing the expiration date comes in second place with 64.8%, while Package sizes for some commodities are large compared to the requirement come in third place with 64.7%, and Lack of awareness of the economic importance of Food waste comes in fourth place with 63.5%. Not planning ahead for the shopping process comes in fifth place with 60%, while as the family income increases, I buy large amounts of food comes in sixth place with 59.8%.

Table 2. Causes of high Food waste

Statements Or variable	Degree of approval										Total marks	Weighted percentage% = (Total marks/1000 (200*5))*100	Rank
	Strongly disagree		Moderately disagree		Neither agree nor disagree		Moderately agree		Strongly agree				
	F	%	F	%	F	%	F	%	F	%			
Offers and discounts in the supermarket	7	3.5	41	20.5	65	32.5	62	31	25	12.5	657	65.7	1

Degree of awareness of Food waste

Respondents interviewed were asked to rank the Degree of awareness Food waste according to the degree of approval. I think it's important that I don't waste food is considered a first Statements It indicates the degree of awareness of Food waste which ranked by Respondents with a percentage of 96.7%, Food waste creates economic damage to the society comes in second place with 92.5%, while Food waste is harmful to the environment come in third place with 86.2%, and I would probably throw away less food if I had more information about Damage of Food waste comes in fourth place with 71%. I think it is better to throw away leftovers rather than to risk of use comes in fifth place with 45%, while I am not worry about the amount of food thrown away comes in sixth place with 42.5%, while I am not worried about the cost of food that I throw away comes in seventh place with 39.7%, finally Food waste is not a problem for the environment as it is natural comes in sixth place with 37.5%.

Table 3. Degree of awareness of Food waste

Food Waste Reduction Practices

Respondents interviewed were asked to rank Food Waste Reduction Practices according to the degree of approval. Preparing a list of purchases is considered a first Practices of Food Waste Reduction which ranked by Respondents with a percentage of 91.4%, Implement good storage practices comes in second place with 89.8%, while Advance meal planning comes in third place with 88.7%, and Planning before the process of shopping comes in fourth place with 88%. To differentiate between the phrases "good before", "consumed before" comes in fifth place with 82.3%, while limited family budget comes in sixth place with 76.6%.

Table 4. Food Waste Reduction Practices

Statements Or variable	Degree of approval										Total marks	Weighted percentage% = (Total marks/1000 (200*5))*100	**Rank**
	Strongly disagree		Moderately disagree		Neither agree nor disagree		Moderately agree		Strongly agree

The relationship of independent variables and the knowledge of food waste

Chi-Square was used to test if there are significant differences between the independent variables and knowledge of food waste. Regarding age of respondents, the calculated output value of Chi-square ($\chi2$) is 11.86, significant at the 5% level of normality, this means, among respondents, there are significant differences between age groups regarding knowledge of food waste. The calculated output value of Chi-square ($\chi2$) for the variable Sex is 6.1, significant at the 5% level of normality which means, among respondents, there are significant differences between men and women regarding knowledge of food waste. Regarding job of respondents, the calculated output value of Chi-square ($\chi2$) is 11.97, significant at the 1% level of normality, which means, among respondents, there are significant differences between job categories and knowledge of food waste. Finally, value of Chi-square ($\chi2$) for the frequency of purchase is 10.79, significant at the 1% level of normality which means, among respondents, there are significant differences between those who buy products daily or weekly regarding knowledge of food waste.

Results of the multinomial logistic model

Holding all explanatory variables mentioned above except education level, the odds for a respondent with university degree of being knowing about the term food waste rather than those who don’t know about it are 0.166 times (83.4% higher than) the odds for a respondent with lower education. In other words, the relative log odds of being knowing what food waste versus no knowledge of it is will decrease by 1.8 if moving from the highest level of education (university degree) to the lowest level (high school). Holding all explanatory variables mentioned above except residence, the odds for a respondent who lives in urban areas of being know about the term food waste rather than those who don’t know about it are 0.335 times (66.5% higher than) the odds for a respondent lives in rural areas. In other words, the relative log odds of being knowing what food waste versus no knowledge of it is will decrease by 1.1 if living in rural areas rather than living in urban areas. Holding all explanatory variables mentioned above except marketing frequency, the odds for a respondent who buy products weekly of being know about the term food waste rather than those who don’t know about it are 0.315 times (68.5% higher than) the odds for a respondent who buy products every day. In other words, the relative log odds of being knowing what food waste versus no knowledge of it is will decrease by 1.15 if moving from buying weekly to buying every day. Holding all explanatory variables mentioned above except Sex, the odds for a female respondent being knowing about the term food waste to some extent rather than those who don’t know about it are 5.132 times (4132% higher than) the odds for a male respondent. In other words, the relative log odds of being knowing what food waste to some extent versus no knowledge of it is will increase by 1.6 if a respondent is a female rather than a male. Holding all explanatory variables mentioned above except residence, the odds for a respondent who lives in urban areas of being know about the term food waste to some extend rather than those who don't know about it are 0.250 times (75% higher than) the odds for a respondent lives in rural areas. In other words, the relative log odds of being knowing what food waste to some extend versus no knowledge of it is will decrease by 1.39 if living in rural areas rather than living in urban areas. Holding all explanatory variables mentioned above except marketing frequency, the odds for a respondent who buy products weekly of being know about the term food waste to some extend rather than those who don't know about it are 0.043 times (95.7% higher than) the odds for a respondent who buy products every day. In other words, the relative log odds of being knowing what food waste to some extend versus no knowledge of it is will decrease by 1.23 if moving from buying weekly to buying every day.

Conclusion

The study examines consumers' behavior towards food waste in Fayoum city, Egypt, through identifying the causes and degree of awareness of Food waste. The results revealed that offers and discounts in the supermarket and dropping off items that are nearing the expiration date comes, and package sizes for some commodities are large compared to the requirement are considered a main cause for food waste, according to respondents, Food waste creates economic damage to the society and it is harmful to the environment, and they probably will throw away less food if they had more information about damage of Food waste. Preparing a list of purchases and implement good storage practices are considered the most important practices of Food Waste reduction. The results revealed that there is a significant effect of education level, residence, shopping frequency, and sex on the knowledge of food waste. Accordingly, the study recommends organizing campaigns to promote food waste reduction among families and students at universities, encouraging food waste recycling for its environmental, social and economic importance and impacts.

Abstract

The current study provides potential expectations for the adverse effects of first wave of the COVID-19 on farmers in Turkey and also describes farmers' responses to mitigate the adverse effects pandemic on the agricultural sector. The study is based on telephone surveys with 2125 farmers in 22 provinces during April and May in 2020 in Turkey. This communication illustrates the possible implications and expected outcomes of the outbreak of coronavirus. Multistage cluster sampling was used as the sampling method in the study. Simple descriptive statistics and Likert scale averages were used to better understand smallholder farmer perceptions regarding the anticipated impacts of the pandemic. The results showed that 61.98% of smallholder farmers would not make any changes in their current agricultural production activities due to Covid-19 restrictions, while 32.14% stated that they were undecided, and another 5.88% reported they were willing to make changes. We identified contrasting responses by the agricultural production mostly driven in animal and crop production. In addition, it was determined that production costs increased in agricultural enterprises due to the excessive increase in input prices. It has been also concluded that the transition of farmers from animal and crop production to other production systems will accelerate in cases. Therefore, the decisions taken by policymakers to handle pandemic's direct and indirect effects can help smallholder farmers draw lessons on how to cope with input prices.

Introduction

The dangerous COVID-19 pandemic, which emerged in Wuhan, China on 1 December 2019 and spread rapidly, adversely affected human life and economic areas all over the world (World Health Organization, 2020). Therefore, as a result of the high number of cases and deaths that emerged after the spread rate and strength of the COVID-19 virus, partial restrictions on economic and social life, and then unprecedented limitations in human history were introduced (Huss et al., 2021; Kumar et al., 2021). As a result of the COVID-19 pandemic and quarantine measures, the whole economic activities, including agriculture, have been significantly affected (Hossain, 2020; Inegbedion, 2020). Pu and Zhong (2020) reported that agricultural production inputs were blocked as a result of COVID-19 restrictions and thus production cycles were disrupted. This has caused many risks in agricultural production due to the COVID-19 pandemic. It has been demonstrated by various studies that it is necessary to be prepared against these risks in the coming years (FAO, 2020; Yoshida and Yagi, 2021). It was stated that if these measures were not taken, there would be lower agricultural production and further increases in food prices in the future (Cevher et al., 2021; Obayelu et al., 2021). World agricultural policy experts reported that the COVID-19 pandemic was causing major pressures on agricultural production (OECD, 2020). They also stated that most of these pressures were due to the policies implemented by the governments to contain the spread of the pandemic (Fei et al., 2020; FAO, 2020). It has been reported in a similiar study that COVID-19 caused a decrease in farmer income and an increase in rural poverty due to its effects on agricultural production branches (Xiao and Torok, 2020; Zhang et al. 2020). On the other hand, many countries have taken quick decisions to prevent COVID-19 restrictions, and thanks to these decisions, they have reported that there is no significant food shortage in the world yet (Gray 2020; Laborde et al., 2020).

The first confirmed case of COVID-19 in Turkey emerged on 28 February 2020, after which the first case of death was reported on March 28, 2020. Therefore, restrictive decisions were taken on 23 March 2020 in order to prevent the COVID-19 pandemic by the Turkish Ministry of Internal Affairs. In order to reduce the negative impact of the decisions taken on agriculture, Turkish Republic (TR) Ministry of Internal Affairs issued a circular on 25 March 25 2020. Thanks to this circular, it was possible to carry out agricultural production without interruption. Turkey has 23.1 million hectares of usable agricultural land. In this respect, agriculture has a multifaceted effect on Turkey's economic and social development. This multifaceted effect is quite remarkable in terms of providing the country's people with food, contributing to employment, continuing agricultural exports, providing raw materials to industry and contributing to national income (Cevher et al., 2021). Therefore, it is important to investigate the effects of the COVID-19 pandemic on the Turkish agricultural economy. Although there are many studies on the impact of the COVID-19 pandemic on agriculture in Turkey until the date of the article was written (Akın et al., 2020; Ceylan and Özkan, 2020; Akbudak and Özgür 2021), there are almost no field studies examining and showing the effect of the restrictions applied for the COVID-19 pandemic on agricultural production branches. For this reason, it is thought that our findings obtained in the study can be a role model in determining the policies to be implemented in the face of similar risks that may be encountered in the future of the COVID-19 pandemic experience and struggle. With this study, it was aimed to determine the effect of the first restriction measures taken to prevent the COVID-19 pandemic in Turkey on agricultural production branches.

Material and Method

The primary data of this study was obtained by telephone survey. Data has been collected from the seven regions namely Eastern Anatolia, Central Anatolia, Black Sea, Mediterranean, Aegean, Marmara, and Southeastern Anatolia in Turkey. The survey was carried out in selected 22 cities in seven geographical regions of Turkey. Survey studies in the research area were carried out between May-June 2020. Cities with a high share in terms of the amount of plant and animal production in each region were selected. Convenience sampling method was used in data collection. Pandemic conditions were influential in the selection decision of this sampling method. According to Acharya et al. (2013), convenience sampling is the most commonly used sampling method. The sample is chosen on the basis of the convenience of the researcher. Farmers (2125) were interviewed by telephone survey. Before participating in the telephone survey, the farmers were asked whether they had consented to participate or not. The design of the questionnaire used in the survey is shown in Table 1.

Table 1. Summary of the survey design and questions

Section Name	Question	Question Type(s)	Possible Responses
Consent	Q1.	Willingness to participate	Will participate/won't
Demographics	Q2	Relationship and activity with farmer organisations; age; gender; district; household size	Yes/no; amount of time; male, female, prefer not to say; age range; open-ended; household size
Farming Systems	Q3	Which best describes your farming system	Crops, Livestock, Mixed farming
The tendency of farmers to change in agricultural production during the pandemic period	Q4	Do you have a tendency to make a change in your agricultural production decision due to pandemic conditions?	Yes, No, Undecided
The level of participation of farmers in possible risks and uncertainties that may affect agricultural production during the pandemic period	Q5	Increase in input costs, Insufficient government supports, Problems in product sales, Problems in labor supply, Problem of access to agricultural land	1: Strongly disagree - 5: Strongly agree

Opinions of the farmers on possible risks and uncertainties that may affect agricultural production during the pandemic were presented with 5-point Likert scale averages. In this study, non-parametric tests were used to determine whether the analyzed data differed among farmers engaged in crop, animal and mixed production. For this purpose, Chi-square independence test was applied for the data obtained by counting and Kruskal-Wallis test was applied for the means. IBM SPSS 22 package program was used in the analysis of the data.

Results and Discussion

One of the most important questions to be answered is to what extent the COVID-19 pandemic can affect the farmers' agricultural production activities. For this purpose, the farmers were asked whether they would make any changes in their agricultural production during the pandemic period or not. Majority of the farmers (61.98%) stated that they would not make a change in their basic agricultural production activities, 32.14% of the farmers were undecided about making changes and 5.88% of the farmers stated that they would make changes (Table 2). The farmers who were undecided about making changes in the basic agricultural production branch stated that they would decide according to input access and changes in input prices. Middendorf et al. (2021) reported that due to the COVID-19 pandemic, the farmers reduced their production and they would turn to different production branches according to the change in the input prices. In another study, they mentioned that 30% of farmers would turn to other activities on their farms as a risk management strategy due to the COVID-19 pandemic (Yoshida and Yagi, 2021). According to Pan et al. (2020) identified that COVID-19 did not have a significant impact on grain production and the change in grain branch would be difficult. In a similar study by Tougeron and Hance (2021) that the fruit and vegetable sector in Europe was the most affected agricultural branch during the pandemic period and that the change from these production branches would be higher.

Table 2. Tendency of farmers to make changes in agricultural production during the COVID-19 Pandemic period

Tendency	Herbal production		Livestock		Mixed production		General		χ^2 Value	p Value
	n	%	n	%	n	%	n	%		
Doesn't think change	1040	68.69	65	45.14	212	45.40	1317	61.98	127.940	0.000*
Undecided on change	377	24.90	75	52.08	231	49.46	683	32.14		
Thinking of change	97	6.41	4	2.78	24	5.14	125	5.88		
Total	1514	100.0	144	100.0	467	100.00	2125	100.0		

*Statistically significant at 1% significance level

At the first beginning of the COVID-19 pandemic, the tendency of farmers to make changes in agricultural production branches was examined separately in terms of agricultural enterprises engaged in crop, animal and mixed production. It has been determined that there is a statistically significant difference of opinion on whether or not to make changes among the agricultural production branches examined. A significant portion (68.69%) of the farmers engaged in crop production stated that they would not make any changes in their agricultural production activities. However; The ratio of those who are undecided about changes in agricultural enterprises with animal and mixed production was found to be around 50%. It has been determined that the intensive use of labor in animal production activities is effective on this result. Vidaurreta et al. (2020) reported that although the COVID-19 pandemic had negative effects on livestock, its impact on employment was not significant. Zhang (2020) stated that animal husbandry was under serious pressure due to the shortage of agricultural labor and raw materials and insufficient animal feed during the epidemic period. In order to reduce these negative effects, it is important to create a network that connects buyers and sellers through a digital platform in order to organize them. Thus, farmers can have faster access to inputs and market information.

According to the results of this study, it has been concluded that it is unlikely that farmers will make a change in their basic production activities in a short time. It has been determined that farmers' habits from the past, soil and climatic conditions are effective in this situation. Gerasimov et al. (2020) reported in their study that organic tea producers did not make any changes in their production decisions due to the COVID-19 outbreak. Pu and Zhong (2020) stated that agricultural production cycles were disrupted and production capacity was weakened due to COVID-19 restrictions, which accelerated the process of making changes in agricultural production branches. During the COVID-19 epidemic in Turkey, grain producers showed less behavioral changes than producers in other branches. This situation is thought to have been influenced by the government's announcement of grain prices right after the COVID-19 outbreak. Therefore, it is thought that it would be beneficial for the government to announce the production and price policies of agricultural products before the production period. Thus, it will be possible to prevent negative behavior changes in the decisions of the farmers regarding the branches of production, albeit partially.

In this study, farmers' views on possible risks and uncertainties that may affect agricultural production during the COVID-19 pandemic period were also examined. In this context, some suggestions were directed to the farmers during the survey study. The level of farmers' participation in these propositions is shown in Table 3. According to likert scale averages, the most worrying issue for the farmers during the COVID-19 pandemic period is the possibility of insufficient agricultural support. Therefore, it can be said that it would be beneficial to reconsider agricultural support policies during the COVID-19 pandemic. The possibility of rising input costs is the second most important issue for the farmers during the pandemic period. Therefore, it may be beneficial to facilitate border procedures on key inputs such as fertilizers, veterinary drugs and pesticides to prevent rapid rise in agricultural input prices. The third issue that farmers were most concerned about was the possibility of the problems in the sales of the products produced. In this context, access to the buyer and logistics are seen as the most important problems. According to the farmers in our country, finding labor force during the pandemic period was not seen as a very important problem. In this situation, 80.7% of agricultural enterprises in Turkey has an impact on the small business structure (TurkStat, 2019). It can be said that it is easier to obtain labor from neighbors and relatives in such enterprises. However, it is known that the level of social solidarity, neighborly relations and cooperation is high in Turkey (Cevher et al., 2021). In conclusion, it can be said that all of these factors contribute to the reduction of behavioral change on agricultural production. Bochtis et al. (2020) In a post-COVID-19 study, they reported that the annual income of 54% of agricultural workers is at medium and high risk. In our study findings, this risk factor was found to be 17.5%. It can be said that the COVID-19 measures taken by the government were effective in keeping this result at a low level. COVID-19 has impacted the agricultural workforce, especially the pool of seasonal agricultural workers. These are often migrant workers typically employed in the crop harvesting, who use highly dexterous and physical skills (Benos et al., 2020; Mitaritonna and Ragot 2020). These consequences have particularly affected vegetable and fruit producers as well as garden nurseries and horticulture (OECD, 2020). Labor supply constraints could stimulate innovations resulting in further mechanisation within the fruit and vegetables and meatpacking sectors (Orden, 2020).

Farmers' views on possible risks and uncertainties that may affect agricultural production during the pandemic were also examined within the scope of agricultural enterprises engaged in crop, animal and mixed production. According to the Kruskal-Wallis test, a statistically significant difference was found between the responses of the three groups to the statements ($p<0.01$). The most important problem of the farmers engaged in the crop production was the support. It was determined that the sudden increase in fertilizer and crop medicine prices had an effect on this situation. In the enterprises engaged in animal production and mixed production, the concern of increasing input costs came to the fore. The most important cost element of animal production enterprises was feed costs. Owners of livestock farms thought that there would be a decrease in the production of forage crops and this would be reflected in feed prices. The fact that the number of farmers benefiting from subsidies in crop production is quite high, causes these farmers to be more sensitive to subsidies. In the initial period of the pandemic, the livestock industry was severely damaged and farmers suffered significant economic losses due to the COVID-19 measures in transportation to feed mills, animal shipments and slaughterhouses. In order to prevent this negative situation, the government soon published regulations stating that animal producers are exempt from the restriction. This enabled the producers to return to their normal production activities, thus eliminating further economic losses. As Thilmany et al. (2021) reported that animal production activities were adversely affected due to COVID-19.

In order to reduce the negative effects of the Covid-19 pandemic and similar epidemics, especially agricultural cooperatives and local municipalities should be more involved in the production, distribution and consumption system. This will shorten the supply chains between producers and consumers. This will contribute to the better evaluation of the produced product and the consumer to obtain products at an affordable price. Our findings show that especially vegetable, fruit and livestock farmers are generally struggling against short-term shocks, accepting lower prices to maintain their sales, interruptions in the flow of products to consumers, and thus increasing food prices in the country. Therefore, it has made it mandatory for governments to develop new policies against COVID-19 and future similar pandemics. In this study, important data are presented for the formation of agricultural policies to prevent the negative effects in agricultural production activities in case of COVID-19 pandemic.

Table 3. The level of participation of farmers in possible risks and uncertainties that may affect agricultural production during the pandemic period

Statements	Herbal production		Livestock		Mixed production		General		K-W test p value
	$\bar{x}$	Std Dev	$\bar{x}$	Std Dev	$\bar{x}$	Std Dev	$\bar{x}$	Std Dev

*Statistically significant at 1% significance level

Conclusions

Study results reflect perceptions and concerns of the COVID-19 pandemic in agricultural systems. It shows the necessity of developing new agricultural policies by addressing these concerns. COVID-19 restrictions have been effective in the increase in input prices, the disruption of livestock trade in animal husbandry and the increase in feed prices. Even if the impact of the pandemic decreases in the upcoming period, it is important to make the agricultural sector more resistant to pandemics and similar shocks. The fact that the epidemic caused sudden and rapid increases in agricultural input prices seriously threatens agricultural production. It does not seem possible for the farmer to make changes between agricultural production systems in a short time. It has been concluded that if the effect of the pandemic lasts for a long time and the necessary agricultural policies are not taken, there will be more transitions to other agricultural systems, especially in animal and vegetable production. Our results show that restrictions will not adversely affect agricultural production, disrupt production cycles and ultimately undermine productive capacity. However, it has been concluded that if the sudden increase in agricultural production input costs cannot be prevented, there will be transitions between agricultural production branches and production amounts will decrease. It is expected that these study experiences in Turkey will make suggestions to other countries, especially developing countries, which have serious problems in agricultural production during the pandemic period.

Abstract

Vegetable production in the Republic of Serbia is carried out on about 130,000 hectares, which is approximately 3.5% of total plant production. Succeeding the production of potatoes, tomatoes and peppers, cabbage is one of the most common vegetable crops grown in the Republic of Serbia. According to the Statistical Office of the Republic of Serbia, cabbage production is in the same group with kale and in 2019 both crops were grown on about 8,000 hectares in the Republic of Serbia, while in the analyzed period these crops were mostly grown on 11,000 hectares in 2015. The aim of this paper is to present the economic and financial aspects of cabbage production in farms in the Republic of Serbia in the period 2015 and 2019 based on data from the Statistical Office of the Republic of Serbia and the income and expenses survey on the family farms, which represent calculations based on variable costs, conducted by the Institute for the Science Application in Agriculture. The data for analysis have been collected from 90 farms, which are also a representative sample, due cabbage production is the dominant production on these farms. The paper also presents the influence of prices and yields on gross margin amounts in cabbage production through sensitivity analysis. The obtained results indicate a constant decrease in the amount of gross margins in cabbage production in the analyzed period, due to a significant variation in the selling price of cabbage. A significant influence of the price and yield on changes in gross margins in cabbage production was confirmed by the data obtained by sensitivity analysis.

Keywords: *gross margin, sensitivity analysis, cabbage, family farms, Serbia.*

Introduction

Vegetables are produced in almost all regions in the Republic of Serbia, comprising different crops grown. Vegetable crops are grown both in an open field and in enclosed space, depending on climate conditions, with open-field production being dominant (Ljiljanić and Rajić, 2018). Vegetable production is a very intensive and profitable branch of agriculture (Novković et al., 2012). As such, it can significantly affect the development of the agricultural sector, but this type of production also depends very much on the level of total agricultural development (Paunović, 2016). Global cabbage production amounts to approximately 71 million tones and it is the seventh largest vegetable production. Cabbage production has been increasing over the last couple of years, not only due to the growth in the global population but also due to the change in eating habits. The total areas under cabbage in the world amount to about 2.5 million hectares. The largest cabbage producers are China, India, Russia, Japan and the Republic of Korea (Petrović, 2020). The cabbage is a very important vegetable crop in the Republic of Serbia, since it is substantially used in human consumption and therefore grown on large areas. The achieved level of cabbage production has been significantly affected by high consumption (around 20 kg per capita per year). High consumption per capita is due to relatively low market price for cabbage, when compared to the price for other vegetables (Vlahović, 2015). The average area under cabbage in the analyzed period in the Republic of Serbia was about 9,650 ha with the average yield of about 25 t/ha. The main cabbage producers in Serbia are family farms. The cabbage is mostly grown in the region of Šumadija and Western Serbia, where 42% of total cabbage production is carried out, followed by the region of Southern and Eastern Serbia with 25%, Vojvodina autonomous province 24% and the region of the city of Belgrade, where 9% of total cabbage production is carried out (Červenski and Medić-Pap, 2018). The aim of this paper is to present the economic and financial aspects of cabbage production in Serbian farms in the period 2015-2019. The authors used the data retrieved from the Statistical Office of the Republic of Serbia and the data on income and expenses obtained from the survey on family farms analyzed by the Institute for the Science Application in Agriculture.

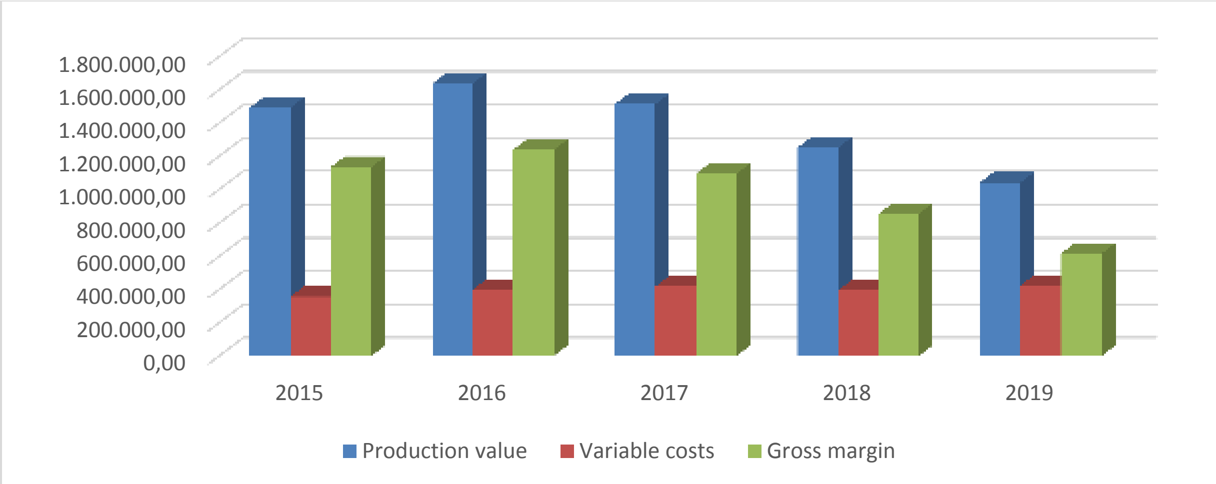
Material and Methods

This research paper contains the data from a survey on gross margins conducted by the Institute of Science Application in Agriculture for the period 2015-2019. For the purpose of this paper, 90 survey questionnaires were analyzed, all collected from family farms on which cabbage production is dominant. The family farms had been selected by the Institute for Science Application in Agriculture to be surveyed by the advisors from the agricultural advisory services of Serbia. The survey was carried out face-to-face on those farms. The main criteria for farm selection was cabbage production as the dominant type production. Due to the fruitful collaboration between the advisors and farmers in the previous years, the survey was carried out without any problems.

Financial indicators are the universal indicators of profitability of every production. For family farms, which are the subject-matter of this analysis, calculations based on variable costs are mostly used when determine the optimal scope and structure of farm production, and the indicators obtained from such calculation can be a good financial instrument for making business decisions on a farm (Gogić, 2014). Using a calculation based on variable costs, the following basic financial business indicators are determined: the value of production, variable costs and gross margin. The business result is expressed as a gross margin, which is a difference between the value of production and variable costs (Savić et al, 2020). A gross margin is a quick and efficient indicator for comparing different lines of production on a family farm and choosing the most profitable one (Andrić, 1998; Tomić et al., 2013). The aim of this paper is to show financial indicators of cabbage production by calculating them based on variable costs.

Results and Discussion

Given the calculations based on variable costs of cabbage production on family farms in the Republic of Serbia in the period 2015-2019, the average annual value of production, variable costs and gross margin were calculated.



Source: Authors' analysis based on the data from the selected family farms surveyed by the Institute of Science Application in Agriculture

Chart 1: Movement of financial indicators of cabbage production, based on a variable cost calculation in the period 2015-2019 (RSD/[41]ha)

Chart 1 shows the movement of financial indicators of cabbage production based on variable cost calculations in the period 2015-2019, calculated for 1 ha. Given the Chart 1, it can be concluded that the highest value of production was achieved in 2016, together with the highest gross margin, whereas the highest variable costs were recorded in 2019. The lowest value of production and gross margin were recorded in 2019, whereas the lowest variable costs were achieved in 2015.

Table 1. Financial indicators of cabbage production in the period 2015-2019 (calculated for 1 ha)

Year	2015	2016	2017	2018	2019
Value of production (RSD)	1,491,503.00	1,637,333.33	1,512,666.67	1,251,571.43	1,040,320.00
BI* (%)	-	109.78	101.42	83.91	69.75
CI**(%)	-	109.78	92.39	82.74	83.12
Variable costs (RSD)	356,326.25	398,640.83	417,882.50	394,497.07	423,706.90
BI* (%)	-	111.88	117.28	110.71	118.91
CI**(%)	-	111.88	104.83	94.40	107.40
Gross margin (RSD)	1,135,176.75	1,238,692.50	1,094,784.17	857,074.36	616,613.10
BI* (%)	-	109.12	96.44	75.50	54.32
CI**(%)	-	109.12	88.38	78.29	71.94
Share of gross margin in the value of production (%)	76.11	75.65	72.37	68.48	59.27

*BI – base indices
**CI – chained indices
Source: Authors' analysis based on the data from the selected family farms surveyed by the Institute of Science Application in Agriculture

[41] RSD(Serbian dinar) is the official currency code for the currency of the Republic of Serbia

Table 1 shows the most significant financial indicators from a variable cost calculation of cabbage production in the period 2015-2019 (calculated for 1 ha). The highest value of production was recorded in 2016, amounting to 1,637,333.33 RSD/ha, whereas the lowest value was recorded in 2019, and it amounted to 1,040,320.00 RSD/ha. Given the indicators calculated based on base and chained indices, it can be seen that in 2016 the value of production increased by 9.78% compared to 2015, which is the highest increase in the value of production in the period in question. In 2017, the value of production was 1.42% higher than in the base year, but 7.61% lower than in the previous year. The value of production kept decreasing in the following two years. In 2018, the value of production decreased by about 17% compared to the previous year (2017) and base year (2015). The lowest value of production was recorded in 2019, being 30.25% lower than in the base year and 16.88% lower than in 2018.
Unlike the value of production that declined over the analyzed years, the variable costs of cabbage production mostly increased. The lowest variable costs (356,326.25 RSD/ha) were achieved in 2015, and the highest (423,706.90 RSD/ha) in 2019. The base and chained indices have shown that the variable costs in 2016 were 11.88% higher than in 2015, whereas in 2017 there was an increase of 17.28% in the variable costs compared to the base year, and of 4.83% compared to the previous year. In 2018 the variable costs were 10.71% higher than in 2015 and 5.60% lower than in the previous year. In 2019 the variable costs were highest, 18.91% higher than in the base year and 7.40% higher than in the previous (2018) year.
The highest gross margin was 1,238,692.50 RSD/ha and it was recorded in 2016, whereas in 2015 and 2017 it was slightly lower. In 2018 the gross margin was lower and in 2019 it was lowest, amounting to 616,613.10 RSD/ha. The indicators obtained from a calculation of base indices have shown that the gross margin mostly decreased over the analyzed years. In 2016 the gross margin was 9.12% higher than in the base year. The amount of the gross margin in 2017 was 5.56% lower than in the base year, and 24.50% lower than in 2018. The lowest gross margin was recorded in 2019, almost half as much as the gross margin achieved in the base year. The indicators obtained from a calculation of chained indices have shown a continuous decrease in gross margin over the analyzed years, except in 2016, when there was an increase of 9.12% compared to the previous year. In 2017 the gross margin was about 12% lower than in 2016, whereas in 2018 it was about 22% lower than in 2017. The largest decline in gross margin over the analyzed years was recorded in 2019, when it was about 28.06% lower than in 2018.
The indicator of farm profitability expressed as the share of gross margin in the value of production was highest in 2015 (76.11%), and lowest in 2019 (59.27%). In 2016 the share of gross margin was slightly smaller than in 2015 (75.65%). In 2017, it amounted to 72.37%, and in 2018 it was 68.48%.
The sale price for the cabbage greatly affected the value of production and, consequently, the gross margin, given that this price was highest in the year when the value of production and gross margin were highest, and then declined in the following years. Cabbage prices ranged from 16.80 to 23.75 RSD/kg. The lowest price was recorded in 2019 (16.80 RSD/kg), and the highest price in 2015 (23.75 RSD/kg). In 2016 and 2017 the cabbage price amounted to about 22.5 RSD/kg, and in 2018 it was 19.43 RSD/kg. One of the elements that affect the value of production and, consequently, the gross margin of cabbage production is the sale price for cabbage. Given that cabbage yield and price significantly affect gross margin, a sensitivity analysis was conducted. The sensitivity analysis of gross margin in cabbage production in Serbia in the period 2015-2019 has shown how the gross margin is affected by changes in the factors that form the value of production. It was analyzed how changes in prices and yields affect the

change in gross margin. The sensitivity analysis took into consideration absolute changes in prices and yields if the parameters in question change for 10% and 20%.
Table 2 shows the sensitivity analysis of gross margin in cabbage production on changes in cabbage price and yield in the period 2015-2019, based on a five-year average of the price, yield and gross margin achieved on the surveyed farms.

Table 2. Sensitivity analysis of gross margin in cabbage production on changes in cabbage price and yield

Yield (kg/ha)		Price (RSD/kg)				
		-20%	-10%	Average	+10%	+20%
		16.90	19.02	21.13	23.24	25.36
-20%	50,883.05	504,646.72	612,162.60	719,678.48	827,194.36	934,710.24
-10%	57,243.43	612,162.60	733,117.96	854,073.33	975,028.69	1,095,984.06
Average	63,603.81	719,678.48	854,073.33	988,468.18	1,122,863.03	1,257,257.88
+10%	69,964.19	827,194.36	975,028.69	1,122,863.03	1,270,697.37	1,418,531.70
+20%	76,324.57	934,710.24	1,095,984.06	1,257,257.88	1,418,531.70	1,579,805.52

Source: Authors' analysis based on the data from the selected family farms surveyed by the Institute of Science Application in Agriculture

The average cabbage price in the analyzed period was 21.13 RSD/kg, the average yield was 63,603.81 kg/ha, whereas the average gross margin in cabbage production was 988,468.18 RSD/ha. If cabbage prices and yields decreased by 20%, it would lead to a significant decrease in gross margin (for about 49%), while an increase of 20% in prices and yields would result in an increase of about 60% in gross margin. It can be concluded that changes in cabbage prices and yields significantly affect gross margin in cabbage production.

Conclusion

The areas under cabbage have been shrinking, consequently leading to a decline in total cabbage production. A large decline in cabbage production happened in 2019, when along with shrinking of areas under cabbage (about 2,000 ha less than in 2016) there was also a decrease in the average yield for about 3 tones/ha. The average cabbage yield in the analyzed period was about 26 tones/ha, and in 2019 it was 22.40 tones/ha. The gross margin of the surveyed farms, where cabbage production is dominant, also decreased significantly over the analyzed period. It averaged about 1,000,000 RSD/ha, and in 2019 it was slightly more than 600,000 RSD/ha. This decrease in the gross margin was mostly due to a decrease in the average yield and price and an increase in the variable costs. The sensitivity analysis of gross margin in cabbage production on changes in cabbage price and yield has determined that an increase of 20% in prices and yields would result in about 60% higher gross margin, while a decrease of 20% in prices and yields would result in about 50% lower gross margin.

FORESTRY AND AGRO-FORESTRY

NORTHERN RED OAK (*QUERCUS RUBRA L.*) IN BELGRADE

Dragana DRAZIC*, Milorad VESELINOVIC, Nevena CULE, Suzana MITROVIC, Vlado COKESA

Institute of Forestry, Belgrade, Serbia

Abstract

In order to properly select plant species, especially dendroflora as the basis of different categories of open green spaces, of great importance is to know the characteristics of development, vitality and decorativeness of already grown specimens in similar environmental conditions. One of the very interesting species for Belgrade region is northern red oak (*Q. rubra* L.). According to the experience from Serbia, *Q.rubra* is easily adapted to different climatic and other conditions. It is suitable for habitats of sessile and common hornbeam forests, mountain beech forests and forests of Hungarian and Turkey oaks. It is relatively fast growing, tolerant on soil conditions. It does not tolerate stagnant water and floods, as also dry land. It tolerates shade better than native oaks. The species is resistant to low temperatures and polluted urban environments. In the area of Belgrade it is often planted in some urban forests, but also on different categories of open green spaces. The paper presents the researching results of development, vitality and decorativity of this species at five sites, in different environmental conditions.

Keywords: *Quercus rubra L., Belgrade, urban conditions, development, landscaping.*

Introduction

Northern red oak (*Quercus rubra* L., syn. = *Quercus rubra* var. *borealis* (Michx.f.) Farw. = *Quercus borealis* F. Mich x. = *Quercus borealis* (var.) *maxima* Sarg. = *Quercus maxima* Ashe. = *Quercus rubra* Du Roi non L.) is a medium to high deciduous tree. Belongs to the family Fagaceae, genus Quercus, secc. (Subgenus) Erythrobalanus Spach. The genus includes a large number of deciduous and evergreen trees and several shrub species, spreaded out from the cold zone to the tropical regions.

Q. rubra from nature occurs in a wide range in eastern North America, across the eastern United States and southeastern Canada, and up to 1000 m in height (Little, Elbert L., Jr. 1979) Extent of occurrence (EOO) is estimated at over 4.150.000 km^2. According to IUCN (2017), the total population size of *Quercus rubra* has not been quantified, but considering its occurrence in wide geographical range, it is estimated that the number of adult specimens of this species is probably very large. In the southern part of its natural occurrence, the number has slightly decreased. However, this is of insignificant extent and is unlikely to have the effect of significantly reducing the population of *Q. rubra* in the near future. It can be concluded that *Q. rubra* is a stable species and, according to NS (Nature Serve), it is listed as a globally safe (G5) species, and that the current population trend is stable (Haavik, L.J., Stahle, D.W., Stephen, F.M., 2011).

This species is one of the tallest and fastest growing from the group of red oaks, as well as oaks in general. It usually reaches a height of about 30 m. It is characterized by a straight, cylindrical trunk, up to 2 meters in diameter and a large wide rounded crown. The bark of the trunk is smooth and gray at a young age, later becoming thickened, with shallow fissures. Young twigs are reddish-brown; the buds are large, ovoid, reddish-brown, hairy scales. The leaves are alternate, simple, oblong or inversely ovoid, 12-20 cm long, 10-12 cm wide, cut into 7-11 lobes with sharper edges. On the face are shiny, light green, with tufts of hairs in the leaf nerves axils. The change in the color of the leaves in the fall is characteristical for this species. The color goes from green to different shades of brown and red, which makes this species very attractive in the autumn aspect. The leaves decompose better and faster than our oak species. Male flowers are yellowish green, clustered in up to 10 cm long, hanging tassels. They bloom at the same time as leafing, in late May. The fruit is a roundish acorn, 1.5-2.5 cm long, 1-2 cm wide, shallowly placed in a scaly cap. It matures 18 months after pollination. *Quercus rubra* has a wide ecological range, but it is most commonly found in a variety of moderately moist habitats, including rich forests, arid slopes, rocky habitats, sandy plains and at the edges of floodplains. It is a dominant species in a wide range of communities such as mixed mesophilic forests, pine-oak communities and south-exposed forests in the lower parts of the mountains. Species that occur with red oak are: *Quercus alba* L., *Quercus velutina* Lam., *Pinus strobus* L., *Fagus grandifolia* Ehrh. and *Acer* spp.

This North American exotic species was introduced to Europe in 1691. and currently covers over 350,000 ha, being found all over the continent, except the coldest part of Scandinavia (Nicolescu, VN et all., 2018). It is also often grown as an ornamental tree in the parks. Of the varieties, the most common is *Q. rubra* var. *maxima*, more rarely *Quercus rubra* 'Aurea'.

According to the experience from Serbia, *Q.rubra* is easily adapted to different climatic and habitat conditions (Drazic et al., 2004., Vuckovic et al., 2008). It is suitable for habitats of sessile and common hornbeam forests, mountain beech forests and forests of Hungarian and Turkey oaks. It tolerates low temperatures and thrives on poor soils that can be acidic, but avoids limestone. It is best suited to sandy loam, especially fresh. It does not tolerate stagnant water and floods, as also dry land. The species is resistant to low temperatures and polluted conditions of urban environments. It is relatively fast growing, tolerates shade, tolerant of soil conditions, and thrives on poor soils as well as acid reaction of soils, though sandy and fresh soils are most suitable. It does not tolerate flooded but also dry habitats (Hirons, A.D. and Sjöman, H., 2019. Due to the quality hardwood, it is used for interior, furniture and flooring (The values of North Carolina Trees, 1995).

Material and Methods

Selecting species for design and establishment new and reconstruction of already existing different types of urban green spaces, requires a good knowledge of not only the general ecological, but also the micro-habitat conditions of the environment. In the urban environment, all important parameters of climate, soil and habitat type have been significantly changed by anthropogenic activity, especially by the increased content of various harmful substances in air, soil and water. The climate of the city significantly differs from the climate of the surrounding area, which is a consequence of the different radiation and the water balances of the city and its surroundings. The consequence of these differences is a stronger heating of the city area and changes of some other elements such as wind, fog and smog. Furthermore, differences also occur in different parts of the city depending on its topography and structure. Air pollution has also a significant influence on climate modification in the city.

The paper presents the following climatic factors: air temperatures and their amplitudes, precipitation, relative air humidity, fog and smog; The characteristics of the localities where the red oak trees were analyzed are shown: altitude, distance from roads, soil and habitat type; The mean diameter values (cm), total height, trunk height and crown height (m) were analyzed and a general assessment of vitality and decorativeness (1-5) was given; The current annual diameter increment, the average diameter increment and the development of the diameter over a period of 15 years has been analyzed; The content of toxic metals in the wood was also investigated; Based on all of the above, recommendations for the further use of this species in Belgrade and similar environmental conditions has given.

Results and Discussion

Climatic characteristics of Belgrade region. Belgrade and its surroundings are characterized by a temperate continental climate with an average annual temperature of 11.6ºC. The coldest month is February (mean temperature 0.0ºC) and the warmest month is July (mean temperature 22.1ºC). An important climatic characteristic is the difference between winter and summer temperatures. January average temperature is 0.0ºC, while the average July temperature is 22.1º. The annual amplitude of the temperature, the difference between the warmest and coldest month was 22.1ºC. There are significant differences between urban and rural conditions due to the heavy morning frosts that occur around the city, while there are none in the city. The spatial distribution of temperatures is determined by the combined influence of the topography and heat island effect of the city. The absolute daily minimum is -26.2ºC and the absolute daily maximum is 41.8ºC. According to the classification (The degree of continentality, Gorcinski), the area of Belgrade is with a value for K = 33.6, at the lower boundary of the continental type. The average air temperature of the vegetation period is 18.3°C, the maximum mean temperature is 22.3°C, while the minimum mean temperature is 14.2°C. The average annual rainfall is 668 liters per square meter. The annual flow of rainfall has predominantly continental-type characteristics, with maximum in summer (June) and minimum in winter half-year. Although Belgrade is quite deep in the continent, it also has some characteristics of a maritime type. Thus, Belgrade has two highs and two lows in the annual rainfall. The average amount of precipitation in the vegetation period is 436 mm, i.e. 65% of the average annual amount. The average annual relative humidity is 70%. July is the month with the lowest humidity (mean relative humidity 62.7%) and the month with the highest humidity is December (81%). The average number of bright days a year is 67, and cloudy 111. The basic information about localities. The following table shows localities in the wider Belgrade area with altitude data (m), distances from roads (m), land type and habitats where existing northern red oaks were analyzed.

Table 1. Overview of localities with basic information

No.	Location	Altitude (m)	Distance from roads (m)	Soil type	Habitat type
1.	Cerak-Vigradi	158	5	Eutric cambisol	*Quercetum frainetto cerris* Rud.
2.	Zeleznik	135	200	Eutric cambisol	*Quercetum frainetto cerris* Rud.
3.	Sremčica	170	3	Eutric cambisol	*Quercetum frainetto cerris* Rud.

No.	Location	Altitude (m)	Distance from roads (m)	Soil type	Habitat type
4.	Baba Velka	265	1500	Eutric cambisol	*Quercetum frainetto cerris* Rud.
5.	Ibar motorway	150	30	Eutric cambisol	*Quercetum frainetto cerris* Rud.
6.	Highway Bg- Zg	80	15	Chernozem	*Carpino quercetum roboris* Anić
7.	Open pit coal mine "Kolubara"	185	-	Deposols	Antrophogenically degraded

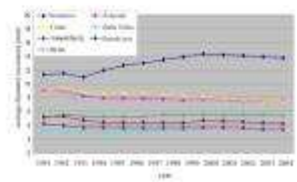
The site selection was based on the coverage of plantations located in the urban area, suburban area, relatively unpolluted environment and the specific location of the open pit coal mine "Kolubara". The first point (1) is located within the Cerak-Vineyard residential area, on the site of *Quercetum frainetto cerris* Rud., on the eutric cambisol, at an altitude of 158m, near the road. The next (2) is located in the suburban settlement of Zeleznik, on the same site and soil type and approximate altitude, but about 200m distance from the nearest road. The third point (3) is in the suburban settlement of Sremcica, on the site and soil with similar characteristics and approximate altitude, close to the road. Beside the very high-frequency Ibar road, is the point 5, on the same site, soil type and altitude. In the vicinity of Belgrade, at a slightly higher altitude (265m), on the same site and type of soil, but about 1.5km away from the road is located urban forest Baba Velka (4). Near the Belgrade-Zagreb highway is a sixth point, on the Chernozem soil and habitat of *Carpino quercetum roboris*, at a lower altitude (80m). In the very specific environmental conditions of the open pit coal mines "Kolubara" is the last analyzed plantation (7), located at 185m altitude, on Deposol (mining waste dump sites). The following table shows results of analysis of mean diameter at 1.30m height in centimeters (cm), the total height of the trees, the height of the trunk and the crown in meters (m), as well as the width of the crown. Based on health analysis (presence of harmful insects, phytopathological diseases and mechanical damages), an evaluation of the general vitality (gradation from 1 to 5), as well as the decorativeness was made in the same scale.

Table 2. Mean values of diameter (cm), total height, trunk height and crown height (m), crown width (m) with average vitality and decorativenes (grade 1-5)

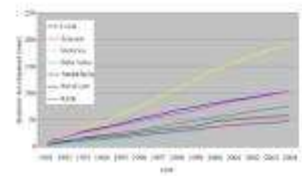
Locality	Mean value of diameter (cm)	Height (m)			Width of crown	Vitality	Dekorativenes
		total	trunk	crown	(m)	(1-5)	(1-5)
Cerak-Vineyard	32.5	**13.75**	2.95	10.63	10.65	3.92	3.88
Železnik	**58.3**	**19.50**	2.10	**17.40**	**18.33**	**4.50**	**4.50**
Sremčica	32.6	14.56	3.19	11.37	11.56	4.20	4.20
Baba Velka	35.0	16.63	3.13	13.50	9.00	3.50	3.00
Ibar motorway	29.8	15.54	**2.00**	13.54	8.30	**3.48**	3.38
Highway Bg-Zg	31.5	18.35	6.40	11.95	7.00	4.20	4.50
Open pit coal mine "Kolubara"	**20.7**	18.54	**8.57**	**9.38**	**4.50**	3.60	**2.80**

The values of trunk diameter ranges from 20.7cm in the Kolubara coal basin on deposols to 58.3cm in the suburban settlement of Zeleznik. The following graphs presents the current annual diameter increment (1), average diameter increment (2), and diameter development (3) for the period 1990 to 2004:

Graph.1 Current annual diameter increment



Graph.2 Average diameter increment



Graph.3 Diameter development

The total height ranges from 13.75 to 19.50 m, and the crown width from 4.50 to 18.33 m. The vitality of all trees is in the range of very good values, while the decorativenes varies in a slightly larger range. Studies (Vučković et al., 2008) in the area of the Majdanpek domain has shown that red oak, by its general condition and growth dynamics, has characteristics of a fast-growing species with high dendromase production. The foundation of 40 $m^2 \cdot ha^{-1}$ and the volume of the large wood 460 m^3 ha^{-1} in the year 41 indicate exceptional production possibilities. Growth in height is characterized by a high positive phototropism. Current growth culminates in year 10 with 0.9 m and average in year 18 with 0.73 m. The following table shows the content of toxic metals in the wood:

Table 3. The content of toxic metals in the wood (mg/kg)

No.	Sample	Zn	Pb	Mn	Cd
1.	**Reference values**	**300**	**100**	**-**	**3**
2.	Cerak-Vineyard	3.256649	1.177697	5.404562	**0.0**
3.	Železnik	2.493287	0.767165	4.411200	0.546605
4.	Sremčica	**6.457013**	2.391486	8.848499	**0.0**
5.	Baba Velka	2.262923	0.990028	45.331513	0.198005
6.	Ibar motorway	5.28238	**2.697386**	13.501484	0.112391
7.	Highway Bg-Zg	**0.938471**	**0.586544**	**3.519267**	**0.692122**
8.	Kolubara coal basin	3.869281	1.045751	**71.256995**	**0.0**

The results showed that the concentration of Zn in the tree ranged from 0.94 mg/kg at the locality Highway Beograd-Zagreb to 6.46 mg/kg at the locality Sremčica. The Zn deficiency in plants is indicated as 20 mg/kg (Kabata-Pendias, 2011). Based on the presented data, it is not possible to draw a conclusion about the actual Zn deficiency in the examined individuals. The concentration of Pb ranged within the normal Pb content in plants (0.1 to 5.0 mg/kg, De Vries and Bakker, 1996). However, it is important to note that the translocation of Pb from the root to the aboveground parts is limited (Kabata-Pendias, 2011). Maximum Pb concentrations of 2.70 mg/kg were detected at the locality Ibar motorway, and the lowest 0.59 mg/kg at the locality Highway Beograd-Zagreb. The results of the study also showed that the Mn concentration ranged within normal natural intervals of 30-300 mg/kg (Kabata-Pendias, 2011). As in the case of the content of other tested elements, the min. Mn concentrations (3.52 mg/kg) were determined at the locality Highway Beograd-Zagreb and the max. concentration of 71.26 mg/kg contained the wood of red oaks at the locality REIK. The concentration of Cd was in the range of average values of Cd content in plant at most localities (Kadović and Knežević, 2002). Based on the presented results, it can be concluded that all the analysed elements in the wood were in concentrations that did not interfere with various physiological and biochemical processes in red oak.

Conclusion

In the wider area of Belgrade, red oak has shown very good development results: diameter, height, crown width; the average, age and the overall diameter increment; Very good vitality and health conditions; No harmful insects or phytopathological diseases have been registered; It is characterized by exceptional decorativeness throughout the year (habitus, bark, leaf, fruit), and especially in the autumn aspect; Due to modest requirements and good success on different habitats and rapid growth in young age, red oak can be a very important species for increasing the stability of our forests and solving the problem of degraded habitats and low quality and poorly produced sessile stands. Also, especially in better quality habitats, it can contribute to the improvement of financial management effects, because of higher timber production compared to native oaks. On tourism and recreation facilities, the population can serve as an attractive species to break the monotonous landscape. All of the above recommends this species for much wider use in Belgrade (as well as other cities with similar environmental conditions), on different categories of urban open green spaces - from the tree-lined areas to forest complexes, as well as for the biological reclamation of coal mine landfills.

FLORISTIC COMPOSITION COMPARISON BETWEEN AUSTRIAN PINE FORESTS OF ZLATIBOR AND KOPAONIK (SERBIA)

Marijana NOVAKOVIĆ-VUKOVIĆ*, Rajko MILOŠEVIĆ

University of Belgrade, Faculty of Forestry, Serbia
*Corresponding author: marijana.novakovic@sfb.bg.ac.rs

Abstract

Austrian pine forests represent a significant complex of azonal foerests on serpentitines of Western and central Serbia. In this research, comparison of floristic composition was conducted between Austrian pine forests (*Erico-Pinetum nigrae* Krause 1957. in Krause & Ludwig 1957) of Zlatibor (western Serbia) and Kopaonik (central Serbia). Austrian pine stands on Kopaonik were registered on altitudes between 900-963 m, NW and SW expositions and 20-35° slopes. Austrian pine stands on Tornik (Zlatibor) occupy a narrow zone of altitudes from 1120-1145 m, varying expositions (SW, S, SE, N) and 20-35° slopes. Phytocoenological table shows great degree of similarity between studied stands, which is expected, considering that they belong to the same community. Given that studied Austrian pine forests belong to different localities, each exhibiting their own specificities, CA analysis of study stands indicates that there are significant differences between them in terms of floristic composition. Records from Kopaonik also show presence of xerophilous species that exist in difficult living conditions: *Carex humilis, Juniperus oxycedrus, Minuartia verna, Euphorbia glabriflora, Polygala supina* and others. Within records from Zlatibor, presence of species that are typical indicators of community degradation is noted: *Crataegus monogyna, Brachypodium pinnatum, Danthonia calycina*. Life forms spectrum shows that phanerophytes are somewhat more numerous on Zlatibor, which is a consequence of intense grazing, while hamephytes are more prevalent on Kopaonik, which indicates more extreme living conditions. Spectrum of floral elements exhibits most differences in terms of Mediterranean-sub-Mediterranean floral element presence. This element is significantly more present on Kopaonik than on Zlatibor, which indicates that Kopaonik is subject to sub-Mediterranean influence.

Key words: *Pinus nigra, serpentinite, Serbia, floristic similarity*.

Introduction

Austrian pine (*Pinus nigra* Arnold) belongs to the group of Mediterranean pines that have disjunct areal – they are present in north Africa, in Europe spanning from Spain on the west, across north Mediterranean, all the way to the Black Sea (Afzal-Rafii and Dodd, 2007, Rubio-Moraga *et al*., 2012). Two main subspecies of Austrian pine are recognized: *Pinus nigra* subsp. *salzmannii* (Corsican pine), occurring from Morocco and Spain to South France and Corsica, and *Pinus nigra* subsp. *nigra* (Austrian pine), occurring from Austria and North-Eastern and Central Italy through Balkans, to Turkey and Crimea Peninsula (Enescu *et al*., 2016). It grows at altitudes ranging from sea level to 2000 m, most commonly between 800 and 1500 m (Govannelli *et al.*, 2019). Austrian pine forests constitute a significant complex of azonal, relict and orographic-edaphically conditioned forests on ophiolitic massifs of central and eastern Bosnia, as well as western and some of the central Serbia (Tomić, 2004). Many authors considers these forests to be relict mainly due to edificatory role of Austrian pine (*Pinus nigra* subsp. *nigra* Vid.), which represents a typical tertiary relict with some subspecies' disjunct areals (Tatić and Tomić, 2006). Considering it's a relict species, primary Austrian pine communities can still be found sporadically, mostly on shaded expositions. Since Austrian pine is a pioneer species that conquers other species habitats, secondary Austrian pine communities on habitats of Balkans sessile oak, beech-fir, beech-fir-spruce, etc. are more commonly found. Austrian pine forests are dynamic systems with pronounced progressive succession. Importance of studying natural stands of Austrian pine does not stem from the surface area of Serbian forest fund which they occupy, but from the facts that Austrian pine is among most important and valuable tree species in this part of the world and it is most commonly used for afforestation of deforested terrains in unfavorable xerothermic habitat conditions (Stojanović *et al.* 2010). The aim of the paper was to broaden the knowledge on the Austrian pine forests on serpentine bedrock and to compare the floristic data in order to determine the differences between the studied forests on two localities in Serbia.

Material and method

For analysis of Austrian pine forest (*Erico-Pinetum nigrae* Krause 1957. in Krause & Ludwig 1957) floristic composition on serpentines of Kopaonik and Zlatibor areas (table 1), data from literature (Novaković-Vuković, 2015) were used. The size of the sample plots was 200 m². Syntaxonomic names were given according to Tomić and Rakonjac (2013). CA vegetation data analysis was performed using the statistical software CANOCO 4.5 (Lepš and Šmilauer, 2003). The cover-abundance score obtained for each species within a relevé was transformed using the method of Van Der Maarel (Van Der Maarel, 1979). Phytocoenological table was made based on phytocoenological relevés. Nomenclature of life forms, floristic elements and their classification into higher phytochories corresponds to the phytogeographical division of the Balkan Peninsula into phytochoria of subregion and province rank given by Horvat, Glavač & Ellenberg (1974), adapted and modified by Stevanović (1992).

Results and discussion

Austrian pine stands on Kopaonik were registered on altitudes between 900-963 m, NW and SWexpositions and 20-35° slopes. Austrian pine stands on Tornik (Zlatibor) occupy a narrow range of altitudes between 1120-1145 m, various expositions (SW, S, SE, N) and same slopes as stands on Kopaonik (20-35°). Austrian pine forests on Kopaonik and Zlatibor feature many mutual species, which is expected, because they belong to the same community. However, each locality has their own specific features, hence the figure (1) shows clear distinctions among phytocoenological relevés from research localities in terms of floristic composition. Relevés from Kopaonik are concentrated on the left side of the graph, with xerophilous species: *Carex humilis, Juniperus oxycedrus, Minuartia verna, Euphorbia glabriflora, Polygala supina,* etc. The right side of the graphs exhibits dominant presence of relevés from Zlatibor, which are slightly dispersed around the axis. These stands are degraded due to intense grazing, which reflects on their floristic composition. There is prominence of species which are typical indictors of community degradation: *Crataegus monogyna, Brachypodium pinnatum, Danthonia calycina*.

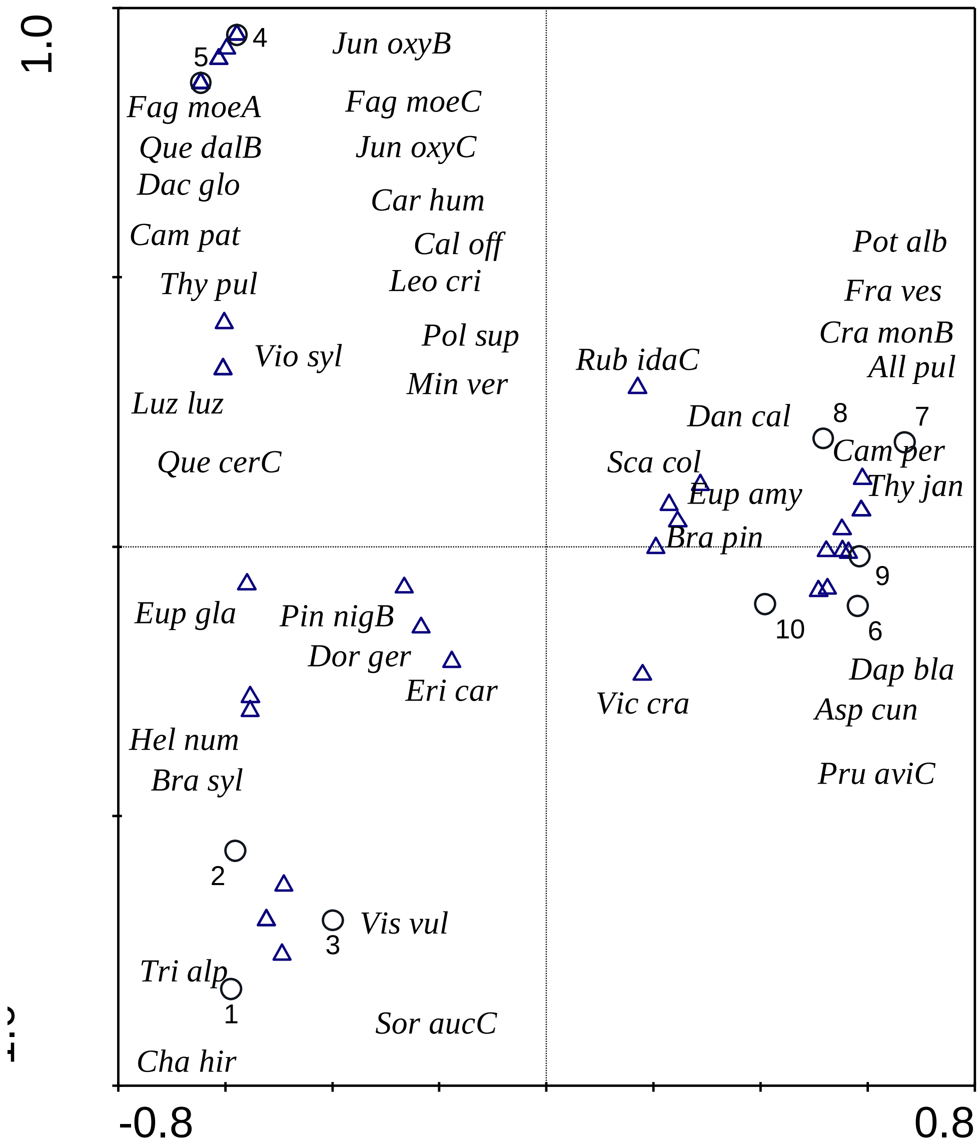

Figure 1: CA ordination biplot, fit range for the species 35-100%, 41 species (○-relevé representation, Δ- species representation; (1-5)- relevés on Kopaonik; (6-10)- relevés on Zlatibor (Tornik)

Cade juniper (*Juniperus oxycedrus*) was registered only on Kopaonik. This species is often present on dolomites and is an indicator of xerophility of study stands on Kopaonik. Austrian pine forests of Kopaonik feature 20% of xerophytes (Novaković-Vuković, 2015), which is almost as twice as the number of xerophytes in Austrian pine forests on Zlatibor, Tara, Šargan and Pešter. *Euphorbia glabriflora*, Illyric endemic and relict, exhibits notable abundance and coverage, which is a clear indicator that Austrian pine forests on this locality have Illyric imprint. "Going south from the center of development in western Serbia, pine forests change their appearance and structure, their vitality gets weaker and their floristic composition gets poorer in most important types of pine forests" (Pavlović, 1964). Austrian pine forests on Kopaonik are lower in height and of weaker vitality compared to these forests on Zlatibor. They don't have typical Illyric species such as *Epimedium alpinum* and *Daphne blagayana,* common inhabitants of black and Scots pine forests in western Serbia, in their floristic composition – which is expected, given that pine forests of Kopaonik are on the easternmost border of Illyric floristic area.

Even though *Erico-Pinetum nigrae* Krause 1957 community on Kopaonik is xerophilous to a significant extent, it still features mesophilic species, because it is situated within climate-regional belt of *Fagetum montanum* and *Abieti-Fagetum* (Jovanović, 1972). Beech (*Fagus moesiaca*) was registered in all the layers, young Balkanic durmast oak (*Quercus dalechampii*) was also noted, which indicates syndynamic connection between pine and forests on serpentinite and more mesophilic deciduous forests. Horvat (1959) classified not only pine but also oak forests into suballiance *Orneto-Ericion serpentinicum* Ht apud. Krause et Ludw. 1957, which represent the sucession according to vegattion climate in serpentinites of Bosia. Syndynamic connection of pine and oak forest was also noted in later reasearch, one of them has been conducted on mountain Ozren in B&H (Blagojević and Govedar, 2009). Authors described *Erico-Pinetum nigrae* Stefanović 1962, localized on inner Dinarides within climate-regional community of *Querco-Carpinetum illyricum* Horvat 1963. Within the association, three subassociations have been noted: *typicum, daphnetosum blagayanae* and *callunetosum.* Durmast oak (*Quercus petraea*) was registered in all the relevés, which may indicate that Austrian pine has "inhabited" former habitats of durmast oak (Blagojević and Govedar, 2009). Subassociation *typicum* and *daphnetosum blagayanae* are characterized by significant presence of species typical for Austrian pine forests of thermophilus habitats, while subassociation *callunetosum* is abundant with mesophilous plant species. Subassociation *callunetosum* is characterized by interference of basophilic winter heath (*Erica carnea*) with acidophilic common heather (*Calluna vulgaris*), which indicates that *Erica carnea* has acido-tollerant properties (Lukić *et al*., 2019). Authors also noted that winter heath is a characteristic species for relict forest communities. Considering the area investigated in this paper, *Daphne blagayana* was noted only on Zlatibor, while *Calluna vulgaris* was not registered at all, which brings us to the conclusion that Austrian pine forests of B&H and Serbia differ significantly in their floristic composition.

Regressive succesion is commonly seen in Austrian pine forests. On Kopaonik, Austrian pine forest (*Erico-Pinetum nigrae*) on shaded expositions is being replaced with pasture community-*Erico-Seslerietum rigidae* (Jovanović-Dunjić and Jovanović, 1987).

Hemicryptophytes are most numerous in spectrum of life forms (table 2) on both research localities. Somewhat greater presence of phanerophytes is noted on Zlatibor than on Kopaonik (24%:18%), which can be a consequence of intense grazing on Zlatibor. Chamaephytes are more represented in Austrian pine forest in Zlatibor (18%:13%), which is an indicator of more extreme life conditions on Kopaonik. Geophytes have significant presence, especially on Zlatibor (10%), because geophytes accompany mesophilic beech forest, and listed communities have been registered on their habitats. Geophytes are also the indicators of low winter temperatures.

Table 2. Spectrum of life forms in Austrian pine forests on Zlatibor and Kopaonik

	Zlatibor	Kopaonik
P scap (trees)	13%	11%
P caesp (shrubs)	11%	7%
Ch (chamaephytes)	13%	18%
H (hemicryptophytes)	51%	58%
G (geophytes)	10%	4%
T (therophytes)	0%	2%
S (lianas)	2%	0%

Considering that it is the same community (both on Zlatibor and Kopaonik), spectrum of floral elements (table 3) shows many similarities, but certain differences are also noted. Group of central European floral elements is most dominant on both localities. Species of colder regions exhibit similar presence. The biggest difference is in the presence of xerophilous, Mediterranean-submediterranean floral element. It is significantly more numerous on Kopaonik than on Zlatibor (11%:3%). Kopaonik and Zlatiobr are both indisputably under Mediterranean influence. Generally speaking, xerophilous floral elements (Mediterranean-submediterranean, Mediterranean-submediterranean-pontic and pontic-Mediterranean-submediterranean) are more prominent on Kopaonik than on Zlatibor (20%:16%), which indicates that Kopaonik is under greater submediterranean influence. Comparison of floral elements in Austrian pine forests on serpentinites in Serbia and B&H (Novaković-Vuković *et al*. 2019) showed that xerophilous floral elements are more dominant in Serbia, while mesophilic floral elements are more represented in B&H, which is another indicator of submediterranean influence in Serbia.

Table 3. Spectrum of floral elements in Austrian pine forests on Zlatibor and Kopaonik

	Zlatibor	Kopaonik
CIRCHOL (circumholarctic)	5%	4%
BOR+CIRCBOR (boreal –circumboreal)	6%	5%
EAS (Eurasian(	18%	22%
CE+CE-CAUC (central European-centra European Caucasian)	41%	35%
MED-SMED-PONT (Mediterranean-submediterranean-pontic)	13%	7%
MED-SMED (Mediterranean-submediterranean)	3%	11%
PONT-MED-SMED (pontic-Mediterranean-submediterranean)	0%	2%
SEP (south European mountain)	8%	5%
CEP (central European mountain)	6%	9%

Conclusions

The paper compared floristic composition of Austrian pine forests (*Erico-Pinetum nigrae* Krause 1957. in Krause & Ludwig 1957) on Zlatibor (western Serbia) and Kopaonik (central Serbia). CA analysis of study stands shows significant differences in floristic compositions. Relevés from Kopaonik indicated notable presence of xerophilous species: *Carex humilis, Juniperus oxycedrus, Minuartia verna, Euphorbia glabriflora*, *Polygala supina,* etc. Within relevés from

Zlatibor, there is marked presence of species that are typical indicators of community degradation: *Crataegus monogyna, Brachypodium pinnatum, Danthonia calycina*.
Spectrum of life forms shows that phanerophyte are somewhat more numerous on Zlatibor (24%:18%), while chamaephyte are more represented on Kopaonik (18%:13%). Spectrum of floral elements on both localities shows most dominant presence of central European floral elements. The biggest difference is in the presence of Mediterranean-submediterranean floral element, which is significantly more represented on Kopaonik than on Zlatibor (11%:3%), indicating stronger submediterranean influence on Kopaonik. Aforementioned findings point out that study stands of Austrian pine on Kopaonik and Zlatibor are very similar, but also exabit notable differences.

Abstract

Greek maple (*Acer heldreichii* Orph.) is subendemic tree species of Balkan Peninsula and tertiary relic. On Jahorina Mt (Entity of Republic of Srpska, Bosnia and Herzegovina), this species occurs on northwestern border of its global distribution. The aim of this research was to investigate taxonomical division of Greek maple on Jahorina, based on morphological markers. For taxonomical research, 20 representative, physiologicaly mature trees were chosen, and from every tree, 20 normally developed leaves were collected, which formed the basis for taxonomical analysis. Measured leaf properties were: leaf length, widths of upper, main and lower leaf lobes, peduncle length and angle between upper and main leaf lobes. Varieties and forms of Greek maple were separated according to leaf shape and dimensions. Two varieties were set apart, var. *heldreichii* and var. *macropterum*; within var. *macropterum* two forms were distinguished, f. *typicum* and f. *dissectum*. Results of taxonomical analysis were statistically processed. Considering that Greek maple is protected species in Republic of Srpska, this research possess special interest in increasing knowledge of variability and genetic diversity of this species, which will help in its preservation and protection.

Key words: *Greek maple, Acer heldreichii, endemic, taxonomy, Jahorina*

Introduction

Greek maple (*Acer heldreichii* Orph.) is one of the most interesting native woody species of Balkan Peninsula, being Balkan sub endemic and tertiary relic (Cvjetićanin et al., 2016). It grows as a high tree, produces good quality timber and possesses ornamental properties. It is also ecologically interesting, considering it grows only on mountain sites, and among native Balkan maples it is most suited for cold climatic conditions of higher elevations (Lakušić, 1989). Capability of Greek maple growth in ecological conditions, where only small number of tree species are able to survive, stresses its ecological importance on native sites, where it protects soil from erosion, improves ecological conditions for survival of other plant species and represents food source for significant number of animal species (Perović, 2014). Greek maple occurs at elevations between 1000-2000 m a.s.l., on mountains of Bosnia and Herzegovina, Serbia, Montenegro, Northern Macedonia, Bulgaria, Greece and Albania. In Bosnia and Herzegovina, it occurs only in Republic of Srpska on the following mountain massifs (Lakušić 1964; Fukarek 1969; Perović 2014): Jahorina, Trebević, Klek, Radomišlje, Treskavica, Zelengora, Volujak, Maglić and Bjelasnica near Gacko, which represents the westernmost world site of this species. Apart from typical subspecies *Acer heldreichii* subsp. *heldreichii* from Balkans, the second subspecies *Acer heldreichii* subsp. *trautvetteri* (Medw.) Murray) occurs on Caucasus Mountain and northeastern Turkey (van Gelderen et al. 2010)

The aim of this paper was to research taxonomical characteristics of *Acer heldreichii* on Jahorina mountain. Perović (2014), concluded that in Serbia and some localities of Bosnia and Herzegovina and Montenegro occur two Greek maple varieties: var. *macropterum* and var. *heldreichii*. Within variety *macropterum* four forms were set apart: f. *typicum*, f. *rotundiloba,* f. *dissectum* and f. *equiloba*. Considering that Greek maple is protected species in Republic of Srpska (*2014), this research is especially important because it will provide better knowledge about variability and genetic diversity of this species, which will help in protecting of Greek maple in researched region.

Material and method

Research was done in mountain Jahorina (Republic of Srpska, Bosnia and Herzegovina), within forest area „Jahorina" in compartments 117 and 120, which belong to forest management unit ,,Gornja Prača". Compartment 117 occurs at elevation 1590-1640 m a.s.l., on northern and northwestern aspect, with inclination 20-25° Compartment 120 is positioned at elevation 1400-1630 m a.s.l., on eastern and southeastern aspect, with inclination 20° (*2015).
In the aim to research taxonomic characteristics of Greek maple on Jahorina, 20 representative, physiologically mature trees were chosen for analysis. From every tree 20 normally developed leafs were collected, which were the basis for taxonomical analysis. Varieties and forms were distinguished by the leaf shape and dimensions. Following leaf properties were measured (Figure 1): leaf blade length (A), side leaf lobe width (B), basal leaf lobe width (C), upper leaf lobe width (D), length of leaf stalk (E), and angle between side and upper leaf lobes (F). Results of morphological analysis were statistically processed using statistical methods: method of correlation analysis and T-test of independent samples of measured leaf properties. Statistical analysis was done using software SPSS 23.0 (Pallant 2011; *2015).

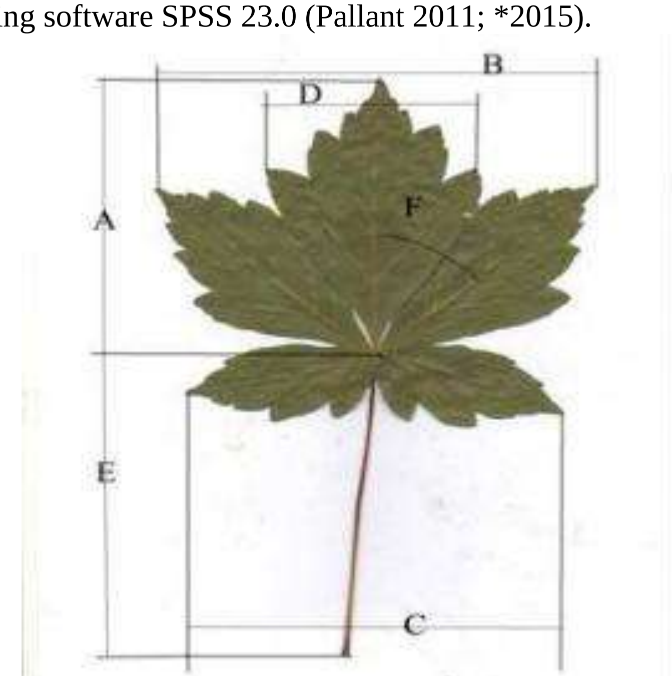

Figure 1 : Analysed morphological leaf charateristics (Perović 2014)

Figure 2. *Acer heldreichii* on researched locality on Jahorina Mt.

Results and discussion

Two Greek maple varieties vere set apart on reserached area (var. *heldreichii* and var. *macropterum*), and within var. *macropterum* two forms were determinated (f. *dissectum* and f. *typicum*).

Acer heldreichii var. *macropterum* is characterized by leaf lobes which are separated and never ovelap. 15 of 20 researched trees on Jahorina belong to this variety. Average values of measured leaf properties of *Acer heldreichii* var. *macropterum* on Jahorina are: length of leaf blade is 10.49 cm, width of side leaf lobe is 14.40 cm, width of basal leaf lobe is 11.98 cm, width of upper leaf lobe is 4.85 cm, length of leaf stalk is 10.44 cm. Within this variety, 10 individual trees on Jahorina belong to f. *typicum* (Figure 3), which is characterized by shallower lobed leaves, while 5 trees belong to the f. *dissectum* (Figure 4), with very deeply lobed leaves, almost to the leaf base. Average values of measured leaf properties of *Acer heldreichii* var. *macropterum* f. t*ypicum* are: length of leaf blade is 10.53 cm, width of side leaf lobe is 14.70 cm, width of basal leaf lobe is 12.48 cm, width of upper leaf lobe is 4.91 cm, length of leaf stalk is 10.58 cm. Average values of measured leaf properties of *Acer heldreichii* var. *macropterum* f. *dissectum* are: length of leaf blade is 10.42 cm, width of side leaf lobe is 13.78 cm, width of basal leaf lobe is 10.98 cm, width of upper leaf lobe is 4.71 cm, length of leaf stalk is 10.13 cm.

Acer heldreichii var . *heldreichii* (Figure 5) is characterized by overlapping leaf lobes. 5 researched trees on Jahorina belong to this variety. Average values of measured leaf properties of *Acer heldreichii* var. *heldreichii* are: length of leaf blade is 10.75 cm, width of side leaf lobe is 14.96 cm, width of basal leaf lobe is 12.07 cm, width of upper leaf lobe is 4.32 cm, and length of leaf stalk is 11.48 cm.

Perović (2007, 2014) researched taxonomical properties of Greek maple in Serbia (on six most representative localities), and he included in this research one site from Bosnia and Herzegovina and Montenegro respectively (localities „Perućica" primary forest on Maglić Mt. in Bosnia and

Herzegovina and "Biogradska gora" primary forest on Bjalasica Mt. in Montenegro). In this research the author determined occurrence of two *Acer heldreichii* varieties (var. *macropterum* and var. *heldreichii*) on researched localities. Interesting is to note that both varieties were represented on all eight researched localities in his work. This paper proves that both varieties occur on Jahorina also.

Figure 3. *Acer heldreichii* var. *macropterum* f. *typicum*, Jahorina Mt

Figure 4. *Acer heldreichii* var. *macropterum* f. *dissectum*, Jahorina Mt.

Figure 5 *Acer heldreichii* var. *heldreichii,* Jahorina Mt.

Corelation analysis of measured leaf properties were applied separately on trees which belong to *Acer heldreichii* var. *heldreichii*, *Acer heldreichii* var. *macropterum* f. *dissectum* and *Acer heldreichii* var. *macropterum* f. *typicum*. It is determined that measured properties occur in very different corelative relations, from strong positive corelation, to insignificant corelative relations to moderately negative corelation.

At variety *heldreichii*, all measured leaf properties show strong positive correlation, except the angle between upper and basal leaf lobes, which shows no statistically significant corelations to other measured properties except the width of basal leaf lobe. Speaking about var. *macropterum* f. *dissectum* correlation has somewhat lower intensity. Neither property shows strong correlation to other, while it is moderate to weak. The strongest correlation is between length of leaf blade and width of basal leaf lobe, as well as between width of side leaf lobe and width of upper leaf lobe. For var. *macropterum* f. *typicum* it is established that measured leaf properties are within moderately strong correlation, except the angle between upper and side leaf lobes, which show weak corelation to other measured properties.

T-test for individual samples, compared mean values of measured leaf properties between var. *heldreichii* and var. *macropterum*. Analysis was done for every leaf property separately. Difference between these two varieties on Jahorina is statistically insignificant respecting to the leaf blade length, side leaf lobe width, basal leaf lobe width, and angle between side and upper leaf lobes. Statistically significant difference between *Acer heldreichii* var. *heldreichii* and *Acer heldreichii* var. *macropterum* on Jahorina Mt. occurs regarding the width of upper leaf lobe ($t(18)=2.67$; $p=0.016$, i.e. $p<0,05$) and length of leaf stalk ($t(18)=2.11$; $p= 0.048$ i.e. $p<0,05$).

Conclusion

Analysis of morphological markers (leaves) in Greek maple (*Acer heldreichii* Orph.) population on Jahorini Mt. in Republic of Srpska, Bosnia and Herzegovina, showed occurrence of two Greek maple varieties on researched locality- var. *macropterum* and var. *heldreichii*. Within var. *macropterum*, two forms were set apart- f. *typicum* and f. *dissectum*.

Correlation analysis ascertained that measured leaf properties of Greek maple occur in positive corelative relations of various level, except the property angle between side leaf lobe and upper lef lobe, which mosty shows no clear correlation to other measured leaf properties.
Analysis made by t-test for small independent samples between individuals belonging to var. *heldreichii* and var. *macropterum* showed statistical significance by properties width of side leaf lobe and length of leaf stalk, while it is not statistically significant for other properties.
Considering that Greek maple is protected species in Republic of Srpska, this research is especially important because it will provide better knowledge about variability and genetic diversity of this species, which will help in protecting of Greek maple in researched region.

Abstract

The paper presents the properties of eugley soil in the floodplain and embankment protected part of the alluvial plain. The floodplain is under the influence of flood and groundwater, while the protected part is exclusively under the influence of groundwater. The properties of the soil in the examined parts differ depending on the method of wetting. Eugley floodplain soil is characterized by lighter granulometric composition and the texture classes of these soils are sand and loamy sand, while the protected part soil is heavier granulometric composition with texture classes: sandy loam, clay loam, sand, loamy sand and sandy loam. In the case of soil in the flood zone, the reduction sub-horizon of gley is located at a smaller depth, i.e. 30 to 35 cm, and in the protected zone it is deeper, and we find it at a depth of 45 to 90 cm. The reaction of the soil of the floodplain is neutral to slightly alkaline, while in the soil in the protected zone is moderately alkaline. The capacity of the humus horizon of the flood zone is lower and is 10 cm, with humus content up to 3.01% in the surface horizon, while the protected part had the more powerful humus horizon with depth, from 45 to 50 cm and higher humus content ranging up to 5.59 %. The examined eugley of the soil according to the depth of the gley horizon in the area of the flood zone is classified as α-gley, and in the area of the protected zone into β-gley and γ-gley. Due to the high level of groundwater and the small depth of the gley horizon, eugley soils in the floodplain are not suitable for raising forest plantations, while eugley soils in the protected zone are suitable habitats for raising white willow plantations due to the greater depth of the gley horizon.

Keywords: *Eugley, Alluvial plain, Flooding, Groundwater, Afforestation.*

Introduction

The area of the alluvial plain is characterized by hydromorphic soils that show regularity in distribution in relation to the riverbed, and can also be musically and irregularly distributed. Eugley soils as a representative of the class of gley soils (Škorić et al., 1985) are mostly found at a certain distance from the riverbed, in the area where the finest soils are deposited after flood periods. Their distribution is related to the lowest terrains and they are located in depressions. The main characteristic of these soils in the morphology of the profile is the heavier granulometric composition, and groundwater that varies to a depth of about 100 cm (Pekeč et al.. 2011a). Certain parts of the alluvial plain that are not protected by the embankment are still under the direct influence of flooding, which, along with the action of groundwater, affects the genesis and characteristics of eugley soil in this zone. The part of the alluvial plain at a greater distance from the riverbed, which is protected from flood waters by the embankment, is not exposed to the influence of surface waters, but only the groundwater affects the genesis and characteristics of this area. Eugley soils (Gleysols according to the WRB classification, 2006) develop a gley horizon of secondary oxidation and a gley sub horizon of secondary reduction with respect to variation and groundwater level, and the depth of the gley horizon is related to groundwater hydro morphism. According to the depth of the gley horizon, eugley soils are classified according to Wilde into α-gley, β-gley and γ-gley (Živanov and Ivanišević, 1986). The depth of the gley horizon is of the most important importance for the productivity of eugley soils, and soils with a greater depth of this horizon are of better credit rating class Antić et al (1982). Based on the examination of the properties of eugley soil in the floodplain of the alluvial plain and the embankment protected from flooding, the paper presents the characteristics of these soils in these two different areas, where in earlier periods afforestation of these areas depending on the depth of the gley horizon.

Material and method

The paper investigates wetland gley soil in the area of the alluvial plain of the Danube in the vicinity of Novi Sad in Serbia. Three pedological profiles were opened in the part of the alluvial plain under the influence of flood waters (N 45°14'8.17"; E 19°40'31.21") and three profiles in the part of the alluvial plane protected by the embankment from flood waters (N 45°17' 44.58; E 19°53'28.87"). External and internal profile morphology is described. Soil samples in disturbed condition were taken from open pedological profiles and the following physical and chemical analysis of soil were performed: Mechanical composition, B-pipette method with sample preparation for analysis in sodium pyrophosphate according to Bošnjak et al (1997), and the texture class of the soil was determined according to the Tommerup classification; CaCO3 content was determined volumetrically using a Scheibler calcimeter; The pH value was determined in a suspension of soil with water, potentiometrically; Humus content according to Tyurin, modified by Simakov; Based on the performed analysis, the characteristics of the examined land are presented.

Results and discussion

Analysing the data from Table 1 for the first three pedological profiles (P1-P3) which represent wetland gley soil wetted by flood and groundwater, it can be concluded that the largest share of fine sand fraction, which ranged from 65.03 to 77.93%. The content of coarse sand is lower and ranges from 7.83 to 20.43%. This soil contains the smallest fractions of clay whose values ranged from 2.63 to 7.03%, while the powder content ranged from 7.53 to 11.63%. The average value of total sand for this land is from 85.42 to 86.03%, while the value of total clay ranged from 13.96 to 14.56%. The texture classes of these soils were: sand in the surface horizon and loamy sand in the lower horizons of the profile. In the case of profiles representing wetland gley soil of the part of the alluvial plain which is protected from flooding (P4-P6) and is moistened exclusively by groundwater, the fraction of fine sand whose values are from 29.16 to 69.73% also predominates. The coarse sand fraction is smaller and ranges from 0.59 to 13.62%, while the increased fraction of powder fraction ranging from 13.91 to 39.00% and the content of the clay fraction whose values are from 12.21 to 31.26%. The average value of total sand for this land is from 29.74 to 73.88%, while the value of total clay ranged from 26.12 to 70.26%. The texture classes of these soils were: sandy clay loam to clay loam in the surface part of the profile and in the lower parts of the profile: sand, loamy sand, sandy loam and clay loam. Pekeč et al. (2011b) exploring the eugley of the soil of the protected part of the alluvial plain lists textural classes such as loam and silty loam.

On the basis of chemical properties of the soils in the floodplain, it can be stated that according to the carbonate content, these soils (P1-P3) have a range from 14.11 to 14.24%, and we classify them as strongly carbonate soils. The pH value ranged from 7.32 to 7.49, ie these are soils of neutral to slightly alkaline reaction (according to the American classification for chemical reaction of soils), and the humus content of the studied soil is on average from 1.27 to 1.43% and these soils are poorly humus (according to Scheffer-Schachtschabel classification). The chemical properties of the soil in the part protected from flooding (P4-P6) indicate a carbonate content of 7.59 to 16.55%, ie this soil is carbonate to strongly carbonate. The pH value ranges from 8.23 to 8.86%, which classifies it as moderately alkaline soils (according to the American classification for soil chemical reaction), and the humus content averages 1.05 to 5.31%, so this soil is in classes from weak to very humus. (according to the Scheffer-Schachtschabel classification).

According to the granulometric composition of the examined soils (Table 1), it can be seen that the eugley soils are in the flood zone of lighter mechanical composition, especially in the surface horizon where the texture class is sand, which is the result of flooding of that area during high Danube water levels. The lower parts of these soils have a slightly higher share of total clay in relation to the surface horizon. Eugley soils in the part of the alluvial plain protected from floods have a heavier mechanical composition, which is especially visible near the humus horizon, while the depth of the profile reduces the share of total clay. The reduction sub-horizon of gley (Gr) in the soil in the flood zone is located at a depth of 30 to 35 cm, which indicates a high level of groundwater, and due to the large amount of water, according to Živkovic et al. (1972) this land is overgrown with hydrophilic vegetation. In the zone protected from floods, the reduction sub-horizon of gley is at a depth of 45 cm, i.e. at a depth of 90 cm, and in this zone the groundwater is at a greater depth. Analyzing the chemical characteristics of the examined soils, the reaction of the soils (Table 2) in the floodplain is neutral to slightly alkaline due to the leaching of the soils with floodplain water, with a slight increase in alkalinity along the depth of the profile. In the flood-protected zone, the soil reaction is moderately alkaline with a significant increase in alkalinity according to the depth of the profile, which is a possible result of wetting with alkaline groundwater. Based on the poorer quality of groundwater, it is possible to increase the alkalinity of the lower parts of the eugley soil profile according to Pekeč et al. (2020). Also, the capacity of the humus horizon of the soil of the flood zone is up to 10 cm deep, and the formation of humus is often interrupted by flood waters and the application of new soil material, and the humus content in the surface humus horizon is up to 3.01%. In eugley soil protected from flood waters, the humus horizon is more powerful, with a depth of 45 to 50 cm, and a humus content of up to 5.59%, which is the result of the accumulation of organic matter that is not interrupted by fluvial sedimentation and flooding. Based on the depth of the gley horizon according to Wilde's classification, according to Živanov and Ivanišević (1986), soils in the flood zone are classified as α-gley (P1-P3), and soil in the protected zone into β-gley (P6) and γ- see (P4 and P5). Considering the depth of the gley horizon and the depth of groundwater retention of the examined areas, the dominant forest species to which such habitat conditions correspond are willows, ie white willow (*Salix alba*). As stated by Antić et al. (1982) White willow stands can have different productivity in relation to the depth of the gley horizon in the profile. The dependence of forest quality and depth of the gley horizon was determined by Antić et al (1972), Milojković et al. (1972) and Jović et al (1972) who stated that the most productive are white willow stands on γ-gley, while the middle productive stands are on β-gley, and the lowest productivity was shown by white willow stands on α/β-gley. According to the data on the productivity of white willow on eugley, we can conclude that the examined lands in the floodplain classified as α-gley are not suitable for raising white willow plantations due to high groundwater levels and small depth of gley horizon, mostly this land covered by marsh vegetation. Eugley soils examined in the part of the alluvial plain which is protected from floods by the embankment and where we find β and γ-gley, with a greater depth of the gley horizon are suitable habitats for raising white willow plantations. Depending on the groundwater level and the depth of the gley horizon, we can expect different productivity of plantations.

Conclusion

The paper presents the properties of eugley soil in the floodplain and the embankment protected part of the alluvial plain. The floodplain is under the influence of flood and groundwater, while the protected part is under the influence of only groundwater. The properties of the soil in the examined parts different depending on the method of wetting. Eugley soil of the flood part is characterized by a lighter granulometric composition, and the proportion of clay increases with the depth of the profile. The reduction sub-horizon of gley near the soil in the flood zone is closer to the surface and is located at a depth of 30 to 35 cm, and the reaction of the soil is neutral to slightly alkaline. The capacity of the humus horizon of the flood zone is smaller, i.e. up to 10 cm deep. The soil in the protected part has a heavier granulometric composition, and the proportion of clay decreases along the depth of the profile. The reduction sub horizon of gley is at a greater depth, ie from 45 to 90 cm, while the reaction of this soil is moderately alkaline. The thickness of the humus horizon is more pronounced and ranges from 45 to 50 cm. Based on the depth of the gley horizon, the soil in the flood zone is classified as α-gley, and in the protected zone into β-gley and γ-gley. The examined eugley soils in the flood zone are not suitable for raising forest plantations, while eugley soils in the protected zone are suitable for raising white willow plantations, whose productivity depends on the depth of the gley horizon.

Acknowledgment

This paper was realized as a part of the project: 451-03-9 / 2021-14 / 200197 financed by the Ministry of education, science and technological development of the Republic of Serbia in 2021 year.

Abstract

The paper presents a study of changes in ground vegetation associated with the conversion of natural, mixed beech-sessile oak forest (*Querco petraeae – Fagetum moesiacae* Glišić 1971.) into artificially established stands of Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) in the area of Kosmaj (Serbia). The study has revealed that there are differences in the floristic composition because the process of artificial stand establishment entails disappearance of some species and the appearance of new ones. The introduction of Douglas-fir increases the plant species diversity. The values determined for beech-sessile oak forest have been as follows: average number of species 22; average Shannon-Wiener index 2.32; average equality index 0.74. The values of the same indicators for artificially established stands of Douglas-fir have been: average number of species 38; average Shannon-Wiener index 2.80; average equality index 0.75. In the spectrum of floral elements, plants of the Central European range type are most represented, amounting to 49% (beech-sessile oak forest) or 59% (Douglas-fir plantations). The study of the plant life forms shows that phanerophytes are the dominant class with 41% (beech-sessile oak forest) or 46% (Douglas-fir plantations). Comparative analysis of ecological indices for plant species shows a higher percentage of plants of mesotrophic and eutrophic character in artificially established stands of Douglas-fir, which indicates a higher nutrient availability

Keywords: *Douglas-fir, beech-sessile oak forest, plant species diversity, Kosmaj.*

Introduction

During of afforestation and reclamation of degraded forests conducted in previous decades, insufficient attention was paid to complex properties of vegetation-forest ecosystems, which resulted in plantation of coniferous monocultures. The most commonly used species in Serbia in the reclamation of oak and beech forests were Austrian pine, Scots pine, spruce, Weymouth pine, Douglas-fir, larch etc.

Long-term processes of reducing the area under forests, changes in the structure of forest ecosystems and the quality of wood mass, as an inevitable consequence of economic and demographic development and the struggle of people for survival, did not pass the researched area of Kosmaj. Since the middle of the last century, in order to solve the problem of coppice and degraded forests in this area, as well as everywhere in Serbia, various types of trees, primarily conifers, have been introduced. It is known that these types of trees can quickly establish a complete set of stands, and thus fully realize their protective and hydrological function, and at the same time can cause negative consequences for the soil and vegetation. The establishment of a new forest ecosystem directly or indirectly affects plant species - in most cases there is a change in the composition and number of species of ground vegetation, ie a reduction in species

diversity. Tree species composition is a key driver of forest biodiversity, influencing structural components of the environment from soil and litter to vegetation layers and the canopy, and ecosystem processes, such as nutrient cycling (Oxbrough *et al*., 2012).
Douglas-fir is a species which was introduced to very different sites in Serbia. Its monoplantations were used in the substitution of natural forests from submontane to subalpine belts. Numerous different experiences have been reported on the effects of Douglas-fir on the soil changes after the substitution of autochthonous forests on different sites in Serbia (Miletić *et al*., 2003; 2013). Proper selection of tree species during afforestation or reclamation of degraded forests, with an appropriate management method, ensures the improvement of biological diversity, while preserving endangered and rare plant species. Therefore, the aim of this study was to determine the extent to which the establishment of artificial Douglas-fir stands (*Pseudotsuga menziesii* (Mirb.) Franco) at the site of beech and sessile oak forest (*Querco petraeae-Fagetum moesiacae*) had an impact on the change of floristic composition and diversity of these forests.

Material and Methods

The research was conducted in the area of Kosmaj Mountain, which is located 40 km southeast of the city of Belgrade (Serbia). The forest cover of the Mt. Kosmaj study area is composed of deciduous oak and beech forest communities (Stajić *et al*., 2021). The research of site conditions and floristic composition was performed by means of series of trials, conducted in mixed beech-sessile oak forest and artificially established stands of Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco). Field surveys were conducted in 2016 and 2017. Floristic sampling was done on a floristically homogeneous surface area with a plot size of 900 m^2 (30 x 30 m). In each plot, a complete floristic list of all vascular plants (tree, shrub, and herb layers separately) was recorded using the Braun-Blanquet scale (Braun-Blanquet, 1964). The transformation of abundance and cover estimation of each species within phytocoenological relevés was performed according to the Van Der Maarel method (1979). Species diversity was measured using *the Shannon-Wiener* diversity index (Shannon and Weaver, 1963); the Pielou Index (E) was used for the estimation of species evenness (1975). JUICE 7.0 software was used to calculate these indices (Tichý, 2002). The spectrum of floral elements was determined according to the systematization of geo-floristic elements by Gajić (1980), the spectrum of life forms according to the Method of Kojić *et al.* (1997), and the indicator values of plants and ecological optimums were determined using the Method of Kojić *et al.* (1997).

Results and Discussion

Mixed beech and sessile oak forests – *Querco petraeae-Fagetum moesiacae* Glišić 1971. on Kosmaj occur in a wide range of altitudes (relevés range from 373 to 585 m a.s.l.), cold northern aspects (northern, north-western, and north-eastern) and slopes of 16° – 26° (Stajić *et al*., 2020). The cover of the ground flora layer ranges from 0.2 to 1.0. Mesophilic species of beech forests occur with the highest degree of presence: *Lamium galeobdolon* (L.) Crantz, *Carex sylvatica* Huds., *Dryopteris filix-mas* (L.) Schott and *Rubus hirtus* Waldst. & Kit. (Stajić *et al.*, 2020). Based on their floristic composition, it is concluded that the Douglas-fir stands were established at the site of beech and sessile oak forest *(Querco petraeae-Fagetum moesiacae* Glišić 1971). The cover of the ground flora layer ranges from 0.7 to 0.8. The study has revealed that there are differences in the floristic composition because the process of artificial stand establishment entails disappearance of some species and the appearance of new ones (Table 1).

Legend: BS- Beech-sessile oak forest; DF- Douglas-fir artificially established stands

The mean number of species in the artificially established stand of Douglas-fir is higher than in the natural beech-sessile oak forest, which is mainly due to the more open canopy of the tree layer in the artificially established Douglas-fir stands (Table 2). Light availability may affect the species richness of the herb layer both directly through species pool effects and indirectly by its positive effect on productivity (Axmanová *et al*., 2012).

Table 2. Average species richness, Shannon diversity index and species evenness (mean ± SE)

Forest community type	*Species rihness*	*Shannon-Wiener diversity index (H')*	*Evenness*
	Mean ± SE	Mean ± SE	Mean ± SE
Beech-sessile oak	21.60±1.740	2.32±0.123	0.74±0.022
Douglas - fir	38.33±2.081	2.80±0.045	0.75±0.006

Mixed beech–sessile oak community have the lower average value of the Shannon-Wiener diversity index (*H′*) and it amounts to 2.32. Evenness index values are slightly lower in natural beech-sessile oak forest (0.74) compared to artificially raised Douglas-fir stand (0.75).
Regarding the spectrum of plant life forms (Table 3), both the natural forest and the artificially-established stand are dominated by phanerophytes and hemicryptophytes. Phanerophytes are the dominant class with 41% (beech-sessile oak forest) or 46% (Douglas-fir plantations). The high share of geophytes indicates favourable soil conditions (moisture, structure, and depth of soil). The intermediate group of plants between therophytes and chamaephytes accounts for 5%, but there is a higher percentage of therophytes in the artificially established stand (3%).

Table 3. Spectrum of life forms

Life forms	Beech-sessile oak		Douglas - fir	
	Share (%)		Share (%)	
Phanerophytes	27	41	33	46
Nanophanerophytes	13		10	
Phanerophytic lianas	1		3	
Herbaceous chamaephytes		3		3
Hemicryptophytes		28		23
Geophytes		23		21
Therophytes		-		3
Therophytes /Chamaephytes		5		5

The spectrum of floral elements (Table 4) is dominated by the central European group, accompanied by other species typical of cold and humid regions, which leads us to the conclusion that both the forest of beech-sessile oak and the artificially established stand of Douglas-fir are dominated by mesophilous species.

Table 4. Spectrum of floral elements

Cumulative range types	Beech-sessile oak		Douglas - fir	
	Share (%)			
Pontic	6	19	-	12
Sub-Mediterranean	9		10	
Balkan	4		2	
Central European	40	49	51	59
Subatlantic	9		8	

<table>
<tr><td>Desert</td><td>1</td><td>1</td><td>-</td><td></td></tr>
<tr><td>Eurasian</td><td>20</td><td rowspan="2">25</td><td>13</td><td rowspan="2">18</td></tr>
<tr><td>Cosmopolitan</td><td>5</td><td>5</td></tr>
<tr><td>Circumpolar</td><td>5</td><td>5</td><td>8</td><td>8</td></tr>
<tr><td>Adventive</td><td>-</td><td>-</td><td>2</td><td>2</td></tr>
</table>

Ground vegetation under Douglas-fir had higher indicator values for moisture and nitrogen than under beech-sessile oak (Table 5).

Table 5. Average ecological indicator values

	Moisture	Soil reaction	Nitrogen	Light	Temperature
Beech-sessile oak	3.03	3.30	2.86	2.71	3.42
Douglas-fir	3.10	3.28	3.05	2.49	3.38

Comparative analysis shows a higher percentage of plants of mesotrophic and eutrophic character in artificially established stand of Douglas-fir, which indicates a higher nutrient availability (*Galium aparine* L., *Urtica dioica* L.).

Conclusions

Forest plant richness, diversity and evenness were higher in Douglas-fir established stands than in beech-sessile oak forests. In the spectrum of floral elements, plants of the Central European range type are most commonly represented, amounting to 49% (beech-sessile oak forest) or 59% (Douglas-fir plantations). The study of the plant life forms shows that phanerophytes are the dominant class with 41% (beech-sessile oak forest) or 46% (Douglas-fir plantations). Comparative analysis of ecological indices for plant species shows a higher percentage of plants of mesotrophic and eutrophic character in artificially established stands of Douglas-fir, which indicates a higher nutrient availability.

The choice of tree species in forest management has economical, biogeochemical and ecological consequences over the long term. With the plantations of forest cultures, the native vegetation changes, as well as the species diversity of ground flora. In the further actions on the reconstruction of coppice forest of beech-sessile oak in this region, autochthonous species should be forced, which are, in any case, bio-ecologically more adapted to these site conditions. In the case when coniferous species are used, whether native or introduced coniferous species, it is recommended to cover the smaller areas, taking into account the bioecological characteristics of the conifers.

Abstract

Wild cherry (*Prunus avium* L.) is one of the most important forest fruit species. It is very valuable forest tree species which grows in mixed forests of South, Central and West Europe. In forests of Serbia it belongs to the group of endangered species which enough attention is not paid to. The main characteristics of seedlings, their individual variability as well as the variability between and within populations were shown using Comparative Morphometric Analysis of half-sib lines of wild cherry originating from seven natural populations. Seed for seedling production was collected in nine natural populations of wild cherry in its natural distribution area in Serbia. The trial was established in the seedling nursery of Institute of Forestry in Belgrade (Serbia). On the sample of 30 seedlings as per half-sib line at their age of 30 days the following characteristics were measured: length of a root, length of a epicotyl, a hypocotyl and a cotyledon, a cotyledon width, mass of a seedling, root collar diameter and number of cotyledons. Descriptive and multivariate statistical methods were used in the study. The obtained results contribute to the knowledge of the analyzed characteristics, the preliminary assessment of the genetic variability at the level of the studied half-sib lines and populations. The presented results are the basis for the continuation of the research which is necessary to be carried out in order to provide guidelines and recommendations for the preservation and targeted use of wild cherry genetic resources on the territory of Serbia.

Keywords: *Wild cherry, seedling, half-sib line, variability, population.*

Introduction

Wild cherry (*Prunus avium* L.) is the most important tree species from the Rosaceae family in Europe and occupies a position within temperate forest belt (Praciak et al., 2013). It is a fast-growing species which mostly grows in isolated positions and forest edges and rarely occurs in dense mixed stands (Santi et al., 1998). In the southern part of the range, the limiting factor is the amount of precipitation during the summer period, while in the northern part it is limited by the cold conditions of Eastern and Northern Europe (Russell, K., 2003). It has a wide elevation amplitude, from lowland areas up to the submontane belts. On larger mountain massifs it can be found up to 2000 m of elevation (Russell, K., 2003). In Serbia it is an autochthonous, indigenous, single-tree mixed secondary species in mesophilic forests *Aceri-Fraxinetum, Fagetum submontanum, Fagetum montanum calcicolum*, as well as in various forests of oak belt and lower beech belt (Tomić, Z., 2004). Due to its widespread use, many European countries have wild cherry gene pool conservation and/or cultivation programs (Russell, K., 2003). In Serbia it is categorized as *species at risk* (Banković et al., 2008) due to a number of threatening factors (Russell, K., 2003; Stjepanović, S., 2012; Jagodić, A., 2014). The wild cherry endangerment at the European level is primarily based on its disjunct range and difficult natural regeneration in selection forests in which sciophyte species are favored (Jarni et al., 2012). Regardless of the distribution in the form of scattered single-tree or group distribution, contrary to previous knowledge, gene flow within and between populations takes place freely and quickly resulting in a low rate of genetic differentiation of populations (Ducci et al., 2013). In addition to a variety of factors (pollinators, anthropogenic impact, seed dispersion by birds, etc.), self-incompatibility during pollination plays a dominant role in maintaining a high level of genetic diversity. However, given its shooting vigor, the genetic constitution of small groups of individuals can be of very low diversity, i.e., it may consist of one or several genotypes (Frascaria et al., 1993; Ducci, F., Santi, F., 1997). The basis for learning about the adaptive potential of wild cherry in an area is a research into genetic diversity and structure (Popović, V., Kerkez, I., 2016). A comprehensive study in the territory of the entire range of the species has not been conducted yet and previous research conducted mainly at the regional level has determined significant diversity of morphological and phenological characteristics of wild cherry (Meier-Dinkel et al., 1997; Kleinschmit et al., 1999; Ballian, D., 2000; Kleinschmit et al., 2003; Russel, K., 2003; Mikić et al., 2004; Tančeva Crmarić et al., 2006; Mikić, T., 2007; Ballian, D., Čabaravdić, A., 2007; Nonić et al., 2013; Popović, V., Kerkez, I., 2016; Popović et al., 2020). Vitality and survival of natural populations of forest woody species in altered environmental conditions depends on the degree of their genetic variability (Šijačić-Nikolić, M., Milovanović, J., 2012). The occurrence of a high degree of variability within populations is typical of most forest tree species (Bogdan, S., 2009). Selection and conservation of key populations and individuals in marginal parts of the range are the basis for the preservation and targeted use of the wild cherry gene pool in Europe, especially in the context of global climate change (Russell, K., 2013). Serbia is located near the southern border of the wild cherry range, and it is predicted that most of its territory will be in conditions ranging from negligible to medium low survival success of this species (Welk et al., 2016), so the assessment of gene-environmental potential of the selected individuals and half-sib lines is of great importance in this area (Popović et al., 2020). The objective of this research was a preliminary assessment of the genetic variability at the level of researched half-sib lines and populations on the basis of the pattern of phenotypic variability of the analyzed characteristics. The obtained results are the basis for the continuation of the research which is necessary to be carried out in order to provide guidelines and recommendations for the preservation and targeted use of wild cherry genetic resources on the territory of Serbia.

Materials and methods

The fruits were collected in nine natural populations (provenances) of wild cherry in the Republic of Serbia (Figure 1, Table 1). Each population was represented by ten trees, while about 1 kg of mature and fully developed fruits was collected from each tree. Only physiologically mature trees that bore fruit in July 2017 were sampled. The fruits were collected from trees in order to raise half-sib lines, in which the mother is known but not the other parent, according to the method of genetic analysis of trees (Isajev, V., Mančić, A., 2001). After collection, the fruits were macerated to prevent fermentation of the mesocarp. Freshly cleaned seeds were washed and dried at room temperature for two days. After that, it was packed in marked plastic bags and stored in the refrigerator at a temperature of 0 to 5 ° C until the moment of sowing. In order to avoid the occurrence of dormancy, the seeds were sown directly in the prepared bed at the beginning of September 2017. The sowing space was divided into fields of equal dimensions so that each field represents one half-sib line. The seeds were sown in furrows about 1 to 2 cm deep. The distance between the furrows was 20-30 cm, and the density was about 60 pieces per meter along the furrow. Measurements of the morphometric characteristics, and the analysis of seedling variability within and between population were performed at the age of 30 days. The following parameters were measured on a sample of 30 seedlings in each of the half-sib lines: root length, epicotyl length, hypocotyl length, cotyledon length, cotyledon width, seedling mass and root collar diameter. The normality of the data collected by the measurements was analyzed by the Kolmogorov-Smirnov test, and the homogeneity of variances by the Levene test in R. Descriptive analysis was performed using the MEANS procedure in SAS to calculate: arithmetic means (x), standard deviations (SD) and coefficients of variation (CV%). Analysis of variance (ANOVA) was performed using the MIXED procedure in SAS, with the aim of determining statistically significant differences between populations and within populations. The analyzed sources (factors) of variability were population and tree, with the tree factor being nested within the population factor. The share of representation of individual studied sources of variability in the total variance (between populations, between trees within a population, within trees) was determined by REML method (Restricted Maximum Likelihood Method). All the above statistical analyses were performed using the statistical program STATISTICA 7.0 (StatSoft Inc. 2004).

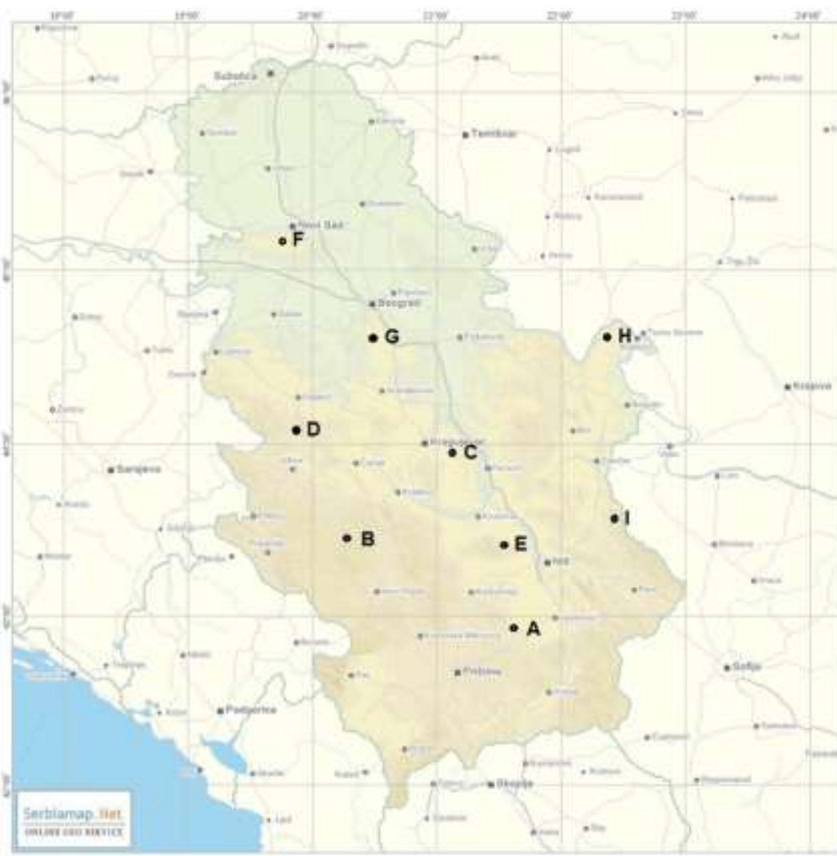

Figure 1. Map of spatial distribution of the studied provenances (A – Radan, B – Javor, C – Bešnjaja, D – Divčibare, E – Jastrebac, F – Fruška Gora, G – Lipovica, H – Đerdap, I – Stara Planina).

Table 1. Basic data on the wild cherry provenances studied.

Provenance Mark	Provenance	Elevation (m)	Latitude WGS84	Longitude WGS84
A	Radan	1159	43° 00' 09"	21° 31' 26"
B	Javor	1178	43° 29' 05"	20° 01' 50"
C	Bešnjaja	512	43° 59' 12"	21° 03' 38"

I	Stara Planina	737	43° 34' 44"	22° 26' 45"

Results and Discussion

The results of descriptive statistics of morphological parameters of wild cherry seedlings at the level of the studied populations are shown in Table 2. The cotyledon width (36.2%) stands out as the most variable trait, while the root collar diameter is the characteristic with the lowest variability (10.5%). The average value of root length at the level of all populations is 95.2 mm. The average value of hypocotyl length is 33.2 mm. The average value of epicotyl length at the level of the studied populations amounts to 29.7 mm. The average value of the cotyledon length is 17.5 mm, while the average value of the cotyledon width is 11.6 mm. The mass of seedlings is 1.1 g on average at the population level, and the average value of the root collar diameter amounts to 1.9 mm.

Table 2. Basic indicators of descriptive statistics of morphological parameters of seedlings

Characteristic	No. of specimens	Mean value	Minimum	Maximum	Standard deviation	Coefficient of variation
Root length (mm)	270	95.2	42	118.6	28.7	30.1
Hypocotyl length (mm)	270	33.2	19	49	8.5	25.6
Epicotyl length (mm)	270	29.7	12	31	7.3	24.6
Cotyledon length (mm)	270	17.5	8.3	22.4	5.9	33.7
Cotyledon width (mm)	270	11.6	5.4	17.9	4.2	36.2
Weight (g)	270	1.1	0.4	1.9	0.3	27.3
Root collar diameter (mm)	270	1.9	1.2	2.3	0.2	10.5

Table 3. Statistical significance (p-value) of trees nested within populations effect (i.e., variability within populations) for analyzed characteristics per provenance and percentage of variance component of the same effect calculated by combined analysis of all provenances (the last column).

Characteristic	Within populations									Variance component (%)
	A	B	C	D	E	F	G	H	I	
Root length	p<0.01	p<0.01	p<0.01	p<0.01	0.53	p<0.01	p<0.01	p<0.01	p<0.01	43.2
Hypocotyl length	p<0.01	p<0.01	p<0.01	0.56	p<0.05	p<0.01	p<0.05	p<0.01	p<0.01	41.4
Epicotyl length	p<0.01	0.62	p<0.05	p<0.01	0.11	p<0.01	p<0.05	p<0.01	p<0.01	45.6
Cotyledon length	p<0.01	p<0.05	p<0.01	p<0.01	p<0.01	p<0.05	p<0.01	p<0.01	p<0.05	39.7
Weight	p<0.01	p<0.01	0.66	p<0.05	p<0.01	p<0.05	p<0.05	p<0.05	p<0.01	48.4
Root collar diameter	p<0.05	p<0.01	p<0.05	p<0.01	p<0.01	0.52	p<0.05	p<0.01	p<0.01	50.2

The obtained results show that the level of variability within populations was high, occupying from 39% to 50% of the total variance (Table 3). The trees within populations differed significantly with respect to most of the researched morphological characteristics (Table 3).

Table 4. Provenance effect variance component percentage (i.e., variability between populations) and its statistical significance for investigated morphological characteristics.

Characteristic	Effect (%)	
	Population	p-value
Root length	6.43	<0.01
Hypocotyl length	7.4	<0.01
Epicotyl length	11.2	<0.01
Cotyledon length	9.4	<0.01
Weight	7.1	<0.01
Root collar diameter	7.9	<0.01

Based on the obtained results of the analysis of variance (ANOVA), it can be concluded that statistically significant differences were found between the studied populations, for all analyzed morphological characteristics of seedlings (Table 4). The level of variability between populations was not high, occupying from 6% to 11% of the total variance.
The of phenotypic diversity of wild cherry leaves, fruits and seeds in this part of Europe has also been confirmed by other studies (Ballian, D., 2000; Ballian, D., Čabaravdić, A., 2007; Ballian et al., 2012; Mratinić et al., 2012; Ballian, D., Mujagić-Pašić, A., 2013, Popović, V., Kerkez, I., 2016, Popović et al., 2020). It has long been considered that the variability parameters of tree seedlings are not of special importance, therefore seedlings characteristics have been presented only on a typological basis (Anić, M., 1983.; Vasilchenko, T.I., 1960). This view is not accepted today. The variability of seedlings is an adaptive trait and is controlled by natural selection, because genetic factors determine the extent and direction of the allowed phenotypic plasticity (Tucović, A., 1990). Seedling variability must be interpreted as the product of the interaction between genetic inheritance and selection. Age changes during the life cycle are the result of two opposing tendencies. One tendency is towards greater differentiation from germination to maturity. The other tendency is towards adaptation at each stage of the life cycle. Some studies have shown that morphological variability is apparently the result of an adaptive response to the environment; e.g., variation of some characteristics related to latitude and elevation

(Kleinschmit, J., 1993). Determining the contribution of heritage or environment to a particular character is of great importance in the field of production and cultivation of species (Tucović, A., Isajev, V., 2000.). The first, often the strongest selection takes place when the plant is in the germination phase. Thereby, larger dimensions of cotyledons, characteristics of hypocotyls or epicotyls, supernumerary cotyledons, characteristics of the root system are later manifested by better characteristics of mature trees (Vasilchenko, T.I., 1960). Some morphological differences may be caused by each genotype adapting to its own environment (Abrams, M.D., 1990). Peripheral or isolated populations found in habitats that differ in soil, climate, and competitors may be a source of new adaptations, and conservation efforts should be made toward such populations (Lessica, P., Allendorf, F.W., 1995). As a result, research into these seemingly insignificant characteristics of seedlings is gaining increasing importance (Tucović, A., Isajev, V., 2000.).

The natural regeneration of wild cherries is weak, and game grazing and poor competitiveness in relation to other species, primarily common beech, contribute to the difficult regeneration. It cannot withstand competition from sciophytic species in selection forests (Jarni et al., 2012). Auxiliary measures for natural regeneration are, for the above reasons, necessary, because wild cherry is an economically and ecologically very important woody species (Stjepanović, S., 2012). In this regard, the importance of the correct choice of reproductive material, along with the correct breeding interventions, is considered the main prerequisite for achieving maximum profit from forestry production (Kingswell, G., 1998; Coello et al., 2013).

There is also an increased risk of extinction in small populations, where reduced genetic diversity may be the result of genetic drift. In subsequent generations, the loss of heterozygosity resulting from genetic drift and inbreeding may lead to reduced fitness in these otherwise stable populations (Bruschi et al., 2003). Peripheral or isolated populations found in habitats that differ in soil, climate, and competitors may be beneficial to the protection of the evolutionary process , and conservation efforts should be made toward such populations (Lessica, P., Allendorf, F.W., 1995). Appropriate *ex situ* conservation measures should be taken to preserve such populations, using generative and vegetative methods of reproduction. Seed propagation is more justified because it is the least harmful to existing populations and would involve the widest range of genetic variability (Bruschi et al., 2003).

The results of this study showed a high level of variability within populations, but also differentiation between populations. It can be stated that the available wild cherry gene pool in Serbia is characterized by a satisfactory degree of genetic variability, and represents a good starting point for the process of further breeding. In order to preserve and improve the ecological adaptability and evolutionary potential of wild cherry populations in Serbia in the long term, it is necessary to start implementing adequate *in situ* and *ex situ* conservation measures.

Conclusion

The results obtained in this research have shown there is a significant level of variability of morphological characteristics of seedlings within populations and differentiation between populations.

The available gene pool of wild cherry in Serbia is characterized by genetic variability, therefore it can be utilized and improved in future breeding efforts.

Planning and implementation of appropriate measures of gene pool *in situ* and *ex situ* conservation will contribute to the preservation and improvement of the condition of wild cherry in part of the range.

Abstract

The research of intrapopulation variability on the basis of morphometric characteristics of acorn was conducted for the purpose of conservation of the available gene pool of sessile oak in the population in the area of Avala Landscape of Outstanding Features and controlled use of genetic resources. Fifty trees of the best quality based on phenotype characteristics, the healthy bearers of sessile oak (*Quercus petraea* (Matt.) Liebl) reproductive material production were selected at the population level. In October 2019, ca. 5 kilograms of healthy, normally developed acorns were collected from each of the test trees. On the sample of 50 acorns per tree, length, width and mass of the acorn were measured. The volume and the shape index of acorns were calculated on the basis of measured values of length and width. The mean values of morphometric characteristics obtained in the research indicate that there is a high variability among the studied genotypes. The latter is confirmed, also, by the analysis of variance which determined statistically significant differences among the sampled mother trees for all the observed morphometric characteristics. The obtained results represent a good starting point for future research in breeding, long-term conservation and improvement of ecological adaptability and evolutionary potential of sessile oak population by means of implementing adequate measures of in situ and ex situ conservation.

Keywords: *Sessile oak, acorn, population, genetic variability.*

Introduction

In the forest growing stock of the Republic of Serbia, sessile oak (*Quercus petraea* /Matt./ Leibl.) is the second most valuable oak species after pedunculate oak. It participates in the total volume with 5.9%, i.e., it occupies an area of 173.200 ha. Pure and mixed stands represent 57.5% and 42.5% of the total volume of sessile oak, respectively. Sprout forest stands are dominant at approximately 75% of the total area (Banković et al., 2009). It mainly occurs on warmer, southern exposures within the alliance *Quercion petraeae-cerris* Lakš. et Jov. 1980. Sessile oak forests in Serbia occur within the special oroclimatogenic altitudinal range, above the climatogenic forests of Hungarian oak *Quercus frainetto* syn. and Turkey oak (*Quercus cerris*). The complex of sessile oak forests encompasses upper part of submontane belt and lower montane belt at the altitudes from 300 m up to 1300 m (Stojanović et al., 2005). In the last several decades forest stands, groups and individual trees of sessile oak on almost whole range have been dying. The causes of forest decline are still insufficiently studied and systematized. The phenomenon is most probably caused by the influence of a complex of factors whose effect is cumulative (Marinković et al., 1990). On the basis of the results achieved so far in the studies relating to the phenomenon of decline of sessile oak forests it could be considered the

consequence of the global climate change, population structure change in sessile oak forests, air pollution, plant diseases, insect gradations, etc. (Isajev et al., 2005).
In sessile oak as in most oak species a haploid number of chromosomes is found, 12, while polyploidy occurs rarely and ranges about 0.5%. It is characterised by great individual and group variability which was confirmed by means of provenance and progeny tests (Isajev et al., 2005). Variability was found in seedling growth, tree formation, resistance to powdery mildew and insect attacks. Significant differences in agglutinins content have been determined in biochemical studies of fruits from different provenances, which can serve to facilitate identification of oak provenances (Jovanović, M., Tucović, A., 1975). In addition to the significant differences between provenances, they have also been determined within the provenances, and between individual trees. The morphological characteristics of trees and acorns are under considerable genetic control. In the scientific literature there are data on the existence of spontaneous hybrids described under various names among several species of oaks: *Quercus petraea* /Matt./ Leibl. and *Quercus robur* L.; *Quercus petraea* / Matt./ Leibl and *Quercus dalechampii* Ten; *Quercus petraea* /Matt./ Leibl and *Quercus polycarpa* Schur. The progeny of the mentioned stock species is characterised by a pronounced variability of quantitative and qualitative characteristics. The high variability of morphological and physiological characteristics of spontaneous hybrids creates great difficulties in production of forest reproductive material and the use of the available gene pool of sessile oak (Isajev et al., 2005).
The high level of diversity in terms of genetic resources, abundance of species and habitat diversity classifies forests under the most complex ecosystems on the Earth (Geburek, T., Konrad, H., 2008). Due to the constant pressure on forests in the last few centuries and the disappearance of natural forests, biodiversity is endangered (Carabeo et al., 2016). The long-term survival of species is closely related to their genetic diversity (Gapare, W.J., 2014). Under the influence of the altered environmental conditions, biotic pathogens and damage the survival and evolution of species depend on the level of genetic diversity (Reed, D.H., Frankham, R., 2003). The research dealing with genetic diversity and identifying populations characterized by high genetic variability can help in reducing the risk of biological diversity loss (Souto et al., 2015). The vitality and survival of natural populations of forest woody species in altered environmental conditions depend on the degree of their genetic variability as a basis for adaptation and undisturbed evolution (Šijačić-Nikolić, M., Milovanović, J., 2012). The occurrence of a high degree of intrapopulation variability is typical of most forest tree species (Bogdan, S., 2009).
The object of research in this study was to determine intrapopulation variability of sessile oak in the population in the area of Avala Landscape of Outstanding Features according to the morphological characteristics of acorn. The results obtained in the research can serve for preliminary knowledge of the genetic variability of the studied population, proposal of measures for conservation of the available gene pool and the improvement of quality seed and planting material production.

Materials and methods

For the research in this study acorns from the 2019 harvest were used. In order to determine genetic variability and evaluate the condition of genetic resources in the area of Avala Landscape of Outstanding Features, 50 trees of sessile oak (*Quercus petraea* (Matt.) Liebl). were selected and sampled. Representative trees of phenotypically highest quality which have been the bearers of healthy reproductive material production were sampled. The trees were evenly distributed over the entire area of the protected area, at least 50 m apart in order to avoid relatedness. About 3 kg of acorns ocularly estimated as healthy and undamaged were collected per each tree, regardless of their dimensions. After the collection acorns were dried at 35% of humidity and stored at temperature of 3 to 5 ºC.

The analyses of measured and derived morphometric characteristics were carried out on a random sample consisting of 50 acorns per each mother tree. Length, width at the widest part and mass of acorns were measured. The length and width of acorns were measured by a vernier calliper with an accuracy of 0.01 mm and mass by an electronic scale with an accuracy of 0.01 g. The shape index, volume of acorns and average number of acorns per 1 kg were calculated based on the measured values. The shape index was calculated as a ratio of the length and the width of the acorn. The volume of the acorn was calculated according to the formula for volume of a cylinder. (The shape of the acorn approximates to the shape of cylinder). The average number of acorns in 1 kg was calculated based on the average mass of one acorn, separately for each sampled mother tree.
Morphological characteristics of acorns were described by means of descriptive statistical indicators such as arithmetic mean (x), standard deviation (SD), coefficient of variation (CV %). The one-way analysis of variance (ANOVA) was used for the purpose of determining intrapopulation variability. The analysed factor of variability was a mother tree. All the aforementioned statistical analyses were carried out using the statistical program STATISTICA 7.0 (StatSoft Inc. 2004).

Results and Discussion

The mean value of acorn length at the population level amounts to 24.7 mm. The acorn length ranges from 20.9 mm (Tree No. 34) to 31.2 mm (Tree No. 49), with the standard deviation ranging from 1.4 to 3.6 mm (Table 1).
The mean value of acorn width at the widest part amounts to 14.5 mm. The acorn width ranges from 12.1 mm (Tree No. 5) to 19.0 mm (Tree No. 48) and the standard deviation ranges from 0.6 mm to 3.3 mm (Table 1).
The highest mean value of acorn mass amounts to 6.6 g (Tree No. 49) and the lowest is 2 g (Tree No. 5), while the mean value at the forest stand level amounts to 3.3 g with the standard deviation ranging from 0.3 g to 3.2 g (Table 1).
The acorn shape index ranges from 1.5 (Tree No. 25) to 2.3 (Tree No. 39), with the mean value of 1.7 at the forest stand level and the standard deviation ranging from 0.1 to 0.3 (Table 1).
The mean value of the acorn volume at the forest stand level amounts to 4.3 cm^3 and ranges from 2.6 cm^3 (Tree No. 5) to 9 cm^3 (Tree No. 48) with the standard deviation ranging from 0.3 cm^3 to 3.2 cm^3 (Table 1).

The most variable characteristic at the level of the forest stand is the acorn mass (41.9 %), while the shape index is the characteristic showing the lowest variability (12.8 %) (Table 1).
The average number of acorns in 1 kg at the level of the forest stand amounts to 301 pcs and ranges from 151 pcs/kg (Tree No. 49) to 489 pcs/kg (Tree No. 5).

Table 2. The analysis of variance for measured morphometric characteristics of acorn.

Parameter	df	SS	MS	F	P
Acorn length	49	11203.2	228.6	45.8	0.0000
Acorn width	49	2550.2	52.0	26.6	0.0000
Acorn mass	49	1417.07	28.92	27.93	0.0000
Shape index	49	34.400	0.702	27.6	0.0000
Acorn volume	49	2336.25	47.68	34.76	0.0000

The results of the conducted analysis of variance are presented in the Table 2. The studied source of variability was a tree (family) within a population. The results obtained showed there are statistically significant differences caused by the observed source of variability for all studied morphometric characteristics of acorn, thus confirming the assumption of significant intrapopulation differentiation.

High statistically significant differences determined between individual stock trees (genotypes) within the population indicate a high level of intrapopulation genetic variability. The occurrence of high level intrapopulation variability is typical of the majority of forest tree species and it can be explained by the process of gene flow (exchange of genes between different populations by means of natural processes, but also by human activity) (Bogdan, S., 2009).

The research of genetic variability of sessile oak populations which cover the major part of its natural range showed wedge-shaped variation trends, decrease of variability with an increase of the researched area. (Zanetto, A., Kremer, A., 1995). Certain studies have shown that the morphological variability is apparently the result of an adaptive response to the environment; e.g., variation of some characteristics related to latitude and altitude (Kleinschmit, J., 1993). Some of the researched morphological traits have been variable among populations without showing any geographical trends. The trend of morphological variability indicates there has been adaptation to local climatic conditions which is confirmed by a significant correlation with climatic parameters and there is no association with population distance (Jurkšiene, G., Baliuckas, V., 2014). Some morphological differences may be caused by adaptation of each genotype to its own environment (Abrams, M.D., 1990). In addition to direct exposure to sunlight, morphological variability can also be affected by water stress and the nutrient content in the soil (Carter et al., 1987). From a conservation perspective large genetic variability of tested populations is encouraging, but adequate ecological management is necessary for *in situ* conservation of populations (Bruschi et al., 2003). In case of excessive felling of trees, which would result in reduction in population size, the risk of extinction would increase (Gilpin, M.E., Soule, M.E., 1986). The increased risks of extinction exist also in small populations, in which reduced genetic diversity may be the result of genetic drift. In subsequent generations the loss of heterozygosity which is the result of genetic drift and inbreeding may lead to reduced condition in this otherwise stable populations. (Bruschi et al., 2003). Peripheral or isolated populations found in habitats that differ in soil, climate and competitors can be the source of new adaptations so an effort should be made to conserve such populations (Lessica, P., Allendorf, F.W., 1995). Appropriate measures of *ex situ* conservation should also be taken to preserve such populations using generative and vegetative means of reproduction. Seed propagation is more justified because it is the least harmful for existing populations and it would involve the widest range of genetic variability (Bruschi et al., 2003).

Conclusion

The results obtained in this research have showed the existence of significant variability of morphological characteristics of acorns and indicated high phenotypic variability of the researched traits in the sessile oak population in Avala Landscape of Outstanding Features. Based on the obtained results it can be concluded that the available gene pool of sessile oak in Avala Landscape of Outstanding Features is characterised by a satisfactory degree of genetic variability so it represents good starting point for the process of further breeding and conservation of natural population. For the purpose of long-term conservation and improvement of ecological adaptability and evolutionary potential of sessile oak population it is necessary to initiate implementing measures of *ex situ* conservation of genetic resources.

The isolated and analysed test trees can serve as a source of planting material for establishment of *ex situ* conservation facilities. The established facility will be of great importance for conservation of genetic resources of sessile oak from the area of Avala Landscape of Outstanding Features and it can also serve as a source of reproductive material for establishing cultivated forests or as a support in natural regeneration of pure or mixed stands of sessile oak in the future.

SUITABILITY OF WOOD OF NATIVE OAK SPECIES (*QUERCUS* spp.) FROM THE IBERIAN PENINSULA NORTHWEST FOR COOPERAGE

Ignacio J. DIAZ-MAROTO*

Department of Agroforestry Engineering, University of Santiago de Compostela, Spain
*Corresponding author: ignacio.diazmaroto@usc.es

Abstract

In the northwest of Iberian Peninsula, the oak wood is scarce used in the forestry industry. Small plots and many owners do not facilitate its exploitation, as well as the later industrial development. Forest management of oak forests is virtually non-existent and the use of oak wood is limited for firewood. This is one of the main reasons why it would be essential to develop a specific industry that contributes to the valorisation of these species. The aim of our research was to study the characteristics and/or properties of wood of native oak species for the manufacture of wine aging barrels. For more than 15 years, from 1993 to 2010 approximately, several inventories were carried out in oak forests of the most abundant species of the *Quercus* genus in the northwest of the Iberian Peninsula, in Galicia, particularly. Subsequently, we calculated the essential parameters of the wood using samples of different oak species felled in the inventoried forests to assess the suitability of their wood for cooperage. At first, this would allow us to even propose in advance whether to carry out certain silvicultural treatments to achieve our goal. The overall objective was to make a description of the most important properties of the wood of these species on the barrel manufacture for aging wines. The current study about wood properties of *Quercus robur* L. and *Q. pyrenaica* Willd. is based on the determination of bark, sapwood, and heartwood to assess their variation in the Galician oaks. *Quercus robur* has a higher proportion of bark (22.9%) than *Quercus pyrenaica* (17.6%), but the high coefficient of variation associated with this value (62.7%) moderate this statement.

Keywords: *Atlantic oaks, Bark, Heartwood, Sapwood, Wine aging.*

Introduction

Hardwood trees differentiate with softwood trees, and they are not necessarily harder than these (Hoadley, 1990; Alden, 1995). This terminology does not necessarily reflect the wood properties; "balsa" (a hardwood) is much softer than average softwood (Plomion *et al*., 2001). There are many anatomical differences between hardwood and softwood species; however, wood parts of a tree system are common to both (Alden, 1997; Zhang *et al*., 2014). The development of the tree trunk is reached by two growth types. The first is produced by the apical meristem and is responsible for the common and ascending primary growth of all vascular plants. Unlike non-tree plants, there is also secondary growth that results in increased trunk thickness (Ramagea *et al*., 2017). This increase is controlled by the multiplying activity of the vascular cambium, i.e., the cambium is only one cell thick that produces bark on one side and wood on the other (Dinwoodie, 2000; Schweingruber, 2007).
Accumulating extracts provides the heartwood of many hardwood species a darker colour than the sapwood (Plomion *et al*., 2001). On the oak trees, the heartwood can be seen easily visible thanks to its dark coloration. (Bary-Lenger and Nebout, 1993; Diaz-Maroto and Sylvain, 2016).

During the fall and winter months, when deciduous trees have no foliage, it is the bark that becomes the focal point. The bark is an essential part of the tree because protects it and provides with the necessary nutrients and moisture to grow (Schweingruber, 2007).
This is why it is important to protect a tree bark by using tree guards, especially over the winter months when rodents are hidden under the snow and eat the bark of the tree. If a tree's bark is deeply eaten in a continuous band (girdled), chances are the tree will not survive. Bark covers the outside of the tree and its branches and is formed by several layers. The outer bark (epidermis) protects the interior of the tree from insects, fungi, humidity, drought, wind, and sun, and during the winter months it insulates from the cold, and in summer from heat (Fernandez-Parajes *et al*., 2005). The inner bark or phloem is how the tree gets its nutrition. It is like a pipeline transporting nutrients made by photosynthesis from the leaves to rest of the tree, carries them to the branches, trunk and down to the roots of the tree. It is short lived and when it dies it becomes part of the outer bark (Myburg *et al*., 2013; Diaz-Maroto and Sylvain, 2016) (Figure 1).

Figure 1. Image of the bark, sapwood, and heartwood of a slice of *Quercus robur* trunk. As we mentioned, the heartwood can be seen easily thanks to its dark coloration.

Sapwood is the tree's pipeline for water moving up to the leaves. Sapwood is new wood. As newer rings of sapwood are laid down, inner cells lose their vitality and turn to heartwood (Hacke and Sperry, 2001). Heartwood is the central, supporting pillar of the tree. Although dead, it will not decay or lose strength while the outer layers are intact.
Trees produce annual rings that reflect the changing environment. Rapid growth during the spring produces "earlywood" which is less dense and composed of large cells with thinner walls allowing for efficient water transport to support photosynthesis. This period is followed by slower growth, yielding "latewood", characterised by more densely packed, smaller cells, production of which stops for winter (Ramagea *et al*., 2017). In softwoods, the transition can be

gradual, distinct, or a combination of each. In hardwoods, vessels may have a different size in early- and latewood (Fernandez-Parajes *et al*., 2005; Myburg *et al*., 2013).

The objectives of this study were: i) to make a description of the most important properties of wood of *Quercus* spp. –*Quercus robur* L., *Q. pyrenaica* Willd., and possible hybrids of both species– for their use in the barrel manufacture industry; ii) to analyse and assess those characteristics and/or properties of the native oaks wood with a greater influence on the manufacture of barrels for aging quality wines.

Material and Methods

Study area, sampling, data collection, and software for image analysis

Study area includes the Autonomous Community of Galicia, located in the northwest of Iberian Peninsula, with an area of ~ 3 million hectares (Figure 2). The average altitude is 508 m, and slopes of more than 20% are present in half of the territory. The lithological conformation is heterogeneous, although siliceous substrates predominate. The climate is miscellaneous and is generally classified as humid oceanic but with different Mediterranean influence in certain areas. The annual precipitation varies between 600 and more than 3000 mm (Diaz-Maroto *et al*., 2005). For more than 15 years, from 1993 to 2010 approximately, several inventories were carried out in oak forests of the most abundant species of the *Quercus* genus in the northwest of the Iberian Peninsula, in Galicia, particularly. The zone under study was considered as a single unit, where regions for sampling were selected, taking care to incorporate a representative number of oak stands with a minimum area ranged between 0.5 and 1 ha, which avoids edge effect problems. In total, 31 trees were selected in 11 different stands located of Galician provinces of Lugo and Ourense, from which we obtained 30 wood slices at 60 cm height on the tree trunk. Around 70% of the Galician territory is 600 m above sea level and many of the stands have steep slopes. Therefore, there could be an important problem in selection of the oak wood for cooperage industry because a steep slope favours the formation of tension wood with a heart outside centre, which is not suitable for the manufacture of barrels (Bary-Lenger and Nebout, 1993; Lehringer *et al*., 2008). Table 1 shows the main characteristics of the trees felled in the oak stands (from normal tree to heart strongly off centre).

Figure 2. Study area: Autonomous Community of Galicia and its four provinces (A Coruña, Lugo, Ourense and Pontevedra), northwest of Iberian Peninsula, in the world context.

Using a ruler with millimetre appreciation we can calculate the length of the different parts of the trunk (Bakour, 2003). However, it is advisable to work with a particular type of software, e.g., ImageJ, given its advantages because it is a public domain image processing program. It is possible calculate the area of bark, sapwood, and heartwood, as well as their relative percentage. The precision is greater, being possible to use a bigger number of samples considering the singularity of each one. ImageJ was created with an open architecture and is multithreaded, so time-consuming functions such as image file reading can be performed in parallel. Age measurement also was done by ImageJ with a scanning resolution of 600 dpi. Spatial calibration is available to provide real measurements in mm.

Table 1. Main characteristics of the trees felled and the wood slices.

Species	Normal tree	Heart a little off centre	Heart off centre	Heart strongly off centre	Total
Quercus robur	7	4	4	2	17
Quercus pyrenaica	5	2	3	3	13
Total	12	6	7	5	30

Results and Discussion

Measurement of the age of wood slices

Through the sample selection program, the following criteria were followed:

- Two oak species: *Quercus robur* and *Q. pyrenaica*.
- Two wood types: sapwood and heartwood; additionally, the bark.
- Four tree types and wood slices: heart a little off centre, heart off centre, heart strongly off centre, and tree with a normal heart (Table 1).

Since Image J software offers a special pointer to assign a number to each ring of growth, the age was calculate done with it, using a scanning of a resolution of 600 dpi. On the whole, the determination of the age was moderately easy. However, some samples showed periods of very slow growth, a characteristic found in many hardwood trees in the study area. In these cases, the latewood is almost absent, and it is very difficult to identify the separation of each growth ring (Bakour, 2003; Myburg *et al*., 2013).

Variability of bark, sapwood and heartwood depending on age

Quercus robur has a higher percentage of bark (22.9%) than *Quercus pyrenaica* (17.6%), but the high-level coefficient of variation (CV) linked with this value (62.7%) moderate this statement. Also, as expected, the accuracy of bark measurements is relatively low because of the irregularities. However, bark has value, be it from selling as landscaping mulch, burning it to heat dry kilns, making charcoal briquettes or carbon filters, or converting it to biomass energy (Hoadley, 1990). The method used when a log is scaled in a log yard excludes the bark content from the purchase price, resulting in it being a free commodity. Every log processed incurs a cost

in separating the bark from the wood. Hopefully, the value of the bark exceeds this cost plus the cost of transportation to its end user. Proximity to a market to minimize transportation costs plays an important role in deciding a profitable end use for the bark. Most sawmills have an idea how much bark is produced by how many trucks they fill over a period of time, thus it is volume based or weight based if the trucks are weighed as part of the sales agreement (Zhang *et al*., 2014). Age does not seem, in this case, to have a significant influence in the bark proportion.
On the contrary, there is a significant relationship between age and the proportion of the heartwood. The relationship of the heartwood age, i.e., the number of rings in the heartwood area, and the proportion of heartwood makes it possible to obtain the best correlation for each of the species. A lower width ring in oak species results in a lower texture (Bakour, 2003; Diaz-Maroto and Sylvain, 2016); the proportion of earlywood is more important than the latewood (Pasztory *et al*., 2014; Zhang *et al*., 2014).

Conclusions

The estimation of the different percentages of bark, sapwood and heartwood of the Galician oaks and its relationship with the age has allowed knowing the following characteristics:
- The proportion of heartwood is positively proportional to the age of the tree.
- When a particular tree grows quickly, the proportion of heartwood is higher at the same age than in other individuals.
- The fast growth of *Quercus pyrenaica* produces the formation of large proportion of heartwood in a few years.
- *Quercus robur* has an intermediate growth between *Quercus pyrenaica* and other oaks.
- In the Galician oaks, the heartwood proportion is between 21.8 and 62.8% (maximum and minimum values ± standard deviation ± accuracy). However, the knowledge of the tree age and the heartwood age makes it possible to improve this range by using different models.
- On the contrary, data from this study do not make it possible to respond to the existence of a relationship between age and proportion of bark and sapwood.

DETERMINATION OF *SALVIA OFFICINALIS* L. VOLATILE CONSTITUENTS BY SPME METHOD

Musa TÜRKMEN*

Department of Field Crops, Hatay Mustafa Kemal University, Faculty of Agriculture, Hatay, Turkey
*Corresponding author: musaturkmen@mku.edu.tr

Abstract

Sage (*Salvia* L.) is a valuable medicinal and aromatic plant from the *Lamiaceae* family. Although there are about 900 taxa of the genus *Salvia*, which is affiliated to the *Lamiaceae* (*Labiatae*) family, the most commercially valuable ones are *Salvia officinalis* L., which is called Medicinal sage or Dalmatian sage. In this study, volatile components of *Salvia officinalis* sage were determined by solid-phase micro extraction (SPME) technique. The aim of this study is to examine the effect of different brewing times on the change of volatile compounds in sage leaves.The extraction of volatile compounds (VCs) was carried out in a water bath at 50 degrees Celsius. After the samples were kept in the water bath for 10, 20 and 30 minutes respectively, the fiber was placed in the headspace bottle and held for 30 minutes. In these techniques, major volatile components were determined as thujone, eucalyptol and camphor. Major components were determined as thujone 28.65%, eucalyptol 15.03% and camphor 11.94% in vials kept in water bath for 10 minutes. In vials kept in water bath for 20 minutes, major components were determined as thujone 37.29%, eucalyptol 15.88% and camphor 14.12%. In vials kept for 30 minutes, major components were determined as thujone 44.21%, eucalyptol 15.66% and camphor 10.88%, respectively. It was observed that thujone ratios increased according to the waiting times of the vials in the water bath.

Keywords: *Salvia officinalis L., SPME, Sage. Lamiaceae*

Introduction

Sage is an herb that has been used for medicinal purposes since ancient times. The most commonly used species is *Salvia officinalis* L, known as medicinal sage. The genus Salvia, which belongs to Lamiaceae, is represented by more than 900 species worldwide (Tundis et al., 2020). Anatolia is an important center for Salvia, with 47 of the 90 species endemic to Turkey (Kan et al., 2007).

There are many types of sage used in treatment and grown in Turkey. Some of these are: *Salvia triloba* L. (anatolian sage), *S. aethiopis* L. (woolly sage), *S. dichroantha* Stapf., *S. multicaulis* Vahl., *S. sclarea* L., *S. tomentosa* Miller, *S. verbenaca* L. , *S. virgata* Jacq. and *S. viridis* L. species (Baytop, 1984).The leaves of this plant, which has versatile uses, are used fresh or dry. The essential oil obtained from the plant is also registered in the codex and has an important place in pharmacy; In addition to the effect of facilitating digestion in nutrition, tea prepared with sage has a cough suppressant effect. Sage is also used as an additive in various cheeses and breads made in Europe. It is known that it restores the lost energy of the body, strengthens the memory and liver, and the tea obtained from the plant is used to strengthen the nervous system. Even in recent years, this plant has started to be used in hair-strengthening shampoos, deodorants, hair dye and skin care creams (Gürbüz, 1993). It has medicinal properties such as

strengthening, carminative, stimulant, antiseptic, against oral wounds and infections (Demirci et al. 2002). In addition to the use of the plant for food, tea and medicinal purposes, it is also used as an ornamental plant in horticulture and landscape architecture. Sage, which produces very showy and abundant flowers, is also important in honey bee breeding. In a study conducted by Sıralı and Deveci (2002), some *Salvia* species it was stated that *S. glutinosa, S. officinalis, S. sclarea, S. verbanaca, S. verticillata* and *S. viridis* species are important for bees. This plant is used in different fields due to its essential oil.
The essential oil content of medicinal sage leaves is between 1.0-2.5%. The essential oil components are 30-50% thujon, 15% cineole and 10% borneol (Baytop, 1984). There are many studies on the essential oil ratio and components of species belonging to the genus Salvia in the world and in Turkey. Along with these studies, the existence of some antimicrobial and antifungal effects of the essential oils and components of these plants has been demonstrated by many studies (Joshi et al. 2021). As a matter of fact, there are studies conducted with some of the species planned to be collected within the scope of this project.

Material and methods

Plant material was collected from the trial fields of Hatay Mustafa Kemal University, Department of Field Crops. The leaves were dried under +35 ^{o}C in oven. VCs analyze of leaves was performed according to the procedures described by Guler with minor modification. Dried samples were cut into in small pieces in cold mortar and taken into headspace vials. Three mL NaCl solution (3 % concentration) was added in samples. The adsorption of VCs was carried out using Solid Phase Microextraction Technique (SPME) by a divinylbenzene/carboxen/polydimetylsilioxan fiber. The extraction of VCs was done in water bath at 50 ^{o}C. The samples were hold in water bath for 10, 20 and 30 min than fiber was inserted to headspace vial and kept at 30 min. For desorption of VCs, fiber hold in injection port at 250 ^{o}C for 5 min. The VCs were analyzed by gas chromatography-mass spectrometry (GC-MS) using TR-FAME model, 5 % Phenyl Polysilphenylene-siloxane, 0.25 mm inner diameter x 60 m length, 0.25 μm film thickness column was used. Helium (99.9 %) was used as the carrier gas at a flow rate of 1 mL/min. Mass spectra were recorded at 70 eV, the mass range was from 1.2-1200 m/z. Scan Mode was used for data collection. The MS transfer line temperature was 250°C, the MS ionization temperature was 220°C, the injection port temperature was 220°C, the column temperature was initially 50°C and the temperature was increased to 220°C with a rate of heat increase of 3°C/min. The structure of each compound was identified using mass spectra with the Xcalibur program (Wiley 9) 35. The individual compositions were determined by comparing their retention index and with Wiley Library (Wiley Interscience, New York). The relative quantities of individual compounds were calculated with the Xcalibur Report program.

Results and discussion

The main components determined according to the three different absorption times (10, 20 and 30 minutes) of SPME fiber are respectively: thujone, eucalyptol and camphor. When the volatile components of the fiber, which was kept in the vial for 10 minutes, were examined, the main component was determined as 28.65% thujone, followed by eucalyptol with 15.63% and camphor with 11.94%, respectively. The main components determined as a result of 20 min absorption of fiber were determined as 37.29% thujone, 15.88% eucalyptol and 14.12%

camphor, respectively. In vials that were absorbed for 30 minutes, the main components were determined as 44.21% thujone, 15.66% eucalyptol and 10.88% camphor (Table 1.). The other studies reported that *Salvia officinalis* compositions were determined as camphor, α-thujone, 1,8-cineole, viridiflorol, borneol, camphene, limonene, salvene, α-pinene, β-pinene, β-thujone and γ-terpinene (Celik et al., 2018). In another study, Raal et al. (2007) determined the major components of *S. officinalis* as 1,8-cineole, camphor, thujone, borneol, and viridiflorol.

Table 1. Main components determined according to three different absorption times of SPME fiber.

Conclusion

Changes in volatile components and composition may have resulted from various different factors such as climatological, seasonal, geographical and geological conditions. Also, different harvest periods, different harvesting stages and different harvest times of plants can affect essential oil content and composition, even if they are grown in the same ecological conditions. In this study, different waiting times and volatile components of sage leaves obtained by harvesting under the same conditions were determined by SPME. Thus, in addition to the standardization in harvesting and growing conditions, volatile components can be determined by different methods and standardization in components will be achieved.

Abstract

Medical and aromatic plants are divided into two groups, those collected from nature and those that are cultivated. Medical and aromatic plants collected from nature are plants that grow spontaneously in natural places such as forests. Two of these plants commonly grown are *Laurus nobilis* L. and *Myrtus communis* L. This study was carried out in order to determine the ratio and components of essential oils obtained by different methods (hydrodistillation, steam distillation and boling distillation) of laurel trees and myrtus growing densely in Hatay flora of Turkey. Hydrodistillation method is a traditional method widely used in obtaining essential oils made with a Clevenger type apparatus in small-scale productions. Whereas, steam and boiling distillation method is carried out in large distillation boilers (retort) in industrial applications. Previously it was determined that the essential oil ratios in Clevenger were between 2.5-3% in laurel, 1.5-2% in myrtle plant. In the essential oils obtained by retort methods (steam and boiling distillation), these ratios were observed between 0.8-1.2% in laurel and 0.3-0.7% in myrtle plant. When the essential oil components were examined, the main components of laurel were determined as eucalyptol, α-terpinyl acetate and sabinene in all methods. Main components of laurel essential oil in the Clevenger were determined as eucalyptol 54.85% α-terpinyl acetate 18.52% and sabinene 3.25%, respectively. Whereas, components obtained by retort methods (steam and boiling distillation) were determined as 57.53-44.48% eucalyptol, 12.06-8.94% sabinene and 7.59-17.98% α-terpinyl acetate. The main components for the myrtle plant were determined as α-pinene, eucalyptol, linalool. Linalool was replaced by limonene in the retort methods.

Key words: *Laurus nobilis L., Myrtus communis L., Essential oil, Clevenger, Retort.*

Introduction

Laurel is a plant belonging to the *Lauraceae* family intensely found in Turkey, especially in the Mediterranean, Aegean and Black Seas. As a species, there are mostly Mediterranean Laurel (*Laurus nobilis* L.). This species is a 3-10 meters high, evergreen tree with yellow flowers in winter. The leaves of the plant are 5-10 cm long, 2-5 cm wide, hard and short-stalked, green-colored; its fruits are in the form of small olives (Baytop, 2000). All parts of the laurel plant are used in terms of the use of leaves, wood and fruits. Spices and essential oil are produced from its leaves, fuel is produced from its wood and fixed fruit oil is extracted from its fruits (Safak and Okan 2004).
Myrtle is a shrub-shaped plant from the *Myrtaceae* family. It is a plant that can rise up to 2-3 meters in height and is seen in places where the Mediterranean climate prevails, especially in coastal areas, sometimes in the form of a small tree. The color of the leaves is light bright green and old leaves are dark green, leathery, egg-shaped or lanceolate with a pointed tip and whole

edges. Its flowers consist of five white oval or egg-shaped segments and have small white knobs at the tip. Its fruits are round or egg-shaped, pea-sized, bluish-black or rarely white. Immature fruits are bitter while mature ones are sweet. Since it is a drought-resistant plant, it blooms throughout the summer (June-September) (Sümbül et al., 2011). The essential oils of the fresh and/or dry leaves of the myrtle plant are used in the cosmetics, confectionery and beverage industries (Akgül, 1993; Akgül and Bayrak, 1989; Boelens and Jimenez, 1992). The fruit of the myrtle plant has an aromatic flavor and can be eaten fresh when ripe or dried for later use as a flavoring agent. The leaves are also suitable for use. Its dried fruits and flower buds are used to flavor sauces and syrups. The essential oils of the leaves and branches are used as a flavoring agent, especially when mixed with other spices. In addition, the flowers have a pleasant taste and are used in salads in Italy (Genders, 1994; Farah et al., 2006).

Material and methods

Essential oil isolation and hydrodistillation

The essential oil was obtained from dried leaves. A total of 25 g of each of the ground plant samples was used for the separate hydrodistillation experiment. Weighed samples were placed into a 1L flask, individually and carefully. Then distilled water was added until it covered completely the sample. Essential oils were obtained in an all-glass Clevenger-type distillation according to hydrodistillation method. The trial was carried out at three times. The essential oils were evaporated with anhydrous sodium sulfate and stored at 4°C in dark bottles until analysis time.

Steam Distillation

Twenty liters of water was put into a 40-liter stainless steel steam generator with 3000 Watt dimmer belt heater. The 10 kg sample was placed in a 40-liter stainless steel distillation vessel with a dome-designed cover, distillation column and cooler made entirely of copper. The water inlet and outlet of the cooler part are provided and the cooling process is started. When the steam generator was started and the temperature rose to 100°C, the distillation process started and the process continued for 4 hours. After the distillation, the oil obtained with a separating funnel was separated from the water and the process was completed.

Boiling Distillation

20 liters of water and 10 kg of sample were put into the 40-liter stainless steel steam generator used as a herbal boiler with a 3000-watt dimmer belt heater with a dome-designed cover, distillation column and cooler made entirely of copper. The water inlet and outlet of the cooler part were provided and the cooling process started. When the steam generator was started and the temperature rose to 100°C, the distillation process started and the process continued for 4 hours. After distillation, the oil obtained with a separating funnel was separated from the water and the process was completed.

Figure 1. Retort distillation methods (steam and boling)

GC/MS analysis

The essential oil components obtained from plants were determined by the Gas-chromatographic method. Determination of the components was carried out with Thermo Scientific ISQ Single Quadrupole model gas chromatographic device under the following conditions. TR-FAME model column consisting of 5 % Phenyl Polysilphenylene-siloxane (0.25 mm inner diameter x 60 m length, 0.25 µm film thickness) was used. Helium (99.9 %) was used as a carrier gas at a flow rate of 1 mL/min. Mass spectra were recorded at 70 eV, the mass range was from 1.2-1200 m/z. Scan Mode was used for data collection. The MS transfer line temperature was 250°C, the MS ionization temperature was 220°C, the injection port temperature was 220°C. The column temperature was initially 50°C and the temperature was increased by a ramp of 3°C/min up to 220°C. The structure of each compound was identified using mass spectra with the Xcalibur program (Wiley 9) 35. The individual compositions were determined by comparing their retention index and with Wiley Library (Wiley Interscience, New York). The relative quantities of individual compounds were calculated with the Xcalibur Report program.

Results and discussion

Essential oil ratios were determined between 2.5-3% in the Clevenger according to hydrodistillation method. On the other hand, this ratio varied between 0.8-1.2% in retort boiling and 1.5-2% in steam distillation method. When the laurel essential oil components obtained by different methods were examined, the main components were determined as eucalyptol, α-terpinyl acetate and α-pinene. While the highest eucalyptol ratio was determined with 57.53% in retort boiling, the lowest ratio was determined with 44.48% in the steam distillation method. The highest value for α-terpinyl acetate was determined in hydrodistillation method with 18.52%, and the lowest ratio was detected in retort boiling with 7.59%. While α-pinene, another main component, was determined at the highest ratio with 7.18% in retort boiling, at the lowest ratio with 3.9% in the hydrodistillation method (Table 1). Özcan and Chalchat, (2005), in their study on laurel essential oil, reported that the essential oil ratios of laurel leaves collected from seven different regions varied between 1.4% and 2.6%. In the component analyzes performed in GC-MS, researchers reported that the main components were eucalyptol (51.73-68.48%) and α-terpinyl acetate (4.04-9.87%), respectively.

When the essential oil ratios of myrtle were examined, the highest essential oil ratio was obtained in the hydrodistillation method with 1.5-2%. On the other hand, the lowest ratio was observed in the retort boiling with 0.3-0.7%, this ratio varied between 0.9-1.2% in steam boiling. When the changes of essential oil components were examined, the highest α-pinene ratio with 52.56% was determined in retort boiling method while the lowest ratio with 28.32% in hydrodistillation method (Table 2). Eucalyptol, another main component, was detected with the highest ratio as 34.25% in hydrodistillation method, while the lowest ratio with 19.78% in steam distillation method.

Conclusion

Laurel and Myrtle play an important role in the essential oil trade. Therefore, it is very important to standardize the essential oils of these plants. As a conclusion, it was determined that the highest essential oil ratio was obtained by hydrodistillation method. When an evaluation is made in terms of the components, it is seen that there are differences according to the methods. Since it is clear that the cultivation of these plants collected from nature and the standardization of essential oil ratios and contents are very important for the essential oil trade, these studies should increasingly continue.

Abstract

It has long been known that certain parts of yellow gentian have medicinal and edible usage value and that as such they find their application in pharmaceutical and food industries as well as in traditional medicine. Yellow gentian (*Gentiana lutea* subsp. *symphyandra* (Murb.) Hayek) is a protected (sub) species in Bosnia and Herzegovina because it is considered endangered. The main reasons for this are over-exploitation and relatively slow natural regeneration. Working on the project of its mass reproduction, we collected and analyzed samples of yellow gentian`s rhizome and root from the mountain Šator in B&H. We found that *Gentianae radix* contains about 66.9% water and about 33.1% dry matter. Total sugars are represented by 5.63%, fats with 3.14% and pectins with 1.04%. Among analyzed elements, the most prevalent was calcium with an average concentration of 3208.7 mg/kg and the least represented was chromium with an average concentration of 0.44 mg/kg. The main part of the mineral spectrum consists of three elements: Ca, K and Mg, with a share of 93.4%. In *Gentianae radix*, 25 fatty acids were detected, of which 12 were sturated and 13 unsaturated. The ratio of saturated to unsaturated fatty acids is 43.16 % : 56.84 %. The most common among saturated fatty acids is palmitic with a share of 26.52 %, while the most common unsaturated fatty acid is a mixture of oleic and elaidic fatty acids with a share of 31.99%. Regarding phytochemicals, *Gentianae radix* contains on average: total phenols – 3820.54 μgGAE/g, total flavonols – 568.22 μgQE/g, non-flavonoids – 4280.49 μgGAE/g and anthocyanins 710.71 μg/g.

Key words: *yellow gentian, rhizome and root, chemical composition, phytochemicals.*

Introduction

Taxon *Gentiana lutea* L. is distributed from the Iberian Peninsula to the mountains of Asia Minor. It consists of four subspecies: the type spp. *lutea*, spp. *symphiandra*, spp. *monserratii* and spp. *vardjanii* (Rossi, 2011). The type spp. *lutea* has a wide range stretching from the Cantabrian Mountains and the Pyrenees in the west to the Central Alps in the east (Stevanović et Jakovljević, 2014), going south to Gennargentu Massif on Sardinia (Chiappini et Angiolino, 1983; Gentili et al., 2013). The exclaves of this area are located on the Mt. Šar in Northern Macedonia, on the mountain massifs on the border of Albania and Greece and on the high mountains within Sterea Hellas Region of Central Greece (Hartvig, 1991; Matevski et Wraber, 2010). The subspecies *symphiandra* also has a wide range covering the Eastern Alps, the Balkan Peninsula, and the Carpathian Mountains, as well as the mountains of the North West Asia Minor. The other two subspecies have significantly narrower ranges. The subspecies *monserratii* inhabits the Central Pyrenees, while spp. *vardjanii* occupies the South East Alps. Yellow gentian grows on upper montane and subalpine belts, above 800-1000 m., where, as a distinct heliophyte, it occurs in the grasslands and mountain barren lands.

The root, *i.e*. rhizome, is used from the yellow gentian. *Gentianae radix* is a part of our and European traditional medicine and its use has been described in most of the world's pharmacopoeias. In folk medicine, it is used to improve appetite and stimulate digestion (Nastasijević, 2016). It is also used against coughs and diarrhea, and very often to strengthen the decrepit organism (Tucakov, 1984). It was previously used in veterinary medicine for stomach diseases and problems with digestion of domestic animals (Jakovljević, 1951). *Gentianae radix* is used in official medicine as well as in the pharmaceutical and food industries. It is used in lack of appetite, in the treatment of anorexia, atonic dyspepsia, gastrointestinal atony, especially in dyspepsia with anorexia (Tasić et al., 2009; Anon., 2014).

Due to its medicinal properties, gentian root has been collected in nature for thousands of years. Since it is a slow-growing species, by non-selective root extraction, the plant can be completely destroyed, so it takes a long time for the damaged populations to recover. Yellow gentian is considered an endangered species in our country and its collection from natural sites is out of the question (Anon., 2013). However, the affirmative results with its artificial cultivation (Bjelić, 2012; Cuena-Lombraña, 2015; Galambosi, 1996; Holobiuc et al. 2006, 2008; Kušar et Baričevič, 2006; Lamproye et al., 1987; Petrova et al., 2006, 2019; Radanović et al. 2005, 2007, 2008, 2013; Skrzypczak et al., 1993; Wesolowska, 1985; and other sources) have restored interest in this medicinal plant and created realistic preconditions for its wider exploitation in our region, especially in the area of its natural habitats along the Dinaric Alps. Bearing in mind that very modest sources dealing with the chemical composition of gentian root from B&H, from which its useful value derives, we analyzed the chemical elements, fatty acids and phytochemicals of *Gentianae radix* from the locality Šatorsko Lake on the Mt. Šator.

Material and method

Material

Yellow gentian is an herbaceous perennial with rhizomatous and branched roots. The stem is erect, unbranched, up to 1.5 m high, round, and hollow. The upper leaves are oblong, wide lanceolate to elliptic, oppositely arranged, with 5-7 parallel nerves. The ground leaves are gathered in a rosette. The flowers are large, golden yellow in color, grouped in the apex of the stem in compact pseudo whorls inflorescences (Fig. 1).

Figure 1: Yellow gentian in full bloom on the slopes of Mt. Jahorina (photo S. Ljubojevć)

Figure 2: Root and rhizomes of yellow gentian from Mt. Šator (photo S. Ljubojevć)

Gentian roots were extracted in October 2020 on Mt. Šator, after the flowering phenophase was completed (Fig. 2). The older root of the adult plant was selected, cleaned of soil and rotten parts. After digging, the heads of the rhizomes with buds were returned to the ground together with the excavated soil and covered with sod. Thus, the plant is preserved from destruction and a new harvest is provided in a few years. Otherwise, the root of the yellow gentian is more or less cylindrical, often times over 10 cm long, up to 5 cm thick. It is reddish-brown on the outside and dark yellow on the inside. It swells very much in water. Its taste is first discreetly sweet and then very bitter, smelling like figs.

According to the Red list of vascular flora of B&H (Anon., 2013), yellow gentian is distributed in the following localities: Mt. Šator, Mt. Cincar, Mt. Dinara, Mt. Treskavica, Mt. Prenj, Mt. Plasa, Mt. Čvrsnica, Mt. Velež, place Petrovac, place Vakuf, Mt. Veliki Cincar, village Prolog near Livno, Rosni Dolac – the ridge of Mt. Kamešnica, Mt. Vlašić, Mt. Bjelašnica, Mt. Vlahinja, Mt. Jahorina, Mt. Maglić, Mt. Volujak, Mt. Zelengora, Mt. Ivan, and has the status: endangered species (EN). Material for analysis was taken in the immediate vicinity of Šatorsko Lake (1448 m a.s.l.). This area is inhabited by dwarf mountain pine (*Pinus mugo* Turra) as the main edificator (Fig. 3). The lake is of glacial origin and one of the main natural beauties of this region. According to the ecological-vegetation regionalization of B&H (Stefanović et al, 1983.), Mt. Šator belongs to two areas. The north-exposed parts belong to the Area of Inland Dinarides (including research site), while the South-exposed parts of this mountain belong to the Area of Mediterranean Dinarides.

Figure 3: Research site next to the Šatorsko Lake – in the foreground is a community of dwarf mountain pine inhabits with yellow gentian (Photo: S. Ljubojević)

Method

Taxon determination was performed using two sources: *Flora Europae*, Vol. 3: *Diapensiaceae* to *Myoporaceae*, CXL *Gentiantaceae*, page 60 (Tutin et al., 1972) and Mountain plants, page 108 (Lakušić, 1982). Gentian root was excavated in mid-October 2020. Immediately after extraction, the root was cleaned and transferred to the laboratory. There it is washed in distilled water, peeled and dried. The collected material of fragmented underground organs of *Gentiana lutea* ssp. s*ymphyandra* complies with the European Pharmacopoeia (Anon., 2019).

The water content was determined by drying fresh tissue to constant mass at 105^{o}C (935.29, AOAC, 2016). Dry weight, total ash and total sugar were determined by the standard AOAC methods (Horwitz & AOAC, 2000). Fats content was determined by the Soxhlet method (920.39, AOAC, 2016). Total pectin substances were precipitated with ethanol. After the addition of carbazole, a red color appears which was measured spectrophotometrically at 535 nm. Total phenol content was determined by the modified Folin-Ciocalteu method (Wolfe et Liu, 2003). Gallic acid was used as a standard compound and the results were expressed as a phenol equivalent to the gallic acid (GAE), i.e. µg GAE/mg. The total flavonoids are determined by the method of Kumaran & Karunakaran (2007), and the total flavonols according to the method of Ordoñez *et al*. (2006). Quercetin was used as the standard compound, and the results were expressed as µgQcE/mg. Anthocyanins were determined by the spectrophotometrically modified "single" pH method (Sun, 2002). Fatty acid methyl esters of the tested samples were prepared by direct esterification with a saturated solution of methanol with KOH, according to Majors (2013). Obtained fatty acid methyl esters were separated in a gas chromatography from Perkin Elmer, model Clarus 680, equiped with flame ionization detector and a capillary column Elite-

WAX, 60 m long, with inner diameter 0.32 mm and film thickness 0.50μm. Initially, the column temperature was set at 60 ºC for 2 min, than raised to 200 ºC at a rate of 10 ºC/min; again, it was raised at 240 ºC at a rate of 5 ^{o}C/min and maintained at 240 ^{o}C for 30 min. Thus, total chromatographic run time was 54 min. The flow rate for the carrier (H_2), auxilary (N_2) and detector flame (H_2 and synthetic air) gases was 1.5 mL/min. The composition of fatty acid methyl esters and the resulting acids is shown as a percentage of individual fatty acids in the total amount of identified fatty acids (g/100 g of total fatty acids). All samples were studied three times and averaged. When determining the chemical elements, 2.5 ± 0.0001 grams of crushed sample was burned in a mixture of nitric and perchloric acid by volume (10 mL of concentrated nitric acid, 10 mL of diluted nitric acid [1: 1], 10 mL of concentrated perchloric acid) and evaporated to dryness. The dry matter was dissolved with 10 mL of diluted hydrochloric acid [1:3] (Trajković et al., 1983). The solution was then filtered into a 50.00 mL volumetric flask and the filtrate was made up with deionized water. ICP OES measurements were performed three times for each duplicate using Optima 8000 Optical Emission Spectrophotometer (Perkin Elmer, USA). The sample solutions were pumped by a peristaltic pump from tubes arranged on a Perkin Elmer auto-sampler model 510. For the calibration of instrument, a CRM solution proposed by the Instrument Calibration standard 2 was used, with a minerals concentration of 100 mg/L (Pb, Cd, ... Perkin Elmer, USA). The obtained results are presented as the mean value from three repetitions.

Results and discussion

The results of the chemical analysis are shown in tables 1 & 2. Root of yellow gentian (*Gentiana lutea* subsp. *symphyandra* (Murb.) Hayek) from B&H contains about 66.93% water and about 33.07% dry matter. The most common group of compounds are sugars (5.63%), followed by fat (3.14%) and pectins (1.04%), while ash has only 0.9%. In this regard, Tucakov (1964) is one of the few authors to mention that gentian root also contains some fat, stating that their content can go up to 5%.

Among the 16 elements analyzed in this study, the most prevalent was calcium with an average concentration of 3208.79 mg/kg_{DW} and the least represented was chromium with an average concentration of 0.44 mg/kg_{DW} (Tab. 1). Cd, Fe, Mo and Pb were below the limit of detection in all samples, while As and Se were not detected at all. The main part of the mineral spectrum consists of three elements: Ca, K, and Mg, with a share of 93.5%, while all other detected elements have 6.5% of total composition. For comparison, elemental concentrations obtained from several locations along the Dinaric Arc are also summarized in Table 1. In the material originating from the Mt. Velebit in neighboring Croatia (Zeiner et al., 2015), there is a slightly different constellation of elements. Calcium is the most abundant element here as well, but it is four times more abundant than in our material from Mt. Šator. At the same time, the concentration of potassium is 10 times lower in the samples from Mt. Velebit compared to our material. There are significant differences in the concentrations of Al and Na. There is twice as much sodium and five times as much aluminum in the material from Mt. Velebit in relation to the material from the Mt. Šator. There are also significant differences in the content of Zn which is 7.5 times more in our material compared to the samples from Mt. Velebit. Comparing the elemental composition of gentian root from the Mt. Klekovača, Mt. Ocječenica and Mt. Vranica in B&H (Predić et al, 2012) and materials from the seven mountains of northern Montenegro (Balijagić et al, 2012), minor differences in the concentrations of individual elements are observed (Tab. 1). In relation to Mt. Šator and Mt. Velebit, the material from these localities is characterized by a significantly higher concentration of Fe and Mn. Concentrations of As, Cd and Pb in our and other observed samples do not exceed the permissible level established by WHO for medical raw plant materials (1.0, 0.3 and 10 mg / kg, respectively), (WHO, 1991, 2007).

Table 1: Elements in yellow gentian root from different localities along the Dinaric Arc

Element	Mt. Šator, B&H		Northern part of Mt. Velebit, Croatia(1)		Western and Central Dinarides in B&H(2)		Mountains in the north of Montenegro (3)

In the root of the yellow gentian, excavated near Šatorsko Lake, 25 fatty acids were detected, of which 12 were saturated and 13 unsaturated (Tab. 2). The ratio of saturated to unsaturated fatty acids is 43.16% : 56.84%. The most common among saturated fatty acids is palmitic acid with a share of 26.52%, while the most common unsaturated fatty acid is a mixture of oleic and elaidic fatty acids with a share of 31.99%. Two more fatty acids are significantly present, stearic with 8,08 % and linelic with 14.81 %.

Root of the yellow gentian also contains chemical compounds from the category of phytochemicals, such as: phenols - 3820.54 μgGAE/g, flavonols - 568.22 μgQcE/g, non-flavonoids - 4280.49 μgGAE/g, anthocyanins - 710.71 μg/mg.

Table 2: Assortment of fatty acids in the root of the yellow gentian, excavated near Šatorsko Lake

Saturated fatty acids				Unsaturated fatty acids			
No	Common name	C:D	%	No	Common name	C:D	%

Conclusions

The results of the research confirmed that yellow gentian is a valuable medicinal plant species. Gentian root, among other things, contains an interesting set of fatty acids, whose potential has yet to be expressed. At the same time, no harmful substances were found in the root of the gentian. By further improving plantation cultivation, the pharmaceutical and food industries could obtain significant quantities of high-value raw materials of wide use value.

Abstract

Fruits of *Viburnum opulus* are very popular not only in folk medicine but they are also used for production of food and medicinal products. Biologically active compounds of these fruits could help in heart diseases and colds, digestive disorders and internal bleeding. In this study, the dynamic of fruit biochemical compounds during ripening and fruit size changes were determined. It was found that the average weight of one fruit increases no longer after the stage of technical maturity. The average ascorbic acid content increased during fruit ripening. The largest amounts of ascorbic acid were accumulated at the biological maturation in fruits of *V. opulus* var. *sargentii* and the clone P1, respectively, 58.4 mg/100g and 56.0 mg/100 g. Quantity of ascorbic acid ranged from 27.0 mg/100 g to 44.3 mg/100 g on average. At the stage of biological maturation, sugars and soluble solids were detected in large quantities also. The soluble solids content must be assessed with a refractometer to determine the exact harvest time. However, the highest titratable acidity was determined in unripe fruits (ripening stage I). Summarizing the performed biochemical studies of *V. opulus* fruits, it can be stated that amounts of biochemical compounds varied greatly during ripening. In order to determine precisely the most appropriate harvest time for *V. opulus* fruits, these characteristics need to be assessed. It is important to define when fruits accumulate large amounts of biologically active substances and acquires good taste also.

Keywords: *cultivar, biochemical compound, fruit, maturation.*

Introduction

Fruits containing high amounts of bioactive compounds are the focus of different studies. The growing interest in less known plants and their fruits has been observed in recent years (Kraujalytė et al., 2013). The species *Viburnum opulus* L. (European cranberry bush) is widespread in eastern, northeastern, western, and central Europe and in western and eastern Siberia. Different phytochemicals were identified as important components in fruits and seeds, for example, ascorbic acid (Rop et al., 2010), α-tocopherol, linoleic and oleic fatty acids (Yang et al., 2011), various polyphenolics, including phenolic acids (Velioglu et al., 2006), flavonoids (Erdogan-Orhan et al., 2011) and anthocyanins (Velioglu et al., 2006; Česonienė et al., 2009). As reported by Velioglu et al. (2006) and Kraujalytė et al. (2013), *V. opulus* fruits are a good source of chlorogenic acid (0.54-6.93 mg/mL of juice) which is characteristic by anti-inflammatory, antiviral, antimicrobial, antimutagenic and anticarcinogenic activities. Traditionally bark, leaves, flowers and fruits of *V opulus* has been used for food and folk medicine in European and Asian countries (Česonienė et al., 2009). Fruits of *V. opulus* are also used for food in Scandinavia, while in Canada they are used as surrogates of cranberries (*Vaccinium macrocarpon* Aiton)

(Velioglu et al., 2006). Studies of frozen fruits have shown different amounts of phenolic acids, anthocyanins (Altun and Yilmaz, 2007; Deineka et al., 2005), organic acids (Çam and et al., 2007), and carotenoids (Česonienė et al., 2008). The antimicrobial properties of these fruits have also been studied and it has been found that their ethanolic extracts inhibit the growth of some pathogenic bacteria (Sagdic et al., 2006). As Kraujalytė et. al (2013) has reported, the phytochemical composition of *V. opulus* fruits is complex and depends on genotype. So, the breeding of new cultivars is very promising. Cultivars of *V. opulus* were usually developed by selecting plants according to the fruit size, yield, colour of leaves and fruits. Russian scientists have achieved good results and have nurture cultivars distinguish by a better taste of fruits and big yield (Česonienė et al., 2009). To date, more detailed research has been conducted in Ukraine also (Gavrilin et al., 2007). The aim of the study was to determine the dynamic of fruit weight and chemical composition of *V. opulus* during the ripening process.

Materials and methods

Fruit samples were collected at the *Viburnum* L. genus collection in Botanical Garden of Vytautas Magnus University in Lithuania. Fruit samples were collected during four stages of fruit ripening: stage I - fruits begin to colour; stage II – fruits are coloured but not yet softened (technical maturity); stage III – fruits are coloured and begin to soften (consumption maturity); ripening stage IV – overripe fruits (biological maturity). Samples were collected from different parts of the plant (from well-lit and middle of the crown places), each sample weighing 0.6-0.7 kg. The average weight of a fruit was measured by using an analytical balance with a sensitivity of 0.01 g (ISHIDA company, Japan, model DJ-150E). The maximum capacity of the balance was 150 g. For each genotype, 50 fruits in three replicates were estimated. Total sugar content was determined by the Bertran method, reducing sugars - by the inversion method, and sucrose content - by the pre- and post-inversion methods (AOAC[a], 1990). Ascorbic acid content was determined by titration with 2,6-dichlorophenolindophenol sodium salt solution and using chloroform (for intense coloured extracts), titratable acidity by titration with 0.1 N NaOH solution, converted to citric acid content (AOAC[b], 1990). Dry matter content was determined gravimetrically, the berries were dried at 105 °C to constant weight (Food ..., 1986). Total soluble solids were determined by digital refractometer (ATAGO PR-32, Atago, Japan).
The data were analysed using SPSS Statistics version 24.0. Duncan's multiple range test was used to assess the data for significant differences. A p-value of 0.05 was set as the limit for significant differences.

Results and Discussion

V. opulus fruit is a juicy stone fruit with a round and flat stone. During the processing of these fruits, the pulp should be separated so it is important to assess not only the weight of fruits but also what a part of fruit weight forms the pulp. It was found that during the first ripening stage, the average weight of one fruit was 46.1 g (Table 1). During the other two ripening stages, fruit weight increased but no statistically significant differences were found between ripening stages II, III, and IV. During the first three ripening stages, the fruit pulp did not change however the largest proportion of a pulp was detected at the stage IV - 73.5%.

Table 1. Changes of *Viburnum opulus* fruit weight and pulp proportion during ripening

Maturity stage	Average fruit weight, g	Fruit pulp, %
I	46,1 a	64,8 a
II	58,5 bc	65,5 a
III	60,3 bc	65,0 a
IV	61,2 c	73,5 b

Means followed by the same letter in the column are not significantly different at $\alpha \leq 0.05$

Unripe fruits are characteristic by an unpleasant bitter taste and are not suitable for either fresh consumption or processing. It is therefore important to determine the optimal harvesting time to ensure an adequate amount of biologically active compounds.

Fruits of *V. opulus* accumulated on average 6.22% of total sugars at the first stage of ripening. The total sugar content increased significantly in fruits at the ripening stage II (technical maturity) and the average amount was 7.98%. Later, overall increase in sugar content was not substantially higher compared to technical maturity stage (Figure 1).

The average content of reducing sugars in fruits was 5.56% at the ripening stage I and the highest content was found at technical maturity (ripening stage II) - 7.46%. The amount of reducing sugars in fruits did not changed significantly during ripening stages III and IV. Sucrose was found in small amounts that varied slightly during the ripening stages (Figure 1).

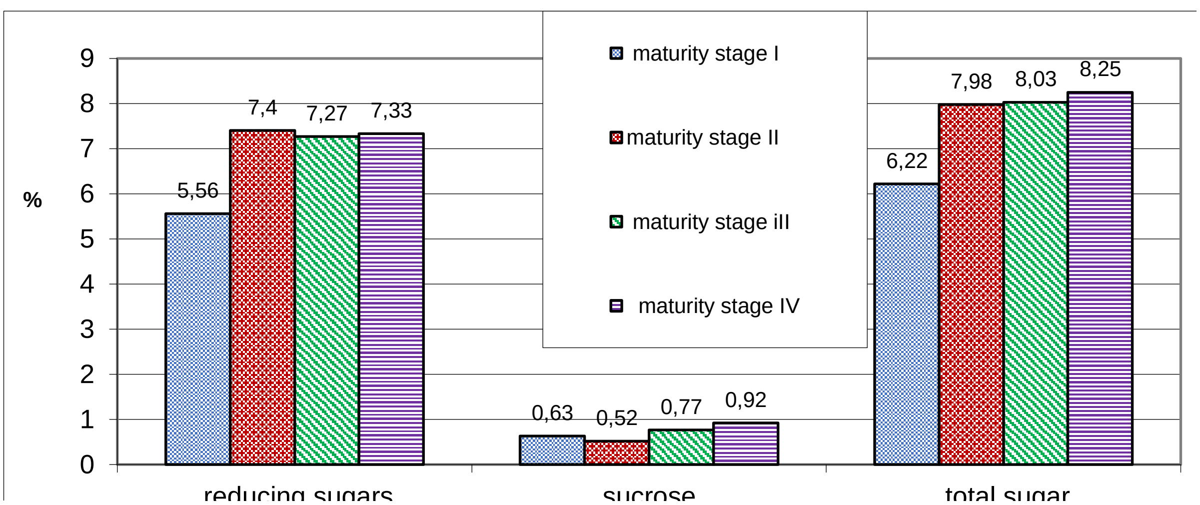

Figure 1. Variation in average amounts of total sugars, reducing sugars, and sucrose of *V. opulus* fruits during ripening, $p \leq 0.05$.

The dynamic of the average dry matter content was not significant during fruit ripening and varied from 13.3% (ripening stage I) to 13.5% (ripening stages III and IV) (Figure 2).

The highest titratable acidity was found in the fruits of ripening stage I and significant differences were not detected during ripening stages II-IV. At the first ripening stage, the total soluble solids content in fruits of *V. opulus* was 8.0%. During ripening, the average soluble solids content of the fruit increased to 12.2% (ripening stage IV).

An important property of fruits is their taste which depends on the ratio of sugars and acids, i.e., sweetness index. The average sweetness index of the tested samples was 3.76 at the ripening stage I. It increased to 6.84 during ripening stage II but did not change significantly with further ripening. The sweetness index was 6.36 and 6.56 at the maturity stages III and IV, respectively.

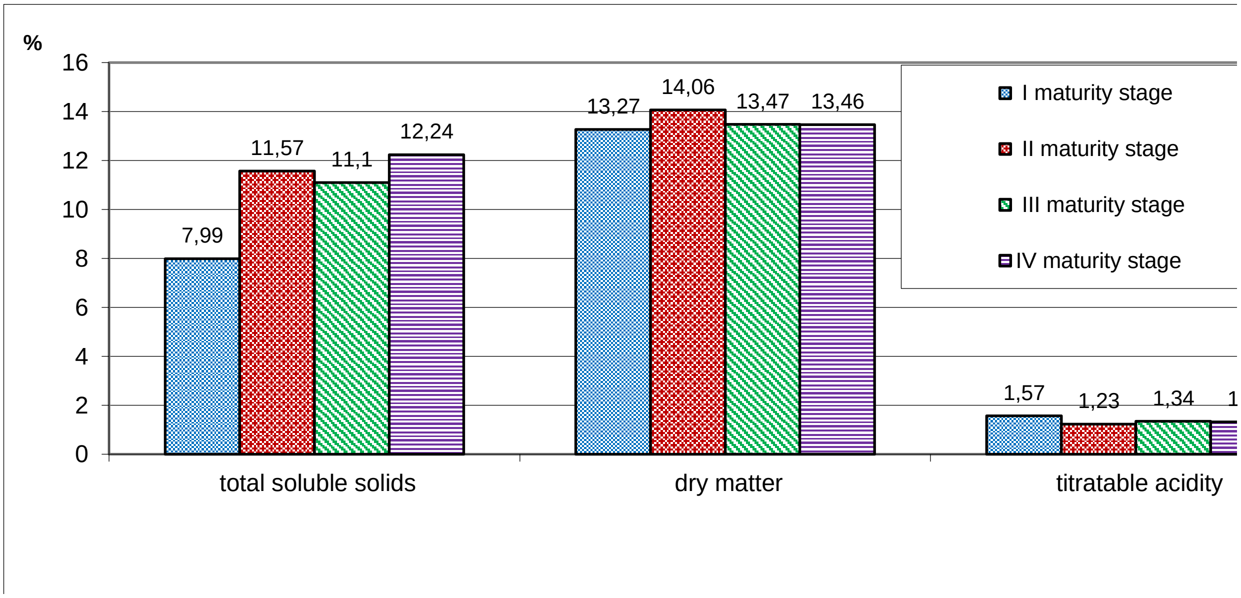

Figure 2. Variation in average amounts of total soluble solids, dry matter and titratable acidity of *V. opulus* fruits during ripening, p≤0.05.

During the I and II ripening stages, fruits of *V. opulus* accumulated the average ascorbic acid content from 18.3 to 19.6 mg /100g (Figure 3).

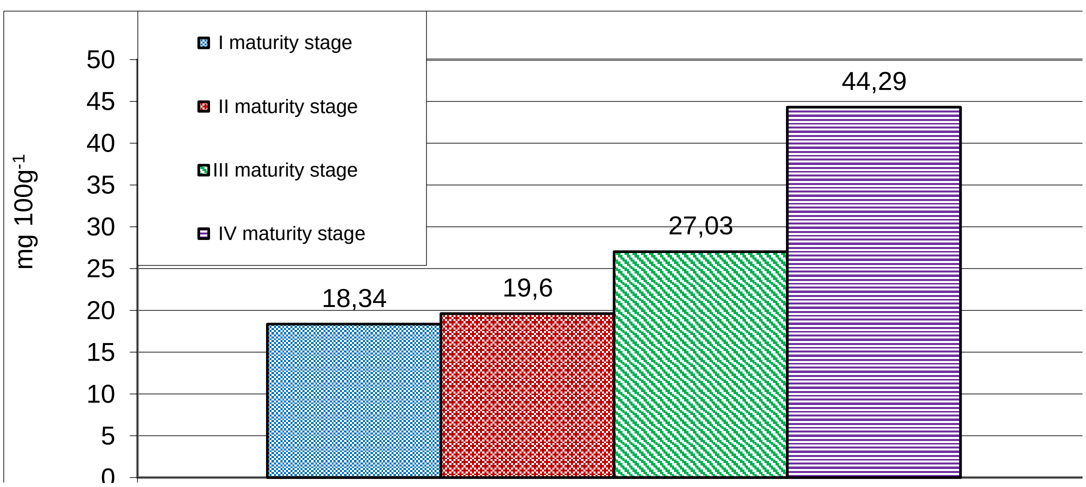

Figure 3. Variation in average ascorbic acid amounts of *V. opulus* fruits during ripening, p0≤.05.

The average ascorbic acid content increased significantly at the ripening stage III. Ascorbic acid was found on average of 27.0 mg/100 g in ripe fruits (ripening stage III) and 44.3 mg/100 g at the stage IV (Fig. 4).

Summarizing the investigations on *V. opulus*, it can be stated that sugars, dry matter, total soluble solids and ascorbic acid amounts varied during different maturity stages. Interest in the chemical composition of *V. opulus* fruit is stimulated by the fact that other biologically active compounds found in them are strong antioxidants (Kraujalytė et al., 2013; Rop et al., 2010). In the food industry, the pulp of fruits is commonly used. Our study has shown that pulp forms more than 60% of the total weight of ripe fruit. However, according to some authors (Çam et al., 2007), *V. opulus* seeds are also a source of valuable biologically active compounds, so the seeds could be used in the pharmaceutical industry for fruit processing.

Conclusions

V. opulus fruits accumulated various amounts of sugars, acids, dry matter, total soluble solids, and ascorbic acid. The content of different biochemical compounds varied during fruit ripening. The largest amount of total reducing sugars and sucrose were detected starting at the technical maturity stage. Ascorbic acid levels increased gradually and the highest levels were found in fruits of biological maturity. Fruit weight changed more slowly with the beginning of technical maturity, but the largest proportion of fruit pulp was detected at the stage of biological maturity.

Abstract

Anthropogenic disturbances of the boreal forest ecosystems are defined as important ecological processes with significant long-term influence on biogeochemical cycles and vegetation. The development of understory plants immediately after clear-cut logging was studied in Lithuanian boreal Scots pine forests. Experiments were carried out in *Vacciniosa* forest types. The mature forest stands and the clear-cutted areas were compared. We have determined the different response of Ericaceae shrubs *Vaccinium vitis-idaea, Vaccinium myrtillus* and *Calluna vulgaris* to changed environmental conditions after clear-cuttings. *Lycopodium annotinum* and *Goodyera repens* were defined as the most sensitive because small populations of these species disappeared in the cutted areas. Juvenile populations of *L. annotinum* most likely were destroyed after soil preparation for new forest planting. Mosses were damaged exceptionally strong, some species disappeared in the clear-cutted areas as well. Considerable decline of dwarf shrub layer confirmed the negative reaction of this dominated understory life form however, the dynamic of different vascular plants demonstrated species-specific response to changing environmental conditions. Because of rapid changes of light as well as damage of rhizomes by soil disturbances, the values of mean cover of the studied Ericaceae species decreased. Spread of *C. vulgaris* renewed through seedlings and the number of new annual and perennial light-demanding and nitrophilic herbs species was significant in both forest types in two years after cuttings. This study corroborated the importance of evaluation of understory plants before cuttings and will promote the implementation of protection of sensitive species and non-wood forest resources.

Keywords: *clear-cutting, life form, understory plants, soil*

Introduction

Deforestation and logging have a very strong impact on forest soil and cause significant changes in the understory vegetation. After clear-cutting, intensive soil preparation and subsequent planting of saplings affect forest biodiversity as these activities significantly disrupt the natural dynamic of forest ecosystems (Bergstedt et al., 2008; Paillet et al., 2010). Clear-cuttings destroy the natural forest structure, plant species composition, distribution and abundance of shrubs and herbaceous plants. Understory plants are particularly drastically affected by clear-cutting, where various felling waste was collected. Vanha-Majamaa et al. (2017) conducted investigations in spruce forests and determined that vascular plant species suffer less and recover better compared to moss species. The results of other studies confirmed that the response of understory plants to the removal of trees from the forest ecosystem depends on the characteristics of a particular species, and some authors also note the different response of plant life forms to clear-cutting (Tonteri et al., 2016). The results presented in the scientific literature confirm that invasive plant species can also enter forest ecosystems after major changes (Gilliam, 2007). Meanwhile, studies

of mature forests demonstrated the resistance of forest communities to invasive species even when there are deforested areas nearby where invasive plants are already recorded (Luken, 2003; McCarthy, 2003). Studies of the primary response of forest plants to clear-cutting can explain the characteristics of species resistance to drastic changes in the environment and justify the restoration of forest ecosystems. Vanha-Majamaa et al. (2017) reported that the state of understory plant species should be determined immediately after cutting. On the other hand, long-lasting assessments are needed to determine the ability of these species to rapidly restoration of population size. Research on a development of herbaceous plants and shrubs in temperate forest ecosystems is essential because the soil cover species make up about 90% of all plant species and are very significant in forest soil nutrient metabolism (Gilliam, 2007).
The aim of these investigations was to determine the changes of understory vascular plant species in Scots pine *Pinus sylvestris* L. forests due to changes in environmental conditions after clear-cutting.

Materials and methods

Ten Scots pine forest plots were selected in Southern Lithuania. According to the nearest meteorological station, the average annual temperature in this region is 6.8 °C, with an average annual rainfall of 700 mm. The average temperature in July is 17.9 °C and the average temperature in January is -3.7 °C. The average age of mature Scots pine stands ranged from 120 to 130 years in the research plots. The stand volume was 330 m^3/ha, the average diameter of trees was 31 cm. The size of selected plots ranged from 2.0 to 2.6 ha. Each plot was divided into two parts. One part of the study plot was cleared, with tree stems and big branches removing in 2015. Our study was implemented on cleared subplots and compared with control subplots in intact (mature) forest sites. The research was conducted in 2016 and 2017. Based on the classification of Lithuanian forest types, plots of mature stands were selected, taking into account the predominant plant species (Navasaitis et al., 2003). The plots of *Pinetum vaccinio-myrtillosum (PVM) and Pinetum vacciniosum (PV)* forest types are located in very infertile soils where the humus fraction is up to 2%, the thickness of the forest floor is on average 2-4 cm. Lingonberry *Vaccinium vitis-idaea* L., bilberry *V. myrtillus* L., common heather *Calluna vulgaris* L. (Hull) are the predominant understory vascular plant species. The total coverage of this species typically ranges from 10% to 16%. Mosses are dominant in the understory vegetation layer covering, on average, from 70% to 85%. The most abundant moss species are *Pleurozium schreberi* (Willd. Ex Brid.) Mitt. and *Dicranum polysetum* Sw. The average cover of understory plant species was determined in the cutting site and mature forest. The cover was assessed in transects using a 1 m^2 frame (with a net with a 1 dm^2 square mesh) with 30 replications. The cover of each plant species was determined by a visual estimation as percent cover. In analysing the response of plants, species abundance was discussed in terms of ecological indicator values (Ellenberg, et al., 1991). During the study, changes in plant life forms (deciduous and evergreen shrubs, annual and perennial herbaceous plants) were also identified.
The data were analysed using SPSS Statistics version 24.0. Duncan's multiple range test was used to assess the data for significant differences. A p-value of 0.05 was set as the limit for significant differences.

Results and Discussion

One year after clear-cutting, the cover of predominant *Ericaceae* Juss. shrubs decreased from 11.2% to 3.0%, i.e., almost 4 times in PVM forest type and from 41% to 13.7% in PVM forest type (Figure 1). Already in the second year after clear-cutting, the total cover of these species increased to 5.7% in PV forests.

The response of *Ericaceae* plants to changes in environmental conditions after clear-cutting depended on properties of each species. A stronger negative effect of clear-cuttings was observed on deciduous *V. myrtillus* compared to evergreen *V. vitis-idaea* and *C. vulgaris* shrubs (Table 1). In the second year after felling, the cover of *V. myrtillus* did not reach 1% at the felling sites. The cover of *V. vitis-idaea* decreased from 16.3% (mature forest) to 1.2% in 2016 but already a significant increase of lingonberry cover to 8.3% was observed in 2017. An increase in the cover of *C. vulgaris* was also recorded in the second year after felling i.e., in 2017. Such changes can be

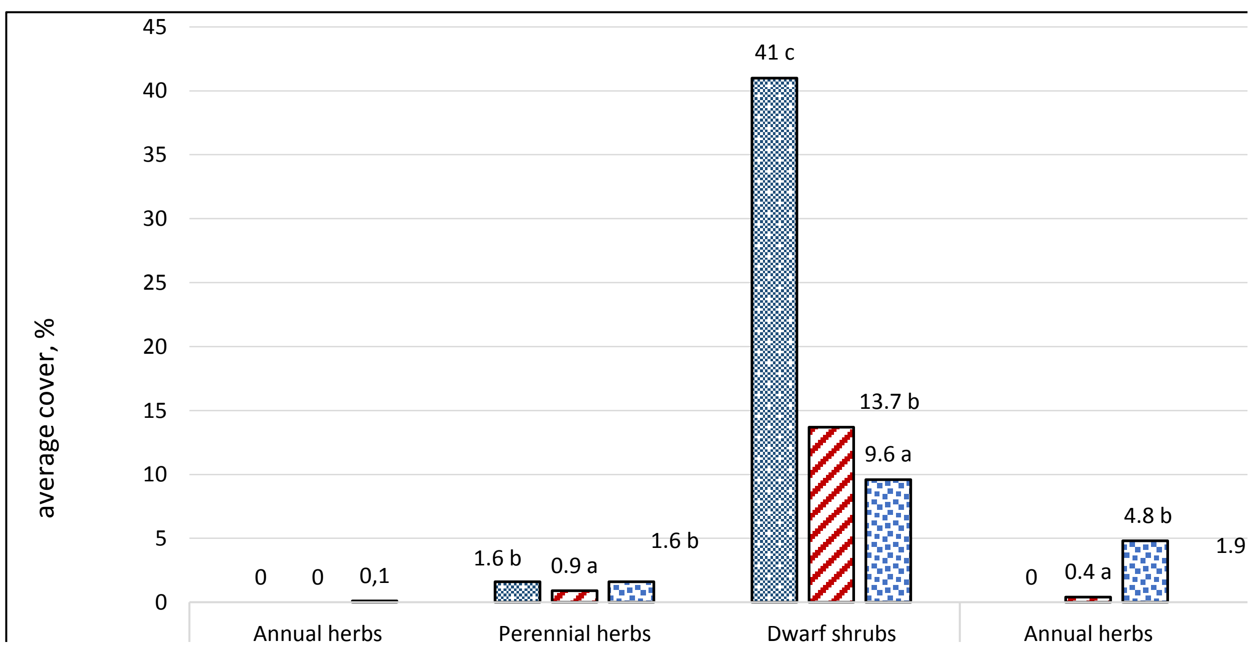

Figure 1. Dynamic of cover of herbaceous plants and shrubs in Scots pine forests after clear-cuttings, p≤0.05. PVM -*Pinetum vaccinio-myrtillosum*, PV-*Pinetum vacciniosum*

explained by the fact that common heather seedlings appeared in the felling site because the indicator value of this species for light reaches as high as 8 (Table 1).

The species diversity of perennial herbaceous plants in mature Scots pine forests was low: a total of six species were recorded in forest plots, with an average cover of 1.9%. In mature forest stands, the cover of perennial herbaceous plants was not significant. This can be explained by the need for light of these species, as their indicator values for light were quite high: from 5 (*Solidago virgaaurea* L.) to 8 (*Lycopodium clavatum* L.). As *Luzula pillosa* (L.) Willd. the indicator value for light is 2, this species was not recorded at the felling site. After felling, new species of perennial herbaceous plants were found, which were not detected in the mature forest: *Epilobium angustifolium* L., *Veronica officinalis* L., and *Rumex acetosella* L. Thus, the prevalence of *R. acetosella* in the first year after felling was low (projection cover was less than 1%), and already in the second year the projection cover was as high as 9.9% (Table 1).

Table 1. Cover and indicator values of understory vascular plant species in mature Scots pine forests and clear-cutting sites

Species	Cover			Ecological indicator values*	
	Mature forest	Clear-cutting, 2016	Clear-cutting, 2017	L	N
Vaccinium myrtillus	6,5	3,3	+	5	3
V. vitis-idaea	16,3	1,2	8,3	5	1
Calluna vulgaris	2,4	+	2,6	8	1
Festuca ovina	1,8	+	1,7	7	1
Luzula pillosa	+			2	4
Arctostaphylos uva-ursi	+			6	2
Lycopodium clavatum	+	+	+	8	2
Corynephorus canescens		+	+	8	2
Pilosella officinarum	+		+	7	2
Spergula arvensis		+	+	7	5
Senecio vulgaris		+	+	7	8
Solidago virgaurea	+	+		5	4
Epilobium. angustifolium			+	8	6
Veronica officinalis		+	+	6	4
Rumex acetosella		+	9,9	8	2
Carex caryophyllea			+	8	2

+ - cover ≤ 1
L – *ecological indicator value for light,* N – *ecological indicator value for soil fertility, according Ellenberg et al., 1991*

In the second year after clear-cutting, annual herbaceous plants also appear, with a cover of 4.8% in PV (Figure 1, Table 1). Even the light-demanding nitrophilous species *Senecio vulgaris* L. has been recorded, with an indicator value of 7 for light and an indicator value of 8 for soil fertility. Other authors have indicated also that the adaptability plants is particularly influenced by their need for lighting and soil moisture (Heinrichs and Schmidt, 2009; Tonteri et al., 2016). The response to fast changes in the environment depends not only on the characteristics of each species, but also on the type of forest. It was found that lingonberry and heather populations were more resistant in Scots pine forests compared to bilberry (Česonienė et al., 2018). Herbaceous

plants recorded in the felling sites are characterized by a high demand for light and a high amount of nutrients in the soil (Table 1).
Similar results were presented in studies by other authors (Atlegrim and Sjöberg 1996; Tonteri et al., 2016). Summarizing the results of the research, it can be stated that new anemochory species *R. acetosella*, *E. angustifolium* and *S. vulgaris*, were particularly widespread. As Pykälä (2004) have presented, the rapid spread of such species in degraded forest ecosystems is driven by the presence of long-term seed banks and air flow. Intensive regeneration of common heather population could also be influenced by species-specific characteristics i.e., ambophilous pollination and anemochory seed distribution (Česonienė et al., 2018). *L. clavatum* was found to have survived in the first and second years after clear-cutting but this species was recorded only in mechanically undamaged areas of the felling site. According to Rimgailė-Voicik and Naujalis (2016), this species is particularly sensitive to changes in the forest ecosystem. Thus, if adult individuals are destroyed, juvenile populations can only occur on forest plots that are free of significant damage. *L. clavatum* is estimated as a light-demanding species because according to Ellenberg et al. (1991), its indicator value for light is 8.

Conclusions

The cover of *Ericaceae* shrubs predominating in Scots pine forests begins to increase already in the second year after clear-cutting due to the significant spread in the common heather populations. Rapid regeneration of lingonberry shrubs has also been observed however, bilberry populations were decreasing in the second year. Comparing mature forest (control) and one- or two-year-old felling sites, annual herbaceous plants were recorded only after clear-cuttings. It was found that light-preferring and nitrophilous species appeared in the first year after felling. Clear-cuttings promoted the rapid spread of perennial and annual herbaceous plant species that are not typical of Scots pine forest ecosystems and are characterized by anemochorous seed dispersal.
